The characteristics of these dams (fig. 9) are that they are formed by a series of vertical buttresses upon which is placed a reinforced concrete deck, the buttresses being also connected, underneath the deck, by reinforced concrete beams or slabs. These dams can be used either on a rock foundation or on uncertain ground; in the latter case they are generally built over a reinforced concrete mattress distributing the pressure over the foundation. Their upstream face is inclined at an angle of 45° and the buttresses are practically vertical on the downstream side. In the case of a spillway, the downstream side is formed in the same manner as the upstream side by a reinforced concrete apron of the shape required by the quantity of water which is expected to flow over the crest. These dams have the advantage of requiring much less material than the

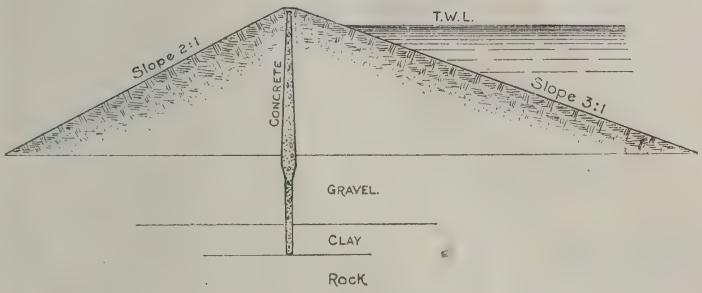

FIG. 6.—Earth Dam.

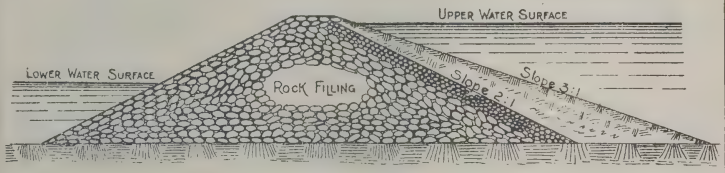

FIG. 7.—Rock-fill Dam.

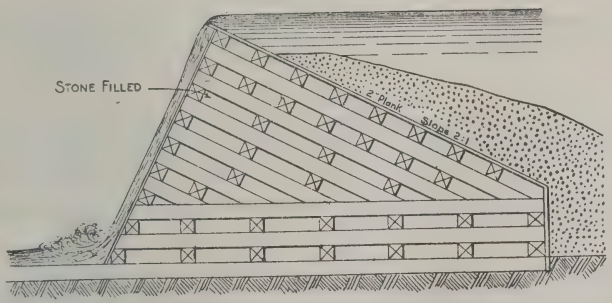

FIG. 8.—Timber Dam.

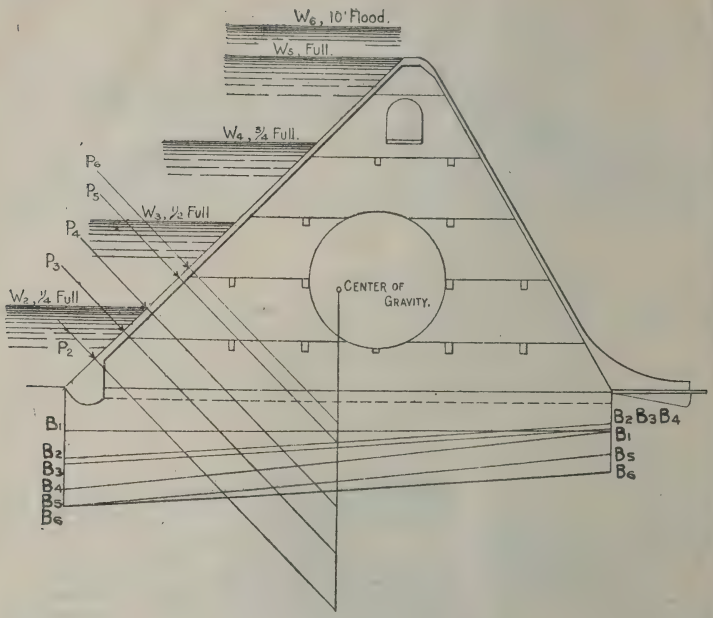

FIG. 9.—Reinforced Concrete Dam.

gravity dams, and are consequently used in places where transportation is difficult. Another advantage also is that their upstream face being inclined at 45° they resist better than the vertical face dams the ice pressures which, on account of their uncertainty, are always difficult to provide for.

Stability of Dams.

When dams are built on rock or solid foundations they can be built up from the bed of the river. If the bed is in hard pan the construction must be started below the bed of the river, and if the bed is composed of sand or gravel the dam generally rests on piles driven into the soil.

CONDITIONS OF STABILITY.

1. The weight of the dam must be sufficient to resist the water thrust tending to overturn it.
2. The dam must be so designed that there is no danger of its sliding upon its base.
3. The pressure on the downstream toe of the dam caused by the overturning moment must not exceed the resistance in compression of either the masonry or the foundations upon which it rests.
4. The resultant of all forces must be such that the upstream face of the dam is not in tension, but rather subject to a compressive stress.

Design of Dams.

Every design of dam must, of course, be tested for the foregoing different conditions, but the following rule will be found useful in arriving at a first tentative determination of the section.

Let h (fig. 10) be the greatest depth of water in the proposed reservoir at the dam. The width of the base B′C′ can be taken as equal to the height h or AB′, and the theoretical section of the dam would then be represented by the triangle B′AC′. In practice, however, it is necessary to give to the crest a certain thickness which can be taken as equal to one-tenth of the height. The portion AH above the highest water in the reservoir is generally made from 3 to 10 ft. When

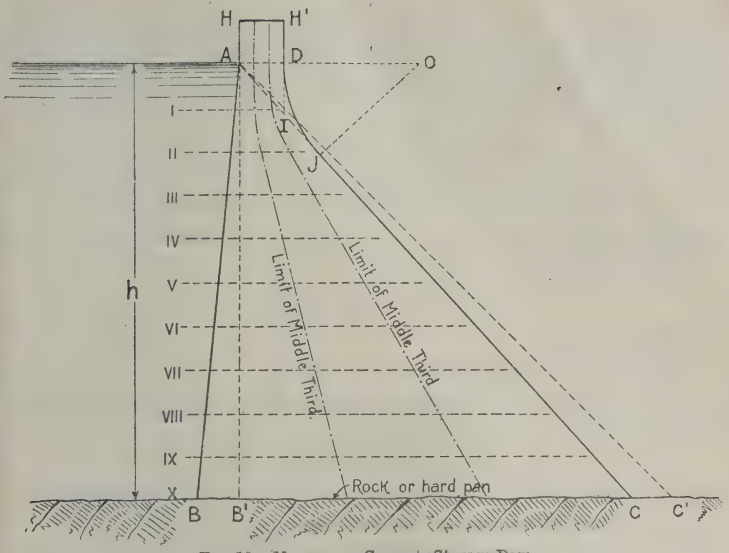

FIG. 10.—Masonry or Concrete Storage Dam.

the dam is very high it is difficult to build the upstream face vertical; it is preferable to give it a batter of 0·10 to 0·20. As it is not necessary to give to the base a greater width than the total height AB', the point C' is therefore brought back to C over a distance equal to BB'.

The downstream face is curved at the upper part into an arc tangent to the vertical H'I at D and to the inclined line AC at J. The section of the dam is therefore represented by the polygon BAHH'DJC.

DESIGN OF SPILLWAY DAMS.

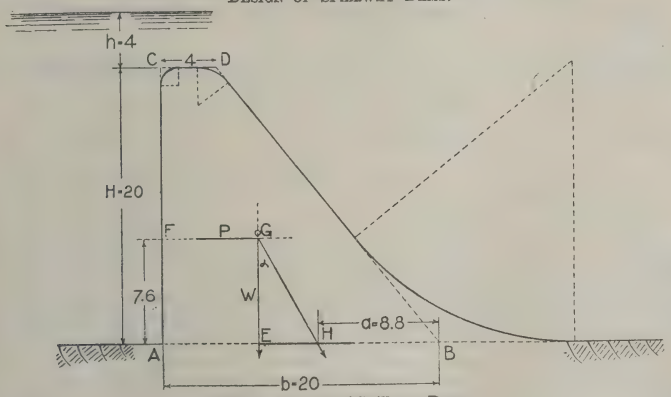

FIG. 11.—Design of Spillway Dam.

Spillway dams, or weir dams, are designed so as to allow the water to flow over their crest. The two first points to decide before beginning the design of such a dam are the elevation of the crest of the dam and the elevation of the highest possible flood.

Assuming that the elevation of the crest is 20 ft. above the bed of the river, and that the greatest flow of the river can be passed over the dam when the water level is 4 ft. above its crest, we can now proceed to design a plain concrete dam to meet these conditions, fulfilling at the same time the requirements as to stability enumerated above.

The width of the crest CD (fig. 11) can be taken as 0·2 of the height of the dam, and the width of the base b equal to the height H.

Referring to the fig. we have the following:

$$A = \text{area of section of dam} = \frac{4+20}{2} \times 20 = 240 \text{ sq. ft.};$$

w = weight of 1 cub. ft. of concrete = 130 lbs.;
W = weight of section of dam 1 ft. wide = $240 \times 130 = 31{,}200$ lbs.

This force W acts vertically through the centre of gravity of the section G, whose position is determined graphically.

The water pressure P tending to overturn the dam has for value

$$P = 62{\cdot}5 \times \frac{(H+h)^2 - h^2}{2} = 62{\cdot}5 \frac{H}{2}(H+2h),$$

and in the case in question,

$$P = 62{\cdot}5 \times \frac{20}{2}(20+2\times 4) = 17{,}500 \text{ lbs.}$$

This force P acts horizontally, and is applied at a height AF above the bed of the river given by the following formula:

$$AF = \frac{H}{3} \cdot \frac{H+3h}{H+2h} = \frac{20}{3} \times \frac{20+12}{20+8} = 7'{\cdot}6$$

Taking the moments about the downstream toe of the dam B we have the following results:

$$\text{Resisting moment} = W \times EB = 31{,}300 \times 13 = 405{,}600 \text{ ft. lbs.}$$

$$\text{Overturning moment} = P \times AF = 17{,}500 \times 7'{\cdot}6 = 133{,}000 \text{ ft. lbs.}$$

$$\text{Factor of safety} = \frac{\text{Resisting moment}}{\text{Overturning moment}} = \frac{405{,}600}{133{,}000} = 3{\cdot}05$$

A factor of safety of 3 is considered sufficient to fulfil the first condition of stability.

The second condition is that there should be no danger of the dam sliding upon its base; this condition is fulfilled if we have the following inequality:

$$\text{Weight of dam} \times \text{coefficient of friction} > \text{Total water pressure.}$$

The coefficient of friction of masonry on masonry, or masonry or concrete on rock, is 0·7, so that we have

$$31{,}200 \times 0{\cdot}7 > 17{,}500.$$

The resultant R of the forces P and W can be found graphically or algebraically by the following equation:

$$R = \sqrt{W^2+P^2} = \sqrt{31{,}200^2 + 17{,}500^2} = 35{,}770.$$

Its direction can be found by the equation

$$\tan \alpha^\circ = \frac{P}{W} = \frac{17{,}500}{31{,}200} = 0{\cdot}56;$$

and the point of application H found thus

$$EH = AF \tan \alpha^\circ = 0{\cdot}56 \times 7{\cdot}6 = 4{\cdot}26.$$

This point of application H must fall within the middle third of the base; this condition must be fulfilled whether the reservoir created by the dam is full or empty.

It is advisable to round up the dam at the upstream corner C to prevent chipping by logs or floating ice. It is also advisable to give to the downstream face a form resembling as much as possible the probable curve of the overfalling water. Corner D should therefore be rounded up, and a concave curve built at B, so as to carry the water x away horizontally and without impact. The foregoing method can, of course, be used also in the case of storage dams.

When the proposed dam is over 30 or 40 ft. it is better to subdivide it into a certain number of sections and to test each block separately according to the method described; the resultant in each case must fall within the limits of the middle third. In the example given it has been assumed that there was no upward water pressure at the base; when infiltration and under pressure must be provided for, this new force is subtracted from the weight and combined with it before calculating the resisting moment.

Head Gates.

Head gates (fig. 12) are placed at the entrance of the head race, in order to permit the emptying of the canal and pipes in case of repairs, and in order to be able to stop quickly the admission of water in case of accident to the canal, flumes, pipes, or water wheels.

The head gates are, of course, built differently, according to the size of the opening they have to close.

Head gates for a canal consist of wooden or steel gates moving between concrete, masonry, or crib piers. The weight of the heavy gates is generally partly balanced by a counter weight, and they are raised and lowered by electric or hydraulic motor. The smaller gates are moved by hand with the help of a mechanical hoist.

The piers must be designed to withstand a pressure equal to the total head of water multiplied

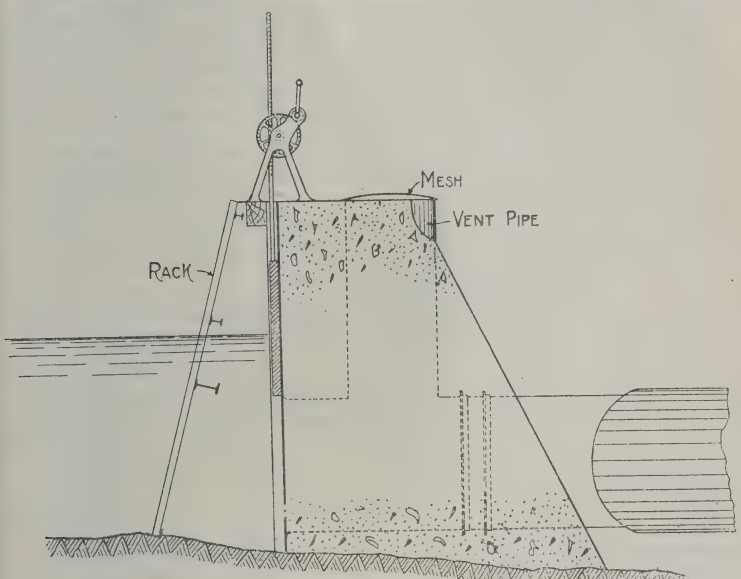

FIG. 12.—Head Gate and Rack.

by the distance between the centres of two adjoining openings. The factor of safety must be at least 3.

When pipes are used to carry the water to the turbines they are generally protected by a concrete head wall designed to resist the full hydrostatic pressure. The gates in this case are much smaller, and are operated by hand.

The force necessary to raise the gate can be calculated as follows:—The total weight of gate in water plus the total water pressure on the gate must be multiplied by a coefficient of friction which varies according to the materials used. To this weight should be added the weights represented by the mechanical losses in the transmission of power, and the grand total increased by about 13 per cent. in order to provide for the extra force necessary to start the gate.

Racks.

Racks are usually made of flat bars having sections from $\frac{5}{16}$ in. by 1 in., to $\frac{3}{8}$ in. by $3\frac{1}{2}$ ins., held together by bolts and separators. These racks may be either of large or small spacing, the former being those in which the bars are from $1\frac{1}{2}$ ins. to 4 ins. apart, and the latter where the bars are from $\frac{3}{8}$ in. to $1\frac{3}{4}$ ins. apart. The spacing is determined by the cross section of the openings of the distributor and runner buckets of the water wheels.

The racks are generally placed at an angle varying from 45° to 60° with the vertical; there should always be an operating platform at least 3 ft. wide, so placed that the attendants can work to best advantage either when cleaning or raising the racks.

The racks should be designed on the assumption that they act as a solid dam, and that all water behind may be drawn off. In such a case the racks and their supports would have to take care of the entire water pressure.

Design of Head Races.

The cross-section area of a head race should be such that the water will rise to about three-quarters to seven-eighths of the height.

Wooden flumes are ordinarily rectangular and designed to carry a depth of water equal to about half the width.

Canal sections are determined by the class of material forming the perimeter and the head which it is found economical to use. The efficiency of a cross-section of a canal is greater with the value of the wetted perimeter minimum, so that a semi-circular section is the most advantageous cross-section that can be used in a channel where resistance to flow is alone considered. When the canal is lined with masonry or concrete walls it is more advantageous to make the face nearly perpendicular, and to place the batter of the wall at the back. When the canal is cut in stone or shales which will not be eroded by the flow of the water, a slope of 90° to 40° may be used. In canals dug through earth the slopes may be from 1 in 1¼ to 1 in 1½. With artificial banks of earth and gravels the slope must frequently be made as low as 1 in 2.

According to Bazin, the relation between the bottom and the mean velocities in channels is the following

$$V_b = V - 10{\cdot}87\sqrt{rs},$$

where

V_b = bottom velocity in ft. per sec;
V = mean velocity in ft. per sec.;
r = hydraulic radius;
s = hydraulic gradient or slope of channel.

The following table, calculated from the foregoing formula, gives the safe bottom velocities for different materials.

TABLE OF SAFE BOTTOM VELOCITIES.

Material of Channel.	Safe Bottom Velocity (V_b) in Ft. per Sec.	Mean Velocity (V in Ft. per Sec.
Soft brown earth	0·249	0·328
Soft loam	0·499	0·656
Sand	1·000	1·312
Gravel	1·998	2·625
Pebbles	2·999	3·938
Broken stone, flint	4·003	5·570
Conglomerate, soft slate	4·988	6·564
Stratified rock	6·006	8·204
Hard rock	10·009	13·127

Flow of Water in Pipes, Flumes, and Channels.

The principal formula of flow in pipes, flumes and channels, is based on the formula for velocity of flow known as Chezy's formula, which is as follows:

$$V = C\sqrt{rs},$$

where

V = velocity in ft. per sec.;
C = a coefficient of discharge;
A = area of cross section considered, in sq. ft.;
p = wetted perimeter in ft.;

r = hydraulic radius = $\dfrac{\text{area of section}}{\text{wetted perimeter}} = \dfrac{A}{p}$;

s = hydraulic gradient or slope of channel = $\dfrac{\text{difference of level}}{\text{distance}} = \dfrac{h}{l}$

h = fall in ft. between points considered;
l = distance in ft. between points considered.

The formula for the flow is $Q = AC\sqrt{rs}$,
where

Q = discharge in cub. ft. per sec.

The value of the coefficient C can be determined either by Kutter's formula or Bazin's formula.

Kutter's formula is as follows :

$$C = \frac{41{\cdot}65 + \frac{0{\cdot}00281}{s} + \frac{1{\cdot}811}{n}}{1 + \left(41{\cdot}65 + \frac{0{\cdot}00281}{s}\right)\frac{n}{\sqrt{r}}},$$

where n = the coefficient of roughness.

Robt. E. Horton gives in 'Engineering News,' of February 24, 1916, the following category of coefficients of roughness for use in Kutter's formula :

TABLE OF 'n' FOR KUTTER'S FORMULA.

(8) Very weedy reaches	0·075	0·100	0 125	0·150

* Values commonly used in designing.

Bazin's formula for the determination of C is as follows :

$$C = \frac{157{\cdot}6}{1 + \frac{y}{\sqrt{r}}},$$

where y = a coefficient of roughness, whose value Bazin gives as follows for different classes of channels.

Class I. $y = 0{\cdot}109$ for smoothed cement, or planed wood.
" II. $y = 0{\cdot}290$ for planks, bricks, and cut stone.
" III. $y = 0{\cdot}833$ for rubble masonry.
" IV. $y = 1{\cdot}54$ for earth channels of very regular surface or reveted with stone.
" V. $y = 2{\cdot}35$ for ordinary earth channels.
" VI. $y = 3{\cdot}17$ for exceptionally rough earth channels (bed covered with boulders) or weed-grown sides.

Design of Pipes.

Pressure in Pipes.

The interior pressure in a pipe due to the presence of water, and tending to burst this pipe, is larger transversely than longitudinally.

The pressure in pounds per sq. in. p, determined by a head of water H expressed in feet, is :

$$p = \text{pressure in lbs. per sq. in.} = \text{head in ft.} \times 0{\cdot}44,$$

and the diametral pressure P, tending to burst the pipe, is represented by the equation

$$P = p \times \frac{d}{2},$$

where d = the diameter of pipe in ins.

The longitudinal tension P in the pipe is equal to

$$P' = p \frac{d}{4}.$$

This explains why steel riveted pipes have generally a single row of rivets at the vertical joints and two rows of rivets along the horizontal joints.

Design of Steel Pipes.

The thickness of metal t (expressed in ins.) required to carry a certain pressure can be determined by the following formula :

$$t = \frac{(p + p')d}{2fe} + c,$$

where
t = thickness of steel shell in ins. ;
d = inside diameter of pipe in ins. ;
p = pressure of water in lbs. per sq. in. ;
p' = allowance for water hammer in lbs. per sq. in. ;
f = allowable tensile stress of steel in lbs. per sq. in. :
e = efficiency of riveted joint ;
c = thickness to be added to plate for corrosion.

The permissible unit tensile stress with ordinary open-hearth steel is assumed at 16,000 lbs. The efficiency of the joint may be taken at 55 per cent. for single riveted pipe, and at 70 per cent. for double riveted pipe. The thickness to be added to compensate for the weakening of the pipe due to corrosion is about $\frac{1}{16}$ in. In large pipes under small pressure, the thickness of metal computed with the above assumptions must still be increased to give the pipe the necessary stiffness.

Design of Reinforced Concrete Pipes.

Reinforced concrete pipes are designed under the assumption that the steel takes care of all longitudinal or transversal stresses in the pipe whilst the concrete acts as a waterproof shell. It is evident that, in this case, the steel can be reduced to the minimum thickness required.

The permissible stress per sq. in. of metal can also be taken at 16,000 lbs. per sq. in.

The area of the circles forming the transversal reinforcement can be determined as follows :

Let p = total internal pressure in lbs. per sq. in. ;
d = diameter of pipe in ins. ;
A_s = area of steel reinforcement per lineal foot, expressed in sq. ins. ;
f = permissible stress in steel in lbs. per sq. in. ;

then assuming that the concrete is to take no part of the tensile stresses, we have

$$A_s = \frac{p\,d \times 12}{2 \times f}.$$

The longitudinal reinforcement is taken with an area per lineal foot of circumference equal to half the area per lineal foot of pipe as determined above.

Spacing of Pipe Supports.

Steel and concrete pipes are not always built resting on the ground, and very often they have to be carried on concrete or masonry piers resting preferably on rock, or having a bearing surface in proportion to the load carried and to the resistance of the foundations.

The spacing of the piers is determined by considering the pipe as a circular beam resting freely on supports and carrying a uniformly distributed load consisting of the weight of the pipe plus the weight of the water. This load determines a longitudinal tension in the lower side of the pipe, and this stress added to the longitudinal tension of the pressure of water caused by the static head, plus the extra head due to water hammer, should not be allowed to exceed f, the safe tensile strength of the material.

The stress due to bending is

$$= f_b \frac{3}{2} \cdot \frac{WL^2}{S},$$

where

L = distance between supports in ft. ;
W = total load in lbs. per ft. of length ;
S = section modulus of the pipe.

The longitudinal fibre stress due to water pressure is

$$f_t = \frac{pd}{4t},$$

where

p = pressure in lbs. per sq. in. ;
d = nominal inside diameter of pipe in ins. ;
t = thickness of pipe in ins.

This formula applies to steel pipe, but can be utilised in the calculation of a reinforced concrete pipe, by reducing the total area of steel reinforcement per foot length to a continuous pipe of uniform thickness. This method, however, would not take into account the resistance in compression of the concrete on the upper side of the pipe.

Adding together the stress due to bending f_b and the stress due to water pressure f_t we have a total stress,

$$f = \frac{3}{2} \frac{WL^2}{S} + \frac{pd}{4t};$$

from this we can get the distance between the supports

$$L = \sqrt{\frac{2}{3} \frac{S}{W} \left(f - \frac{pd}{4t} \right)}.$$

The permissible value of f, in a steel riveted pipe, can be taken from 8,000 to 11,000 lbs. per sq. in. according to the efficiency of the joint ; in a reinforced concrete pipe 16,000 lbs. per sq. in. could safely be assumed.

Design of Wood Stave Pipes.

In Canada and in the United States extensive use is made of pipes composed of wooden staves held in place by steel wires wound continuously around the pipe, or by separate steel bands or rods connected by malleable iron shoes.

The steel is designed to take care of all the stresses and the wood forms only the shell. These pipes are very cheap, and have a greater carrying capacity than either steel or reinforced concrete pipes; they have been used for heads as high as 200 ft.

The following information has been compiled from the writings of Robert E. Horton and of Andrew Swickard.

The staves are made of California redwood, Douglas fir, and Canadian red pine. Practice varies somewhat as to the thickness of staves to be used under given pressure for a pipe of given diameter. The following considerations should govern the thickness of staves to be adopted in a given case.

1. The thicker the staves the greater stability of pipe against deformation by its own weight, and accordingly the staves must be thicker for large than for small diameter of pipes.

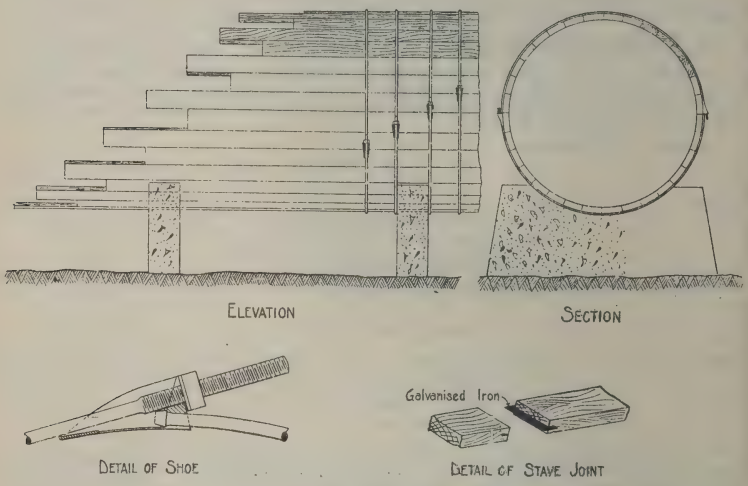

Fig. 13.—Details of Wood Stave Pipe.

2. The staves should be thick enough to prevent material loss by percolation, and accordingly should be thicker for heavy than for lighter pressures.

3. The staves should not be so thick as to prevent their being thoroughly saturated. This and considerations of economy require the use of as thin a stave as is compatible with the first two conditions named.

The following rule serves as a general guide for determining the approximate thickness of staves to be used in any case; the actual thickness of staves may be made equal to the nearest $\frac{1}{8}$ in. or $\frac{1}{4}$ in. greater thickness than shown by the rule:

$$t = 1 \text{ in.} + \frac{\text{Head in ft.} + \text{Diameter of pipe in ins.}}{100}$$

The minimum radius of bends which may be made with continuous pipe increases with the diameter of the pipe and with the thickness of the staves. An approximate rule is

$$\text{Minimum radius, in ft.} = 4 \text{ to } 5 \times (d+4t^2)$$

where,

d = inside diameter of pipe, in ins.;

t = thickness of staves, in ins.

Wood stave pipes should be supported through an arc extending about 55° each side of the vertical axis, in order to prevent deformation of the pipe by its weight and that of the water it contains.

Stave pipes (fig. 13) are generally carried on wooden or on concrete cradles, concrete being preferable for large pipes. Joseph P. Frizell says that wooden cradles are best made of 6 in. × 8 in. or 8 in. × 8 in. timbers, spiked or drift-bolted together, of a length somewhat greater than the diameter of the pipe, and at distance apart about equal to their length. Robert E. Horton is of the opinion that the spacing of the supports is about the same for wood stave and steel pipes.

The abutting end joints of the staves are connected together by iron plates inserted in a slot sawn in for that purpose. This iron tongue should be about $\frac{3}{16}$ in. wider than twice the depth of the slot and about $\frac{1}{8}$ in. longer than the slot, allowing a projection of $\frac{1}{16}$ in. into the adjoining staves.

Creosoted wood-stave pipes put in place twenty-eight years ago were said, at the recent convention of the American Wood Preservers' Association, to be still in perfect condition. The best method of treatment for the staves was described as being the empty-cell process with 50 lbs. initial air pressure, following the creosote pressure period with several minutes' reheating at about 25° F. in excess of any previous temperature, then a vacuum of not less than 20 ins. maintained for from 30 mins. to 1 hour. By this process a satisfactory creosote penetration is obtained, and the staves come out thoroughly clean, and so dry as scarcely to soil the hand.

Area of Bands and their Spacing.

The two principal considerations governing the size and spacing of bands are as follows:—

(1) The area of section of the band per ft. length of pipe must be such as to safely withstand the water pressure plus the stress in the band due to swelling of wood when saturated.

(2) The size and spacing of bands must be such as not to produce crushing of the wood.

Taking into account both the stress due to water pressure and that due to swelling of the staves, the following formula has been derived for determining the necessary area of cross-section of metal in the bands per in. length of pipe.

$$a = \frac{pd + 200t}{2f},$$

where,

a = required area of band section per in. length of pipe;

p = pressure in lbs. per sq. in.;

d = inside diameter of pipe in ins.;

t = thickness of stave in ins.;

f = permissible unit stress in lbs. per sq. in., taken generally as 16,000 lbs.

In order to avoid dangerous crushing of the wood, the bearing pressure between bands and staves should not exceed about 800 lbs. per sq. in. of contact between the band and stave. For round bands the width of contact between the band and stave should be about equal to the radius of the band.

From these data the following formula is obtained for determining the maximum permissible spacing S in ins. between bands of given size under a given pressure.

$$S = \frac{400 \times \text{diameter of round bands in ins.}}{\text{Pressure in lbs. per sq. in.}}.$$

Shoes or Band Couplings.

The band couplings should be made of malleable iron. The weight of these shoes will vary with the size of the band and the diameter of the pipe, but the following table gives average weights for various sizes of bands, which are accurate enough for estimating purposes:

Diameter of Band, ins.	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1
Weight of Shoe, lbs.	0·35	0·40	0·65	1·00	1·75	2·75	4·00	6·00

Length of Bands.

Before the length of a band can be determined it is necessary to know how much lap-over of the rod there is in the shoe. This differs in shoes for different sizes of pipe, increasing with the increase in size of rod However, this quantity will average about as follows for various sizes of bands :

Diameter of Band, ins. . . .	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1
Lap-over of Band in Shoe, ins. .	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	$1\frac{3}{16}$	$1\frac{1}{4}$	$1\frac{1}{3}$	$1\frac{3}{8}$

The end of the rods should be upset and threaded over a length of not less than $4\frac{1}{2}$ ins. for $\frac{3}{8}$ in., 5 ins. for $\frac{7}{16}$ in., and 6 ins. for other sizes. There are three types of head in use—button, square, and tee heads. The tee head has the advantage of keeping both ends of the rod closer to the staves, and shortens the space over which the rod is raised from the staves ; it also permits the use of a shorter shoe. The length of rods under the head should be such that, after the pipe is finally tightened, at least $1\frac{1}{2}$ ins. of thread will remain ahead of the nut. The length of the rod, excluding the head, is determined in the following manner, where the rod is in one part and 6 ins. of thread is being used :

$$\text{Total length} = (d+2t+r)\pi+k+4\tfrac{1}{2} \text{ ins.}$$

where,

d = nominal inside diameter of pipe in ins. ;
t = thickness of staves in ins. ;
r = diameter of rod in ins. ;
k = lap of rod in shoe in ins.

If the rod is in two parts, the following formula applies

$$\text{Total length} = (d+2t+r)\pi+2k+9 \text{ ins.}$$

From 68 tests on wood-stave pipe lines with diameters from 4 to 162 ins., and velocities ranging from 1 ft. to 8 ft. per sec., it was found that with diameters from 4 to 24 ins. the average value of n in Kutter's formula (p. 1191) was 0·0109 and with diameters from 31 to 162 ins., the average value of n was 0·0124.

(*Mallett ; Flow of Water in Pipes, Vol. CCVIII* (*April* 1921), *Proceedings Inst. C.E.*)

Discharge of Water through Orifices.

The theoretical velocity, v, with which water flows from an orifice in the side of a vessel at a depth h from surface is the same as that of a body falling freely by gravity from height, h, viz.

FIG. 14.

FIG. 15.

FIG. 16.

$v = \sqrt{2gh}$, but practically the converging currents produce a contraction of the jet, which assumes the form of the vena contracta, d, e, f, g, fig. 91.

h = height from surface of water to centre of orifice, in feet. v = velocity of issuing water

FIG. 17.

Fig. 18.

in feet per second. A = area of orifice, in feet. Q = cubic feet discharged per second. g = coefficient of terrestrial acceleration.

$$v = m\sqrt{2gh}. \qquad Q = mA\sqrt{2gh}. \qquad 2g = 64{\cdot}4 \qquad \sqrt{2}\,g = 8 \text{ practically.}$$

m.

·625. Where the orifice is a thin plate, bc (fig. 14), with thickness less than $\frac{1}{2}$ smallest dimension of orifice.

·97. Orifice shape of vena contracta, d, e, f, g (fig. 15) ; A is measured at f, g.

·82. Orifice with an adjutage (fig. 16) ; O = $2\frac{1}{2}$ to 3 times least dimension at A.

·95. Sides converging at angle of 13½° (fig. 17). m depends on diameter and angle of convergence.

1·46. Sides diverging at angle of 5° 6′ (fig. 18). O = 9 times least dimension at A, which is of form of vena contracta. (Seldom used.)

·548. Where 2 sluices in thin plates are so close as to interfere with each other; m being reduced from ·625.

·62. For sluices of moderate size in lock gates, etc.

·82. For narrow-bridge openings.

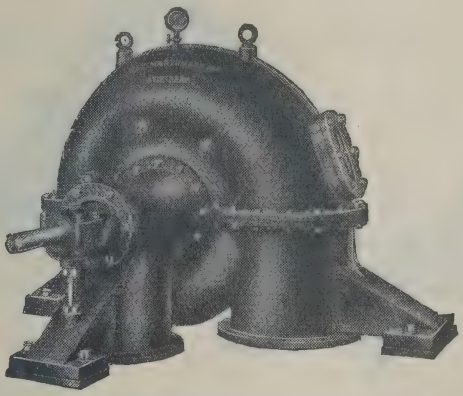
·92. For very large sluices and bridge openings.

To raise a River a certain Height by a Weir.

Q = discharge of river in cubic feet per second; h_1 = height by which river is to be raised in feet; h_2 = depth of top of weir below original surface of water necessary to raise surface by height h_1; h_a = head corresponding to velocity of approach; l = length of weir in feet; m = coefficient of contraction = ·628; $2g$ = 64·4.

$$h_2 = \frac{Q}{ml\sqrt{2g(h_1 + h_a)}} - \tfrac{2}{3}\frac{(h_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}}{\sqrt{h_1 + h_a}}$$

If h_a is not taken into account, then



$$h_2 = \frac{Q}{ml\sqrt{2gh_1}} - \tfrac{2}{3}h_1.$$

WATER POWER

has greatly increased in value during recent years owing to high fuel costs. Only turbines of first-class design and efficiency should be used; others mean waste of power and money.

OUR EFFICIENCY GUARANTEES

are the highest obtainable and are all based on the results of actual tests.

SECTION XXIV

PART IV

WATER PRESSURE ENGINES—PELTON WHEELS—TURBINES

Water-pressure Engines.

SINGLE-ACTING ENGINES

consist of single cylinder and piston. The water is admitted under the piston, raises it, is allowed to escape, and the piston falls by its own weight. Average velocity of piston should not exceed 140 feet per minute. Stroke should be as long as possible, generally from 6 to 10 feet.

Water-pressure engines are also made rotatory with single or double acting cylinders, and single and double acting rams are extensively used for working cranes, dock gates, etc., the stroke of the ram being multiplied by gearing or chain tackle. The pressure generally used is 700 lbs. per square inch.

POWER OF WATER-PRESSURE ENGINES.

$P = 62{\cdot}42Qh \times {\cdot}66$ to ${\cdot}8$ ft. lbs. per sec. H.P. $= Qh \times {\cdot}07491$ to ${\cdot}09080$,

where Q = cub. ft. of water per sec., h = height of fall, in ft.

Diameter of supply-pipe = diameter of cylinder × ·41 for single cylinder engines, = diameter of cylinder × ·68 for double cylinder engines.

EXAMPLE.—A single-acting pressure engine has a pressure cylinder 50 ins. in diameter, a head of water of 132 ft., a stroke of 10 ft., and is worked 4 to 7 strokes per min.

$$Q = \frac{25^2 \times 3{\cdot}14}{144} \times 10 \times \frac{4}{60} = 9{\cdot}1 \text{ cub. ft. per sec.}$$

H.P. = 9·1 × 127 × ·09080 = 105 horse-power, with 4 strokes per min., or 184 with 7 strokes. The actual work was about 168 horse-power.

PELTON WHEELS.

In this wheel, fig. 1, the water striking the buckets in the middle is deflected to both sides equally, and in such a way that the discharge from one bucket clears the one following. The construction of the buckets is shown in fig. 2. An improvement of the Pelton semi-cylindrical

bucket is the Doble bucket, fig. 3, each half of which is ellipsoidal in form, and has a part of the outer lip cut away, so as to avoid hitting the jet when moving under it.

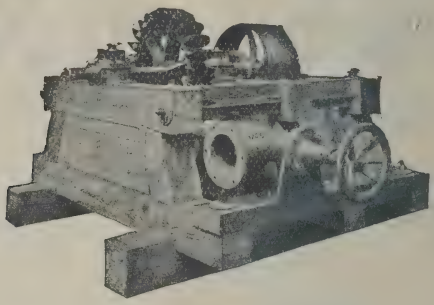

FIG. 1.

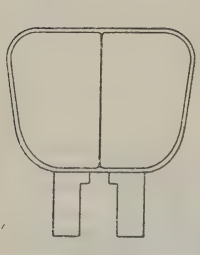

FIG. 2.—Pelton Bucket.

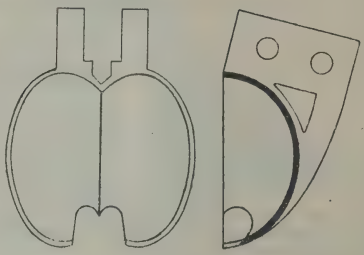

FIG. 3.—Doble Bucket.

PROPORTION OF PARTS OF PELTON WHEELS.

The area of the jet should not exceed 0·1 the projected area of the bucket, or the diameter of the jet should not exceed 0·3 the width of the bucket. The ratio of the wheel diameter to jet diameter should not be lower than 9, 12 being a common value, so that the diameter of the wheel in feet should about equal the diameter of the jet in inches.

The size of the jet depends on the amount of power desired, per unit, under the given head; the peripheral speed of the wheel varies between 0·43 and 0·47 of the theoretical jet velocity. Two and three jets are sometimes used upon one wheel but a single jet is preferable. Sometimes two wheels are used to drive a single generator mounted between them.

The efficiency of the Pelton wheel has been found to exceed 86 per cent. Since this wheel operates by utilising the kinetic energy of the water, it is best adapted to a small discharge under a high head: its range of usefulness varies from 50 foot heads to 3,000 and even 5,000 foot heads.

Pelton Wheel Regulators.

GENERAL.

The section of the nozzle is either square or circular, but more generally circular, with a needle, fig. 4, to secure a more uniform velocity in all parts of the jet; this needle can be moved back or forward by the governor, varying the area of the opening and regulating the amount of water discharged. For very high heads, where the interruption or partial suppression of flow by such an arrangement might involve danger to the pipe-line, deflecting nozzles of various kinds are

employed. The movement of a regulating nozzle of this description is accomplished with comparatively little expenditure of energy, and thus the control of Pelton wheels is simple, unless affected by irregularities. A deflecting nozzle, as used by Messrs. Theodor Bell & Co., is shown in fig. 5. This nozzle is rectangular in section, the upper side being formed by the piece E pivoted at A. This is moved by the governor attachment B, so as to increase or diminish the area of the nozzle at the mouth. A secondary nozzle D is closed by a cap C, which also rotates about the pivot A, and is moved through the same angle as E. As the two nozzles have the same width, a partial closure of the larger nozzle is compensated by an opening of the smaller, so

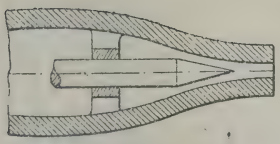

FIG. 4.

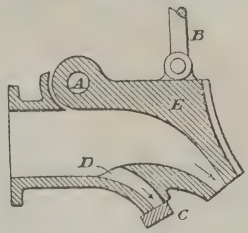

FIG. 5.

that the spouting area is always a constant, and the flow through the pipe is steady, while the wheel receives that fraction of it which is required to maintain the speed constant at all loads.

The foregoing device, however, is wasteful of water even with the best of attention. Since the water hammer caused in the pipe by a sudden opening of the nozzle is less dangerous than the hammer due to the sudden interruption of the flow, a device, fig. 6, has been perfected, consisting of an

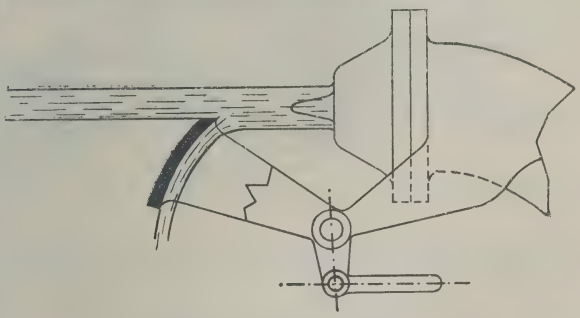

FIG. 6.—Needle Nozzle with Deflector.

automatic jet deflector and an ordinary nozzle needle, which causes the governor to act on the deflector only in case of closing, the needle being afterwards slowly closed by means of a dash-pot mechanism, whilst the deflector becomes tangential to the reduced jet. When the governor moves to increase the discharge of the nozzle, it controls simultaneously and rapidly the deflector and the needle.

COMBINED SPEAR AND DEFLECTOR REGULATOR CONTROLLED BY SHAFT GOVERNOR.

(Gilbert Gilkes & Co. Ltd., Sole Makers and Patentees.)

For high-falls (100 ft. and upwards), Pelton wheels or other impulse turbines may be controlled by an arrangement similar to that shown in fig. 7, as made by *Gilbert Gilkes & Co. Ltd.*, of Kendal.

The arrangement consists of a pendulum mounted upon the turbine shaft and coupled direct

P. 6, P. 9, P. 12, etc., represents approximately the diameter of the wheel in inches.
The power stated is the maximum. The wheels can be constructed to develop smaller powers, without impairing the efficiency.
The capacity stated is for a single jet. Double nozzle wheels will develop nearly double the power stated at the same speed.

(*Gilbert Gilkes & Co. Ltd.*)

to the deflector shaft, the design of the deflector being such as to impose the least resistance to the passage of the water through the jet.

Movement to the spear is given by a piston moving in a hydraulic cylinder fixed to the end of the branch pipe.

The position of the spear is dictated by a poppet valve controlled by levers and links connected to the deflector shaft, and so arranged that if the load be thrown off the deflector is brought instantaneously into the jet, the spear slowly following and the deflector finally taking up a position just clear of the jet. If the load is thrown on, the spear is drawn rapidly back.

When economy of water on reduced loads is immaterial, as in the case where the supply is from a stream without storage, the automatic spear-following combination is dispensed with a hand-regulated spear being substituted.

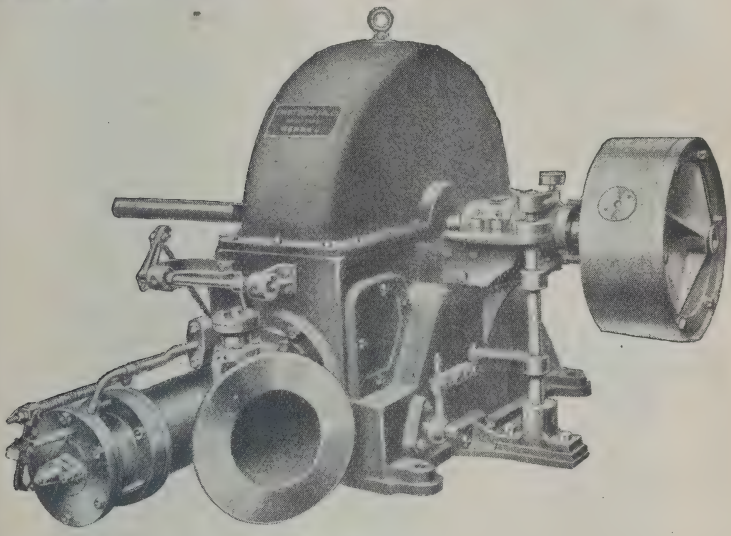

FIG. 7.

The pendulum being mounted directly on to the shaft ensures a perfectly steady drive, saves space, and is immune from all risks due to breaking of chains, belts, etc.

As the pendulum is connected directly to the deflector without the intermission of servo-motors, etc., extreme rapidity of action is obtained, the movements being instantaneous and dead time eliminated, the results showing a momentary variation of less than 1 per cent. with full load thrown off.

COMBINED SPEAR AND DEFLECTOR REGULATOR FOR PELTON WHEELS CONTROLLED BY OIL PRESSURE GOVERNOR.

(*Designed by Messrs. James Gordon & Co., Windsor House, Kingsway, London, W.C. 2.*)

The general arrangement and design of the nozzle is shown by fig. 8, p. 1204. It consists of the following principal parts :—

Pelton wheel nozzle A of the ordinary circular type fitted with an internal spear regulator, the shaft B of which carries a spear head at one end and an oil dashpot piston at its opposite end. The nozzle is also provided with a deflector plate D supported on a spindle, and bearings being carried on the lower part of the nozzle casting. The governor is connected direct to lever E, which is keyed on to shaft M, the deflector being operated positively from this shaft by means of a lever and connecting rod, as indicated in the figure. The shaft M also carries a double lever F, which is provided with a spindle and square steel block working inside the box G in the spear regulator shaft, lever F having sufficient travel in the box G, independent of any movement of the spear, to allow the deflector to be moved far enough into the jet by the governor to practically deflect all the water below the Pelton wheel buckets. The spear shaft is provided with a helical spring

H, which always has a tendency to close the nozzle, and this shaft is provided at its outer end with an oil dashpot C, the piston of which is provided with a flat valve J, allowing rapid movement of the spear shaft in the opening direction, when oil can freely pass from one side of the piston to the other through the holes under the valve plate. For any movement in the closing direction of the spear shaft the valve J is closed, and the oil must escape from one side of the cylinder to the other through the small adjustable valve K. Under normal working conditions the spear regulator would be opened a sufficient distance to pass the quantity of water required to maintain normal speed with the load carried by the wheel, and the deflector would be in such a position that its forward edge would be just clear of and above the jet of water. In this position the square block on lever F would be at the rear end of the box G, the oil pressure of the governor pressing against the spring H, preventing the spear regulator from moving forward. In the event of any load being taken off the plant, the governor would immediately move the deflector into the jet, and the spear rod B would be prevented from quick forward movement by the dashpot. Immediately this occurred the spear would slowly travel forward, its rate being adjusted by the valve K, and as the spear reduces the quantity of water discharged by the nozzle, the deflector would be gradually brought back by the governor. During this time the box G on the spear shaft and the square block carried by lever F would be moving in opposite directions, and the forward movement of the spear would stop when the box G engaged with

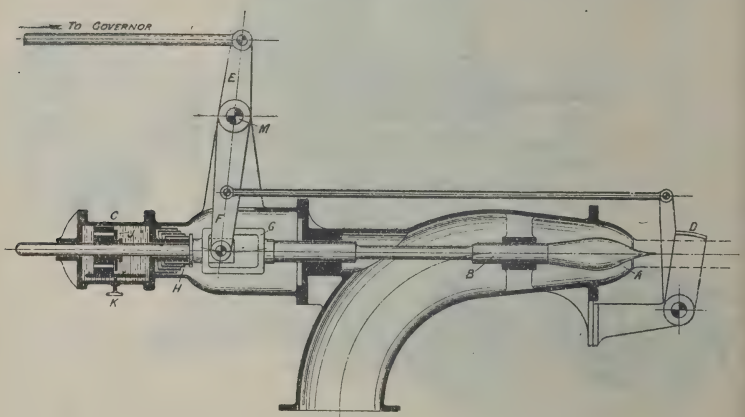

Fig. 8.

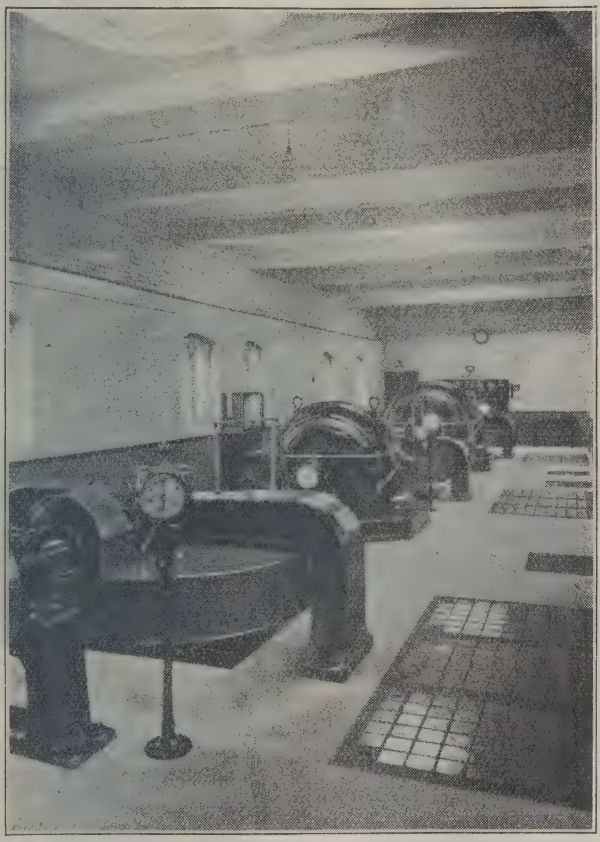
the square block on lever F. At this point the deflector would be quite clear of the jet, and the quantity of water discharged should then be exact for the new load conditions. In the event of any load being added to the plant, the governor would move the lever E in the opposite direction, taking the deflector away from the jet, and as the block on lever F would be in contact with the outer side of the box G the spear regulator would have a positive movement in the opening direction in proportion to the movement of the governor, movement in this direction of the spear being free.



The nozzle can be regulated by hand either by means of the hand wheel on the governor, which would operate the deflector and spear in combination in the same manner as when operated by the governor itself, or the wheel can be regulated by hand by means of a hand wheel on the end of the spear shaft B.

This type of nozzle acts in the same manner as a combined relief valve and nozzle; rapid alteration of the velocity of the water in the supply pipe, and consequent 'water hammer' effects when the nozzles are closed, is impossible, as to meet any reduction in the load a proportionate amount of the water is deflected below the buckets, and the closing of the spear can be regulated to suit the hydraulic conditions of the pipe line in the same manner as the dashpot closing of an ordinary relief valve.

In the event of a breakdown of the governor oil pumps, or failure of oil pressure from any other cause, the governor would then be unable to hold the spear shaft back against the pressure of spring H, and the wheel would then be automatically and slowly shut down by the combined action of the spring and dashpot.

THE 'SEEWER' PELTON WHEEL REGULATOR.

A new type of spear regulator for Pelton wheels has recently been introduced by M. Seewer, a Swiss engineer, and has been successfully tested at the Zurich Polytechnic.

The distinctive feature of the arrangement, fig. 9, consists in the use of a series of pivoted

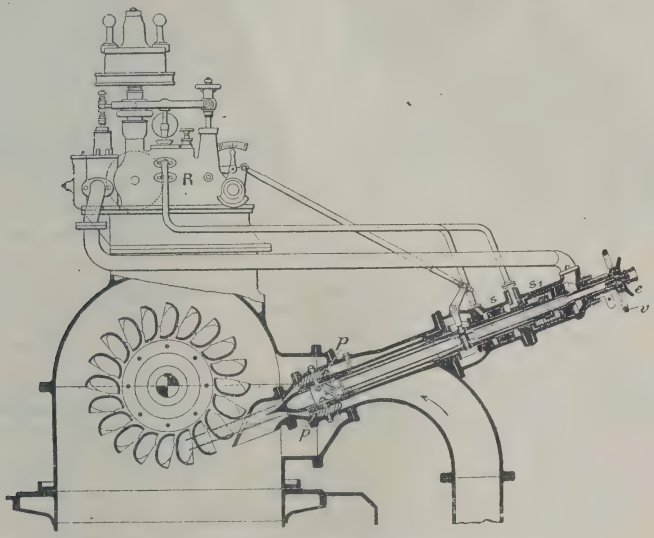

FIG. 9.—Longitudinal Section of 'Seewer' Regulator.

vanes P inside the nozzle, arranged round the central spear in the shape of a symmetrical star. By means of a simple mechanism the vanes are all equally inclined or kept parallel to the axis of the nozzle. In the latter position they produce no effect upon the issuing cylindrical water jet, fig. 10, which then exerts its maximum force upon the runner buckets. A small

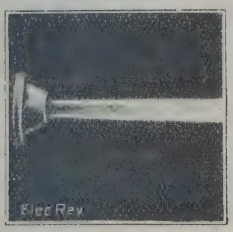

FIG. 10.—Normal Form of Jet.

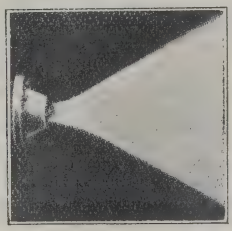

FIG. 11.—Jet formed when the Vanes are Inclined.

inclination, however, acts upon the jet in a remarkable manner, changing it, as shown in fig. 11, into a hollow cone, this effect being more and more accentuated as the inclination of the vanes

is increased. The deflector used is pierced to pass the cylindrical jet, but on the operation of the vanes it intercepts the coned jet, and in this way suppresses its action upon the wheel buckets.

As the vanes only effect the dispersal of the jet without reducing the rate of flow, their action does not give rise to any excess pressures or water hammer in the pipe line. Moreover, the reactions of the water on the front and back faces of the vanes being balanced, they can turn on their axes, and respond almost instantly to load fluctuations, whilst the power required to actuate them is reduced to a minimum. The maximum inclination of the vanes is 20 degrees. They are actuated by means of the servo-motor s, through the governor R, which also controls the movement of the spear through the second servo-motor s_1. Hand regulation can also be made, if desired, by engaging the hand-wheel v with the control spindle through the clutch e.

When sudden changes in the load occur the two servo-motors act together; the one controlling the vanes acts instantly, that of the spear completing its effect. With only small fluctuations in the load the spear servo-motor alone comes into play, and the vanes remain inoperative.

In the *Schweizer Bauzeitung* of May 31 and June 7, 1919, Prof. Prasil, of the Zurich Polytechnic, who supervised the tests, gives the results with a number of tables and diagrams, and reports in favour of this system as constituting a notable advance in the regulation of Pelton wheels. (*'Génie Civil.'*)

The English Electric Co. has acquired the patent rights of this governing system, for the whole world, and applications of the system have proved thoroughly satisfactory. (*The English Electric Co.*)

Notes on Regulators.

The best makes of hydraulic regulators for medium and high falls will govern within the following limits, the per cent. being that of the mean speed :—

For a sudden variation of load of 25 per cent.	4 per cent.
" " " 50 "	6 "
From no load to full load	10 "

The relative speed with which gates may be closed by hydraulic and mechanical regulators is greater for the hydraulic, the ratio being generally about 5 to 1 in favour of the hydraulic.

TURBINES.*

Classification of Turbines.

Action, Impulse, Tangential, or Pressureless Turbines.

In these turbines the passages are never completely filled with water and the flow of water is always under atmospheric pressure. During flow through the wheel the absolute velocity of the water is reduced as the water gives up its kinetic energy.

Reaction, or Pressure Turbines.

In these turbines the wheel passages are completely filled with water under a pressure which varies throughout the flow. During this flow through the runner, both the pressure and the absolute velocity of the water are reduced as the water gives up the energy to the wheel.

Direction of the Flow of Water.

In the radial outward flow, or centrifugal turbines (Founeyron type, fig. 12), the guide-vanes ring is contiguous to the runner, and the water passes through the runner whilst moving away from the axis of rotation but in the plane perpendicular to it.

In the parallel, or axial flow turbines (Jonval type, fig. 13), the guide-vanes ring is superposed to the runner, and the water passes through the runner buckets whilst moving along a circular cylindrical surface having for axis the shaft of the turbine.

In the radial inward flow, or centripetal turbines (Francis type, fig. 14), the guide-vanes ring is contiguous to the runner, and the water moves towards the axis of rotation in a plane perpendicular to it.

---

* The following books have been consulted and quoted: *Hydraulic Turbines*, by R. L. Daugherty; *Elements of Hydraulics*, by S. E. Slocum; *Water-Power Engineering*, by Daniel W. Mead; *Water-Power Plants and the Type Characteristic of Turbines*, by W. Baashuus; and *La technique de la houille blanche*, by Etienne Pacoret.

In the mixed (radial, inward, and axial) flow turbines (American type, fig. 15) the water enters the wheel radially, in the direction of the axis, and during its flow through the runner. buckets turns and discharges axially.

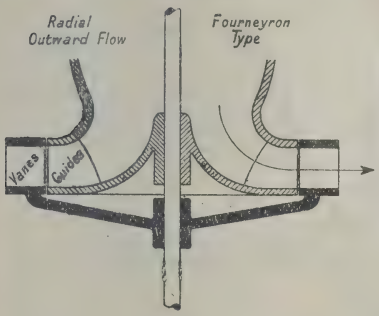

FIG. 12.

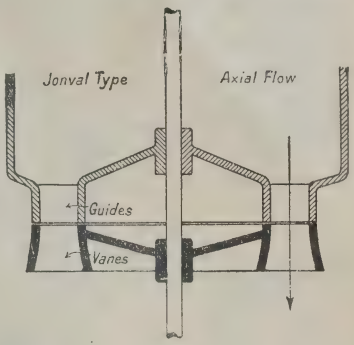

FIG. 13.

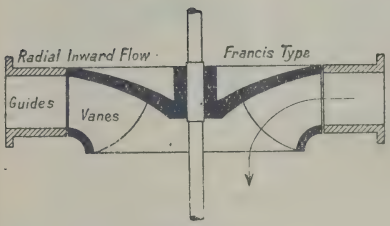

FIG. 1 .

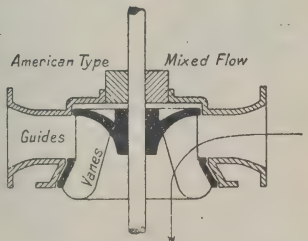

FIG. 15.

POSITION OF THE SHAFT.

Turbines have either (*a*) an horizontal shaft, or (*b*) a vertical shaft; the latter are further classified as right-hand or left-hand turbines according to the direction of their rotation. If in looking down upon the wheel from above the rotation appears clockwise it is called a right-hand turbine. The reverse of this is a left-hand turbine.

Turbine builders have now reduced their production to three types, viz. the tangential or Pelton wheel, the centripetal flow or Francis turbine, and the helico-centripetal or American turbine, each of which satisfies special conditions.

Types of Turbines.

THE FRANCIS TURBINE AND THE AMERICAN TURBINE.

These two types of reaction turbines have now superseded all the others, because they are cheaper to build, smaller, more easily regulated, and have a higher speed than the turbines of the Fourneyron or Jonval type.

The Francis turbine is a radial inward flow turbine of low or medium speed and is better suited for medium heads up to 500 feet. The American turbine, or mixed flow turbine, fig. 15, is a modification of the Francis turbine, resulting from a demand for higher speed and power under low heads. Higher speed is obtained by reducing the diameter of the runner, greater power by increasing the capacity of the runner, making the buckets deeper and reducing the number of vanes. Since this decreased the discharge area, the vanes were curved so as to discharge axially; combined together these alterations have produced the high-speed high-capacity mixed-flow runner of to-day.

The best peripheral wheel speed for a reaction turbine varies between 0·57 to 0·87 of the theoretical spouting velocity of the water under the head considered. The efficiency of the modern reaction turbines is high, ranging between 80 and 85 per cent. under average conditions, and going up to 90 and 92 per cent. under the most favourable conditions.

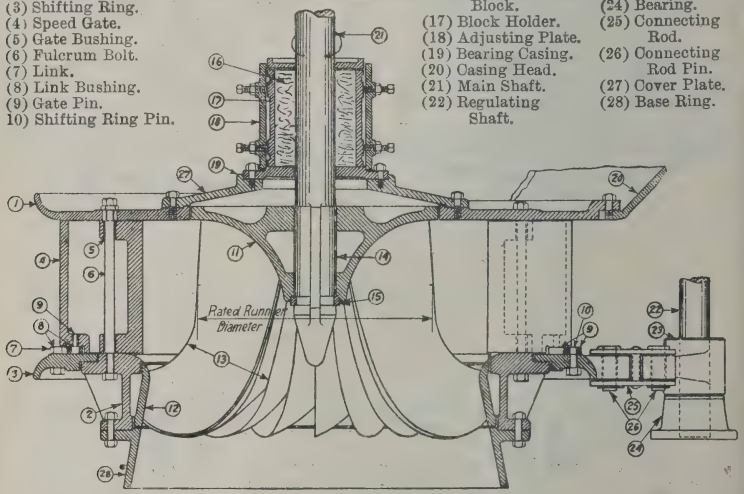

FIG. 16.—American Turbine Nomenclature.

CONTROL OF ADMISSION OF WATER INTO REACTION TURBINES.

There are three different systems of regulating the amount of water supplied to the turbine in case of a variation of the load; these are (1) the cylinder gate, (2) the register gate, (3) the wicket gate.

(1) The **Cylinder Gate**, fig. 17, as its name indicates, consists of a cylinder closely fitting the guides and moving in a direction parallel to the axis of the turbine, thus decreasing or increasing

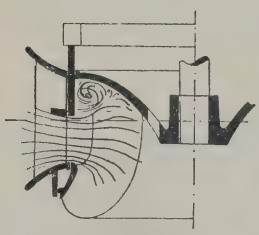

FIG. 17.—Cylinder Gate.

FIG. 18.—Register Gate.

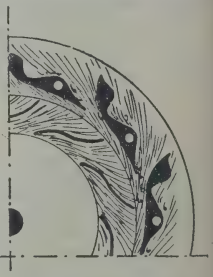

FIG. 19.—Wicket Gate.

the area left between the guide-vanes for the passage of the water. This type of gate is the simplest and cheapest but also the poorest, as the sudden contraction of the vein when passing

under the partially closed cylinder gate and the sudden expansion that must take place in the bucket produces eddying which results in decreased efficiency.

(2) In the **Register Gate**, fig. 18, the guide-vanes are made in two parts. The inner portion next to the runner is stationary, the outer portion is on a ring which may be rotated far enough to shut the water off entirely if necessary. While this is more efficient than the preceding type, there is still a certain amount of eddying when the register gate is partially closed, with a consequent decrease in part gate efficiency.

(3) The **Wicket Gate**, fig. 19, also called the pivoted guide-vane, consists of a connection rod from the governor operating a shifting ring, which, by means of links, causes the vanes to rotate about their pivots, thus altering the area of the passages through them. This system has the working parts outside the case, which is a great advantage; its maximum efficiency is obtained before the gates are opened to the greatest extent.

The Little Giant Double Turbine.

(*S. Howes Co., London.*)

The form of the wheel of this turbine is shown by fig. 20, and general views of vertical forms of complete turbines by figs. 21 and 22.

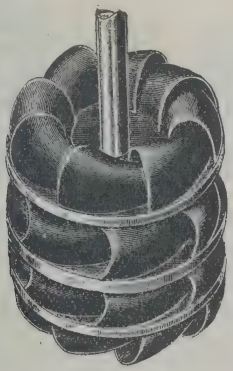

Fig. 20.—Side view of Little Giant Turbine Wheel, showing Form of Double Buckets.

The Little Giant is a double turbine having two tiers of buckets, or, strictly speaking, two turbines keyed to the same shaft, one above the other, and both running in the same case, the upper tier discharging at the top, and the lower one under the bottom of the case. The shaft is supported at the bottom end, and revolves upon an adjustable lignum-vitæ step in the bottom bridge-tree. The case is made of iron in the form of a scroll. This scroll, for larger sizes, is made of boiler-plate, which is planed parallel on the sides, and is held firmly between the cast-iron top and bottom plates by bolts. The case is supported by the bottom bridge-tree, which is bolted firmly to it. The bridge-tree is bolted firmly to the bottom of wheel-pit, upon which it rests. The gate box is made of cast iron and bolted to the case. The gate is also made of cast iron, and the surface of it, as also the ways or seat upon which it slides, are planed, thus forming a perfectly watertight joint. The pressure of water always holds the gate to its place, and the joint remains tight as the gate wears. The gates for the larger sizes of turbines, particularly if to be used under high heads, are mounted upon friction rollers.

The Division Plate.

Figs. 21 and 22 each show an iron plate passing horizontally through the turbine case, and dividing it into two compartments corresponding to the two tiers of buckets, one set being above this plate, discharging at the top of the case, the other below the plate, and discharging at the bottom; in fig. 21 the plate is shown as shut down, and in fig. 22 the plate is raised. Referring to fig. 22, the gate is shown raised clear up, or at 'full gate,'

admitting the water to both tiers of buckets with the full pressure due to the head, giving the full power of both parts, or of the whole turbine. If but one-half of the power of the turbine were required, the gate could be dropped or closed down to the division plate, thus shutting the water off from the upper tier, but maintaining the full pressure on the lower buckets, which would give one-half the full power with half the quantity of water, thus obtaining as high a percentage of power at half-gate as at full-gate, which could not be done if there was only one set of buckets. If no division plates were used, the full pressure of water due to the head would be on the turbine only when the gate was full open, but when used at half-gate the water, after passing through the gate-opening, would pass to both tiers of buckets but with less pressure; consequently the turbine would lose from 20 to 25 per cent. of the power in the water used.

Horizontal Little Giant Double Turbine

(S. Howes Co., London.)

There may be many situations where a turbine placed upon a horizontal shaft can be used to better advantage than one on a vertical shaft. By using a horizontal turbine and placing it

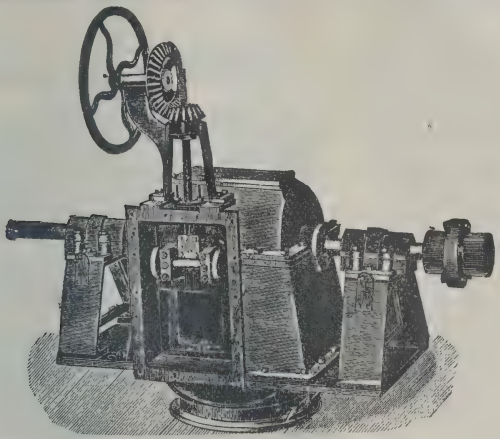

Fig. 23.—Horizontal Little Giant Turbine.

some distance above tail water, nearly the whole effect due to the head can be obtained with an air-tight discharge tube. This mode of setting a turbine (fig. 23) admits of placing a pulley directly on the turbine shaft, and belting to the line shaft.

TURGO TURBINES.

The peripheral velocity of these turbines, figs. 24 and 25 (*Gilbert Gilkes & Co. Ltd.*), is about 77 per cent. of that due to the head of water, compared with 63 per cent. for the 'Lunedale' and 'Trent' types. The capacity, that is to say, the quantity of water used by the turbine in relation to its diameter, is very large.

On account of their high speed, the 'Turgo' turbines are specially useful, on low falls, for coupling direct to electric generators. The shaft may revolve with its axis either horizontal or vertical, and in either position one or more of the wheels may be keyed on the same shaft. If an odd number of wheels are used there is a certain amount of end-thrust on the shaft due to the inequality of pressure; this must be provided for by a thrust bearing, which may be of the plain collar type, ball-bearing type, or the oil-pressure forced lubrication type. When an even number of wheels are used, the shaft runs in longitudinal equilibrium, and no thrust bearing is necessary for the horizontal shaft type.

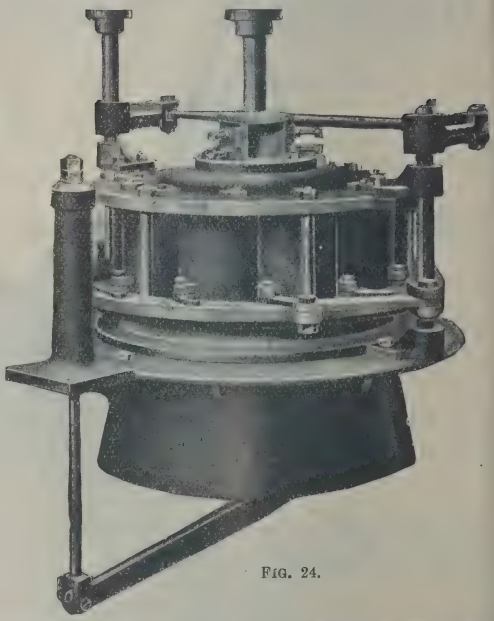

FIG. 24.

In the 'Turgo' turbine, regulation is effected by means of movable guides which are pivoted on steel pins. The recent method of adjusting these vanes does away with the radius rods which are used on many turbines of this type. The guide blades are coupled together by means

FIG. 25.

of connecting links, attached to lugs, so that all can be simultaneously opened or closed by automatic or other means, with the least possible wear.

The guides are so pivoted that they are as nearly as possible balanced in all positions. This fact is of great importance when it is required to control the turbine speed automatically by a governor. All the wearing parts of the guides themselves and their connecting links are bushed with bronze, and the pins are made of hard steel.

The wheel is made of steel buckets bent to mathematically accurate curves, and then cast into an iron boss and outer skirt. In some of the larger sizes the buckets themselves are also of cast iron. The stationary parts of the turbine consist of suction flume and guide-blade chamber, guides with the mechanism for operating them, and guide-blade cover.

The weight of the wheel is carried by a footstep bearing of lignum vitæ, which is fixed in the suction flume. An upright bearing of lignum vitæ cast on to the guide-blade cover serves to keep the shaft in position. No lubrication is needed with this type of bearing.

Medium Fall 'Turgo-Francis' Turbine.

(For Direct Coupling.)

(*Gilbert Gilkes & Co. Ltd.*)

Fig. 26 shows a turbine recently installed at San Juan Mines, in the Argentine. It is designed to develop 750 h.p. when using 7,270 cub. ft. of water per minute under a head of 70 ft. and running at 500 r.p.m.

Owing to the comparatively high speed in relation to the head, two runners are employed each with its own casing but discharging into a central suction flume common to the two

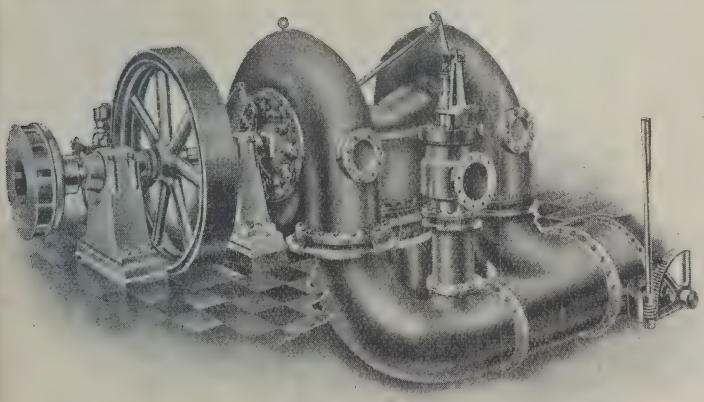

Fig. 26.

wheels, thus putting both wheels into balance and avoiding the necessity of thrust bearings. The casings are of the spiral form, which allows the kinetic energy of the water flowing through the pipes and casing to be utilised with a minimum of loss. The runners and guide blades are of the Francis type, the former being constructed with steel buckets cast into a c.i. boss and skirt.

The guide blades are of cast steel working in phosphor bronze bushes, and have a stem cast on which is accurately turned and carried through glands to the outside of the casing; on the end of each stem is keyed a c.i. lever, the lever being coupled together by means of bronze bushed links. Two of the stems are coupled by means of special levers to the governor. By this means all pins joints, etc., are placed outside the turbine, where they are not affected by the

As the Turgo Turbine gives its highest efficiency at $\frac{3}{4}$ to $\frac{7}{8}$ of full capacity, it is advisable to sele a turbine with at least 10 per cent. margin over the actual requirements.

(Gilbert Gilkes & Co. Ltd.)

action of the water and can easily be lubricated. Although this method of outside gate mechanism is rather more costly in the first place, its extra cost is soon compensated for by smoothness in running and absence of repairs. It has been known that pins acted upon by the water, assisted sometimes by electrolytic action, have required renewing after a few months' wear, entailing the shutting down of the plant for a considerable time to gain access to the inside of the turbine.

The speed of the set is controlled by a Gilkes oil pressure governor, assisted by a cast steel flywheel. In order to prevent shock on the pipe line due to the rapid shutting off of the water, an automatic by-pass valve is provided. The valve is connected direct to the governor and is so arranged that, directly any water is shut off the turbine, the valve lifts immediately, allowing an equal quantity of water to pass through the valve, but immediately the movement of the gate ceases the valve slowly closes without shock on the pipe line. By the arrangement, the valve anticipates any rise in pressure in the pipe line. The speed of closing is regulated by an oil cataract which can be regulated to close at any desired speed.

This type of turbine is commonly adopted for falls varying from 30 ft. to 300 ft. On the higher falls a single spiral is used, discharging its water either from one side of the wheel or from both sides.

The Banki Turbine.

(Boving & Co., Ltd., London.)

This new type of turbine, invented by M. Banki of Budapest University, is manufactured by *Messrs. Boving & Co.*, who hold the sole licence for the British Empire ; fig. 27 shows the general principle of its action.

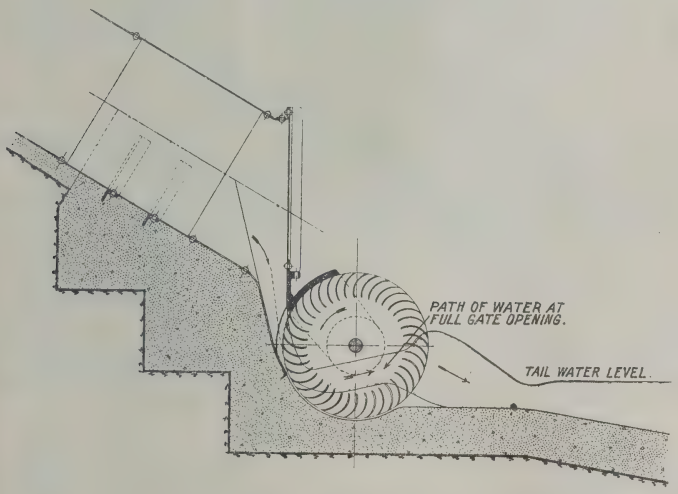

FIG. 27.—Diagrammatic Illustration of Banki Turbine.

The special feature of this turbine (which distinguishes it from ordinary waterwheels) is that the water passes through the blades, across the intervening space inside the wheel, and out through the blades on the opposite side. This enables the blades to be designed to the correct shape and with the correct angles, and accounts for the exceptionally high efficiencies obtained,

which are impossible with ordinary water wheels. As will be seen from fig. 27, the buckets, or vanes, are quite open at the back, are circular in section, and of the simplest possible form. Energy is thus transmitted to the wheel in the first and second pass of the water.

During this passage across the wheel, the water jet is turned through an angle of 154°, and leaves at a low velocity quite free of eddies. It is preferable, but not absolutely necessary, that the wheel is not 'drowned,' as if the tail race banks up to a higher level than the discharge point of the water, the efficiency of the machine is somewhat impaired.

This turbine, which is of the impulse type, differs from the Pelton wheel in that the water jet is rectangular in shape instead of round, and can be increased longitudinally to any desired amount, being limited only by the mechanical strength of the wheel, which for practical purposes occurs when the breadth of the wheel equals twice its diameter.

In the case of a simple impulse Pelton wheel, the wheel diameter must increase proportionally to the jet diameter, and the speed is correspondingly reduced. In the Banki turbine, on the other hand, with a rectangular jet, the wheel diameter and speed can remain the same, whilst the jet is increased longitudinally; it can easily be seen therefore, that with this type of turbine, an exceedingly compact and cheap machine can be produced for any given power, and its speed be higher than in the case of a Pelton wheel working under the same conditions.

Careful tests have proved that the Banki turbine has a very high efficiency, up to 90 per cent. having been obtained under favourable conditions; an efficiency of about 85 per cent., however, is obtained under normal conditions.

Another feature is that the efficiency does not fall appreciably at partial gate openings, and about 82 per cent. can be obtained at one-quarter gate opening; this turbine is therefore particularly adaptable where the quantity of water varies considerably, and a maximum output is required when the water volume is low.

Governing can be effected by means of a single balanced shutter.

The chief advantage claimed for this type of turbine are extremely low first cost, very high efficiency, which is maintained at all gate openings; low installation costs, as no building is required to house the machine; extreme simplicity, and no parts are subject to friction working under water.

Selection of a Turbine Runner.

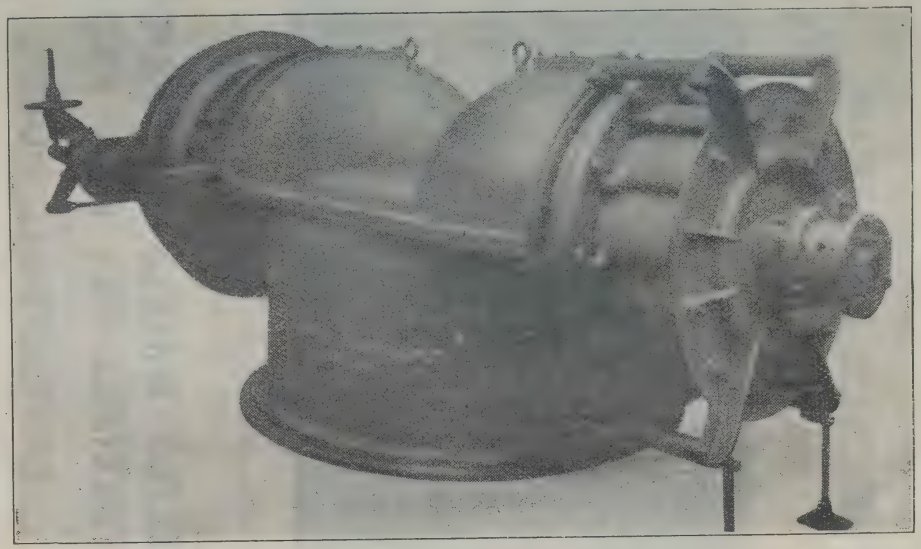
There are a certain number of commercial constants which are of great help to the engineer who is not a turbine designer, when attempting to select the best type of turbine to adopt for a given development and a chosen capacity per electro-generating unit.

The **Specific Speed** (N_s) is a theoretical characteristic which gives the means of comparing the relation between the conditions of speed, head and power of a runner in one installation with the same conditions relative to a runner in a totally different installation. This comparison is made after the conditions governing the design of both runners have been reduced to a common base, viz. the specific speed.

The specific speed of a runner may be defined as the speed at which any runner will run when it is reduced to such a size that it will develop one horse-power when operating under a head of unity. The numerical value, expressed in the metric system, of the specific speed of any runner may be found by first calculating the speed and power output of the runner under consideration for one metre head, and then mathematically reducing the runner in size until it will deliver one horse-power. The speed of this reduced runner when operating at its point of maximum efficiency is its rated specific speed; this speed is generally expressed in the metric system in order to adhere to an international standard. The formula is

$$N_s = 4{\cdot}45 \text{ r.p.m.} \sqrt{\frac{\text{h.p.}}{h^{\frac{5}{4}}}},$$

in which the horse-power and head are expressed in the foot-pounds system, while N_s remains in the metric system. The equivalent given in the foot-pounds system is called the 'unit speed,' or 'type characteristics.'



$$N_u = \text{r.p.m.} \sqrt{\frac{\text{h.p.}}{h^{\frac{5}{4}}}}$$

In figuring the specific speed of any reaction turbine having more than one runner, or any impulse wheel having more than one nozzle, the horse-power used in the formula, of course, is the power developed by one runner only, or one nozzle only.

For a given number of revolutions per minute (r.p.m.), and head (h), the h.p. output is

JAMES GORDON & Co. Ltd.

F. 1217

proportional to the square of the specific speed; also for a given head and h.p. the r.p.m. of a turbine is proportional to the specific speed.

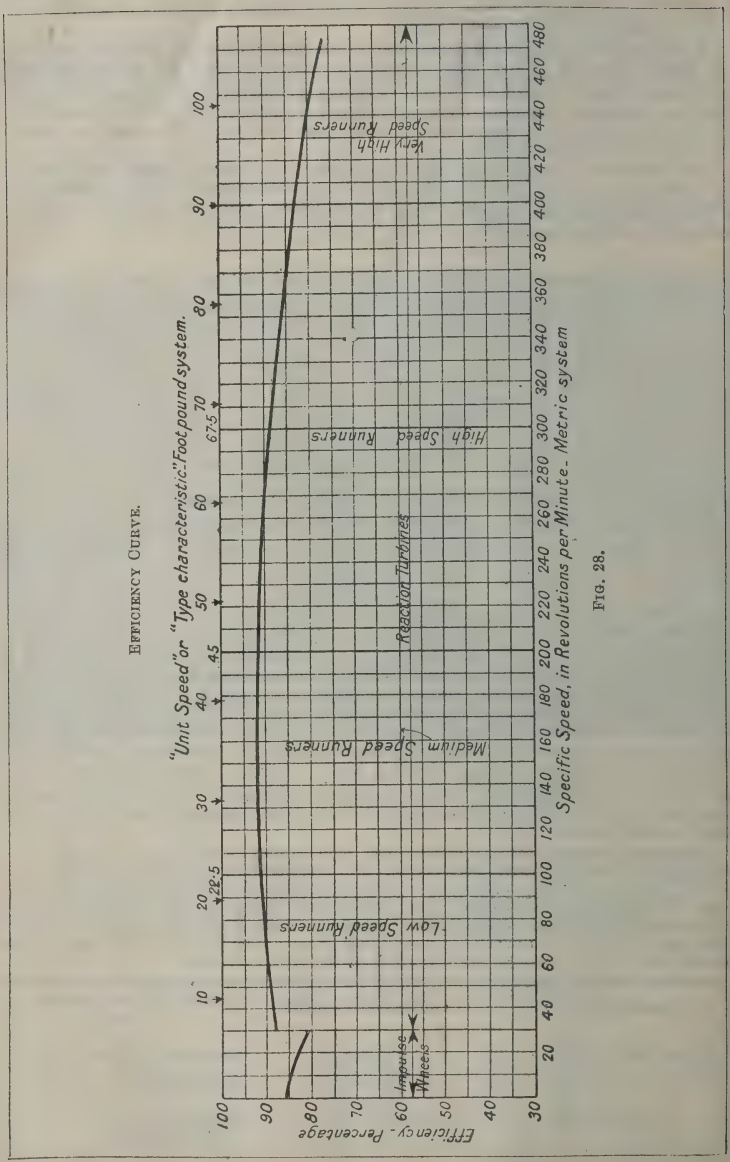
In applying the formula for the specific speed to turbines already built it will be found that the data of an impulse wheel will give a low specific speed, between 5 and 25, while the data on the radial inward-flow turbine and on the radial inward axial flow turbine will give a high specific speed between 40 and 450. It will be noticed that there is a gap between the impulse wheel and the reaction turbine, as values of N_s between 25 and 40 do not exist with either type; but by using more than one nozzle on one impulse wheel it is possible to increase the value of N_s, so as to cover the entire field.

The formula for the specific speed contains only the two quantities, 'speed' and 'capacity for a certain head,' but as these quantities determine the areas and angles of the turbine, and thereby again the losses which take place during the passage of the water through the turbine, it will be understood that the specific speed is inherently related to the efficiency which can be expected from the turbine.

EFFICIENCY AT THREE-QUARTER POWER OF IMPULSE WHEELS.

Specific Speed.	Efficiency.
	Per cent.
5	80
9	79
13	78
18	77
22	76

EFFICIENCY OF RADIAL INWARD-FLOW TURBINES.



Type.	Specific Speed.	Maximum Efficiency.	Efficiency at half power.
		Per cent.	Per cent.
Low speed . .	40—100	82 at 0·75 power	76
Medium speed .	130—220	82 at 0·75 ,,	75
High speed . .	260—360	80 at 0·80 ,,	70
Very high speed . .	400—450	73 at 0·90 ,,	53

This table shows that the different types of radial inward turbines are of different qualities. The low-speed turbines are very favourable as to efficiency over a wide range of loads, but they are practically limited to high heads. Medium-speed turbines are also very favourable as to efficiency over a wide range of loads. High-speed turbines are favourable as to efficiency at about 0·8 load, but show a marked decrease at about half load. The extreme high-speed turbines may in some cases be tolerable as to efficiency at about 0·9 load, but at about half load the efficiency is below the limit of rational utilisation of the water. The use of such turbines is only justified for low heads, with a supply of water ample in all seasons, and where the head remains rather constant.

The curve (fig. 28), based on tests of higher grade turbines, shows that if one desires the best efficiency possible a specific speed should be chosen between 110 and 220.

The modern practice is towards the use of large units running at the highest speed compatible with the exigencies of economical and prudent operation, so that, although the choice of a turbine depends on the power and speed desired as well as on the head available, it would seem as if the head was in most cases the deciding factor. The following table, based on this assumption, gives the type of runner desirable in function of the head.

Heads from 500′ up.	Specific speed 5 to 25.	Type of Runner Impulse Wheel.
For heads up to 500′ . .	40 to 100	Low speed, reaction.
,, ,, ,, 300′ . .	100 to 150	
,, ,, ,, 150′ . .	130 to 180	Medium speed.
,, ,, ,, 60′ . .	175 to 250	
,, ,, ,, 30′ . .	260 to 360	High speed.
,, ,, ,, 15′ . .	400 to 450	Very high speed.

EFFICIENCY CURVE.

FIG. 28.

Relation between the Speed and the Discharge of a Turbine and the Head.

For maximum efficiency the peripheral speed (U_1) of any runner is a definite fraction of the spouting velocity under the given head,

$$U_1 = \phi \sqrt{2gh};$$

the best wheel speed is given by values ranging from

0·43 to 0·47 for impulse wheels,
and 0·53 to 0·57 for reaction turbines.

The discharge through a turbine is like the discharge through any orifice and varies as the square root of the head, and the coefficient of discharge has a definite value for the best value of ϕ; it follows that *the best speed and the discharge of a given turbine vary as the square root of the head* ($h^{\frac{1}{2}}$).

Relation between the Input and the Output of a Turbine and the Head.

The power available in each unit volume of water is proportional to the head, and since the quantity of water discharged varies as the square root of the head, then *the power input varies as the three-halves power of the head* ($h^{\frac{3}{2}}$).

The losses of head in any turbine vary as the squares of the various velocities concerned. Since these velocities vary as the square root of the head, their squares will vary as the first power of the head. The amount of water varies as the square root of the head, and since the power lost is the product of these two items, it follows that the *various hydraulic losses vary as the three-halves power of the head.* As the hydraulic losses vary in just the same proportion as the power input, *the hydraulic efficiency will be independent of the value of the head.*

The power output of a given turbine varies as the three-halves power of the head.

Relation between the Diameters of Stock Runners of the same Type.

When a certain type of runner has been perfected, a whole line of stock runners of that type may then be built with diameters ranging from 10 to 70 inches. All of these runners will be homologous in design, that is to say they will have the same specific speed and each runner will simply be an enlargement or reduction of another. Having the same characteristics, that is the same value of ϕ and c (coefficient of discharge), they will therefore follow certain laws of proportion, which can be summed up as follows for a series of runners of homologous design:

1. The best r.p.m. will be inversely proportional to the diameter.
2. The discharge of any turbine of the series will be proportional to the square of the diameter.
3. The power of any turbine of the series is proportional to the square of the diameter.

These relations are of practical value, because if the speed, discharge and power of any runner is known by accurate test, predictions may then be made regarding the performance of any other runner of the series.

Relation between the Diameter of a Runner and its Discharge.

Since the discharge of any runner is proportional to the square of its diameter and to the square root of the head, we may write

$$q = K_1 D^2 \sqrt{h} = \text{cub. ft. per sec.}$$

The value of K_1 depends upon the velocity of the water entering the runner and the area of the passages in the runner. The velocity depends upon the value of the coefficient of discharge c, which varies from 0·6 to 0·8, and the area depends upon the diameter, the height of the runner, the angle, and also the number of buckets and guides. To summarise, the values of K_1 vary

for the tangential water wheel, from 0·0002 to 0·0005;
for the reaction turbine, from 0·0014 to 0·0360.

Relation between the Diameter of a Runner and its Power.

Since the power of any runner is proportional to the square of the diameter and to the three halves of the head, we may write,

$$\text{h.p.} = K_2 D^2 h^{\frac{3}{2}}$$

for the tangential water wheel, $K_2 = 0{\cdot}000018$ to $0{\cdot}000045$;
for the reaction turbine, $K_2 = 0{\cdot}00012$ to $0{\cdot}0033$.

Determination of the Constants.

The constants given may be computed from theory, but for practical use they should be secured from test data. The engineer who has to select a type of turbine can determine these factors by taking the information given in the catalogues of the turbine manufacturers. The tables contained in these catalogues are supposed to be made from actual tests, and give the discharge, power, and speed of runners of various diameters under various heads. Of course, as each manufacturer usually makes several lines of runners, there will be as many distinct values of the constants as he makes types of runners.

The Draft Tube.

It is generally found advantageous to install the turbine at an elevation above the elevation of the water in the tail race, but in order to do this without any loss of head it is necessary to connect the turbine discharge with the tail race water by means of an air-tight steel or concrete tube whose efflux is below the water level. This tube was formerly known as the Jonval device, but now generally called a 'Draft Tube.'

In considering the effect of the draft tube it should be remembered that a given static head may exist either wholly in the form of pressure or pressure head, or wholly in the form of vacuum or suction or draft head, or part of the head may be in the form of pressure head and the remainder in the form of draft head.

Also, a given head may exist wholly in form of pressure or static head, or wholly in the form of velocity, or part of the head may be in form of pressure and the remainder in the form of velocity, and pressure can be converted into velocity or velocity into pressure.

The effect of a draft tube on a turbine is to remove a part of the back or counter pressure due to the pressure or weight of the atmosphere, by a hanging water-column creating a partial vacuum. This water column being held in equilibrium by the pressure of the atmosphere, its height or head cannot be greater than 34 feet.

The draft head is the vertical distance between the centre of the shaft and the tail water for horizontal wheels, and between an horizontal line passing through the centre of the runner buckets and the elevation of the tail water for vertical turbines.

It is never possible to realise an effective draft head of 34 feet, as it is necessary to subtract the various losses due to the friction of the water in the draft tube, to the change in the speed of the water between the turbine runner and the lower end of the draft tube, and to the momentum or velocity still contained in the water while leaving the draft tube.

The absolute velocity in feet per second with which the water issues from the runner buckets and enters into the draft tube, assuming its diameter to be that of the outside of the runner, should be from $\cdot 30\sqrt{2gh}$ to $\cdot 15\sqrt{2gh}$, and the velocity at the outlet of the draft tube may be $\cdot 1\sqrt{2gh}$, especially if the discharge is in the direction of the flow.

When no draft tube is used, the heads corresponding to the velocities of discharge from the turbine are completely lost, whilst with a properly designed draft tube it is possible to recover about 75 per cent. of the gain in head, due to the difference between the velocity head at the turbine and the velocity head at the outlet of the draft tube.

The following table gives the greatest draft-head permissible in practice, under average conditions, and for different diameters of draft tube.

Draft Head Permissible in Practice.

Diameter in feet.	Draft Head in feet.	Diameter in feet.	Draft Head in feet.
0·5	31·0	6	17·0
1·0	29·5	7	15·4
1·5	28·1	8	14·2
2·0	26·7	9	13·2
2·5	25·3	10	12·3
3·0	23·9	11	11·4
3·5	22·6	12	10·6
4·0	21·4	13	9·8
4·5	20·2	14	9·0
5·0	19·0		

The draft head given in this table is equal to the difference of elevation between the turbine and the tail water plus the velocity head corresponding to the speed with which the water leaves the draft tube.

The draft tube should be calculated to resist the atmospheric pressure, which tends to make it collapse.

REGULATION OF TURBINES.

In many hydraulic plants, and notably in the hydro-electric plants, it is necessary that the rotating speed of the turbines should be constant, regardless of the power developed. This can be done either by a hand or by an automatic regulation of the water openings, in proportion to the power utilised. The automatic regulation is adopted in preference to the hand regulation in all important plants.

The water wheel governors are controlled by a centrifugal ball mechanism just as in the case of the steam engines, with the difference that, as the force required to move the turbine gates is large, it cannot be supplied by the centrifugal ball governors, but must be borrowed either from the hydraulic motor itself or from an exterior source.

The gates are therefore moved by a 'relay,' which is a device for transmitting energy from a source of energy independent—as to quantity—of the centrifugal governor balls but controlled by them in its application. If the relay is of 'mechanical type' the power required to operate it and the gates is transmitted, when needed, from the wheel by means of shafts, gears, friction-clutches, belts and pulleys, or other mechanical devices. In mechanical governors the flyballs may actuate pawls, friction gears, or other mechanical devices which will bring the relay into action.

If the relay is of the hydraulic type, it usually consists o a piston connected by some mechanical device to the gate rigging and moved by means of the hydraulic pressure of water taken from the penstock, or other source, or by oil supplied under high pressure from a reservoir. The pressure of the oil in the reservoir is maintained by compressed air supplied by power taken from the wheel itself. The oil thus used in moving the piston is exhausted into a receiver, from which it is pumped back into the supply reservoir. The hydraulic relay is commonly controlled by the ball governor through the medium of a small valve, which by its motion either admits the actuating water (or oil) directly to the cylinder or to a secondary piston controlling a larger admission valve.

Electrical methods of actuating the relays controlled by means of governor balls have been used to some extent but are not nearly so common as mechanical or hydraulic devices.

The best makes of hydraulic governors for medium and high falls will regulate the speed within the following limits, the percentage of variation being that of the mean speed :—

	Speed Variation. Per Cent.
For sudden variation of load of 25 per cent.	4
" " " 50 per cent.	6
From no load to full load	10

Regulation due to Flywheel Effect.*

Flywheel effect is the capacity of a rotating mass to store or supply energy. This effect is expressed at 1 ft. radius and is equal to the moment of inertia of a mass, that is the weight by the square of the radius of gyration, or pounds feet squared. Modern alternating current generator rotors are built in the shape of a common flywheel and usually have sufficient flywheel effect to obtain satisfactory regulation. The flywheel effect of the rotating parts of a turbine varies with different types and usually is not considered, but it should be carefully considered for large low-head multiplex and large diameter impulse turbines. In smaller turbines it may be regarded simply as introducing a factor of safety.

The regulation due to any given flywheel effect can be computed by means of the formula,

$$d = \frac{800{,}000 \times \text{h.p.} \times T}{\text{r.p.m.} \times \text{r.p.m.} \times W r^2}$$

where,

d = percentage of variation in speed allowed ;
T = time of closure of governor in secs. ;
W = weight of rotating masses in lbs. ;
r = radius of gyration in ft. ;
W_r^2 = moment of inertia of the rotating masses in lbs. ft. squared.

* Adapted from *Speed Regulation of Hydro-electric Plants*, by Wm. F. Uhl.

Actually the relative change of speed (d) on account of the friction load of the turbine and generator is smaller than that given by the above formula. The effect of this friction load will vary according to the various types of turbines used, but the original formula may be modified safely as follows:—

$$d_1 = 0{\cdot}8d.$$

Another cause which should be taken into consideration, providing the turbine is properly designed so as to give its maximum efficiency at normal or synchronous speed, is that the efficiency is reduced with either increasing or decreasing speed, which has the tendency to reduce further the relative change of speed (d).

The amount reduced varies with the type of runner, being greatest for a high-speed, high-power runner, and least for a low-speed, low-power runner, since if correctly designed, and therefore following the laws of hydraulics, the change in efficiency will be greater for a high-speed than for a low-speed runner for the same per cent. of variation in speed. The formula modifying d_1 for this cause is as follows:—

$$d \text{ eff.} = \frac{d_1}{1+\frac{d_1}{\frac{n_2}{n_0}-1}}.$$

The value of $\frac{n_2}{n_0}$ varies with the specific speed, and we have

Specific speed	60	90	130	180	220 to 280	310 to 370	400 to 460
Value of $\frac{n_2}{n_0}$	1·8	1·7	1·6	1·5	1·4	1·3	1·2

For impulse turbines 1·8 can be used as the value of $\frac{n_2}{n_0}$. To find the speed variation for any other than a full load change, the following must be considered: If T is the regulating time for the total governor stroke or 100 per cent. load of the turbine, it would appear that for 50 per cent. load or stroke, the regulating time would be $\frac{T}{2}$, and for 25 per cent., $\frac{T}{4}$, etc.

The regulating time for the total governor stroke or the governor closing time should be adopted only after a thorough study. Sensitive governing means severe wear and tear on the gates as well as increased shocks in the penstocks, and should be avoided where possible. Many lighting plants are successfully operated where it requires 20 seconds to close the gates, and while 20 seconds may be extreme, a closing time of 5 seconds is quite satisfactory for all but the most important or special plants.

Turbine Governors.

(*Hay, Maryon & Co., Ltd.*, 14 *Bride Lane, London, E.C.* 4.)

The sole efficient survivor of all the various types of governors made in the past is practically represented now by the latest forms of oil-pressure types. Oil-pressure governors as now designed are capable of giving extremely close speed regulation, the degree of regulation obtainable depending in a large measure on the hydraulic conditions under which the plant has to operate, as, although governors can be constructed which will entirely close or open the turbine gates in even as short a time as 1 second, it has been found in practice that from 2 to 3 seconds is about the maximum rate of operation which can be adopted, and even this rate is often not possible on turbines supplied through long pipe lines, owing to the dangerous water-hammer effects which would be set up. In installations of this description, relief valves can be used and quick rate of action of the governor maintained, and, on high falls, Pelton wheels provided with combined spear and deflector regulation similar to that described on pp. 1203-4 can be successfully operated without any danger of water-hammer effects. In practically every case it is necessary that a certain amount of flywheel effect should be provided in the plant, to assist in speed regulation and to give up or absorb power as required during the time taken by the governor to operate. Owing to the quick rate of governor action generally adopted, it is of extreme importance that the turbine guide blades and operating gear should be of heavy and solid construction, as otherwise considerable lost motion and excessive wear will soon be set up in the gate operating gear when worked in connection with a quick-acting governor. The light construction of guide vanes and operating gear in turbines, generally known as the American type, is not suitable for obtaining efficient results and long life of working parts when used in connection with quick-acting governors.

One of the latest and most efficient forms of oil-pressure governors is shown by fig. 29, and the very highest possible degree of speed regulation can be obtained with governors of this type. The governor consists of a cast-iron box type bed, containing an oil reservoir and drum type oil-pump. On the right-hand end of the bed is mounted a cast-iron receiver which, under working conditions, is about three-quarter parts filled with oil and the remainder with compressed air under a pressure of from 150 to 200 lbs. per sq. in. Connected to the receiver is the main operating cylinder, the piston rod of which is connected to a lever on the main shaft,

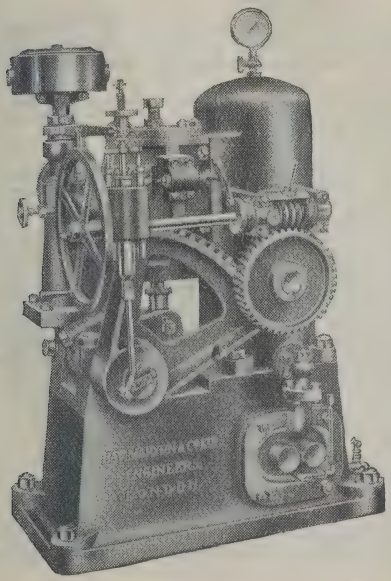


FIG. 29.

this shaft being connected at one end to the turbine gate operating gear, and has a movement of about 60° for the full range of gate movement. The shaft also carries on one end a spur quadrant connected to the hand operating gear, the design and arrangement of which is shown in the figure; this gearing can be connected or disconnected, as required, by the small lever shown over the worm. A connection is also provided on the worm shaft to a valve on the operating cylinder, which automatically relieves the pressure on the piston when the hand gear is connected. The governor head, which is mounted on pedestal on one end of the bedplate, is of the combined spring and deadweight type, supported in ball bearings and driven by means of totally enclosed bevel gears and a pulley on a horizontal spindle, by belt from the turbine shaft.

The operating gear for the governor consists of a floating lever, shown on the left-hand side of the figure, having at one end a pair of damping springs (not visible in the figure); this lever is connected first to the governor head, second to the distributing valve, and third to the compensating gear, which in turn is connected to the main shaft of the governor. The action of the governor when in operation, and assuming the speed of the turbine to have risen, is as follows:—

The governor head would rise, carrying with it the sleeve with the end of the floating lever together with the distributing valve, the compensating gear on the end of the rod acting as a fixed pivot. The rising of the distributing valve would admit oil under pressure to one end of

the cylinder, at the same time opening the other end of the cylinder to exhaust, the turbine gates would then commence to move in a closing direction, any movement of the turbine gates being transmitted back to the compensating gear, which would rise carrying with it the opposite end of the floating lever and replacing the distributing valve in its normal position. After the movement had taken place the dashpot on the compensating gear would gradually return its end of the floating lever to the normal position ; the time required for this can be adjusted to correspond with the return of the governor head to the position for normal speed, this arrangement giving a constant speed for the turbine at any stage of load between no load and full load.

An adjustment is provided on the compensating gear so that, if required, a fixed variation in steady speed between no load and full load can be obtained for automatically dividing the load between any two or more generators when operating in parallel.

The distributing valve of the governor is also capable of adjustment, so that the closing time can be varied from a maximum of about 2 seconds to any slower rate, to suit the hydraulic conditions under which the plant is operating.

Special attachments can be provided on the governor, first for automatically shutting down the turbine in the event of the driving belt to the governor head breaking or coming off, and, secondly, to prevent the governor opening the turbine gates beyond a predetermined limit. The latter arrangement is a great advantage in connection with turbine plants working in parallel with steam or other sources of power where the water supply is limited—as the governor can be set for a gate opening to suit the water supply available at the time, and with the turbine governor speed adjusted slightly ahead of the other prime mover, the governor will then keep the turbine gates open to the limit decided on, ensuring that full advantage is derived from the water available.

The governor described and illustrated is constructed in ten standard sizes, with capacities ranging from 360 ft.-lbs. to 36,000 ft.-lbs., the former being suitable for small turbine installations, and the latter for the largest size of turbines constructed.

The Gilkes Fluid Pressure Governor.

(Gilbert Gilkes & Co. Ltd.)

This oil pressure governor (fig. 30) is the type constructed by Messrs. Gilkes for use on small and medium-sized turbines, but it may be used for high and low fall turbines of the reaction type, or for Pelton wheels.

The base of the governor forms a reservoir, from which the oil is drawn and pumped up to the necessary pressure by means of a rotary pump ; the oil is then passed under pressure to the distributing valve and from there is directed to one or the other of the governor cylinders, as the speed conditions may dictate, thus giving motion to pistons fitting in the cylinders and in turn to the rocking shaft, from which motion is taken to actuate the turbine gate mechanism. The position of the regulating valve is dictated by a pendulum of the drum type driven by machine-cut gears, the power being taken both for the pendulum and the pump from the turbine shaft by a silent chain drive. In order to overcome over-riding and consequent hunting, the governor levers are mounted upon a floating fulcrum, taking its motion from the rocking shaft.

The arrangement of valves in this governor is such that when the speed is steady and the governor is not called upon to move the gates, the oil is automatically by-passed, thus very considerably reducing the power to drive the governor and prolonging its life. It also keeps the oil cooler, as the constant discharge against pressure through a relief valve would soon heat the oil.

A hand gear control is provided, consisting of a worm and wheel, as shown in the figure. The throwing into gear of the worm at the same time automatically puts the governor out of control. When desired to shut down suddenly this can be quickly done by means of the small hand wheel seen at the fulcrum end of the governor levers.

Speed Variation.—The permanent variation is usually 4 to 5 per cent., although it may be made higher or lower if desired. By means of an additional gear, the permanent speed may be kept the same at all loads. The momentary variation depends upon two factors : (1) the speed

at which the governor closes the gate, and (2) the inertia of the moving parts of the set. Although governors are designed to move the gate from open to shut in from two to three seconds, it is often impossible, for other reasons, to shut the water off so rapidly, and in such cases heavy

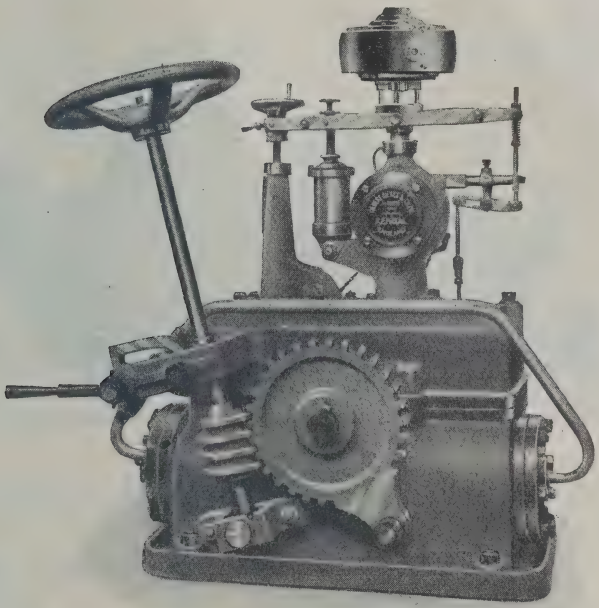

FIG. 30.

flywheels must be used. Under favourable conditions it is practicable to obtain with the full load thrown off a momentary increase of speed of 8 per cent., but it is more usual to specify that the speed variation should not exceed 15 per cent.

TURGO IMPULSE TURBINE WITH SHAFT GOVERNOR.

(Gilbert Gilkes & Co., Ltd., Sole Makers and Patentees.)

Fig. 31 is a general, and fig. 32 a diagrammatic, view of this arrangement, showing the movements of this regulator. In fig. 32 the pendulum is shown mounted on a separate shaft, but as seen in fig. 31 it is actually mounted on the turbine shaft, and is connected directly by means of levers to a shaft on which is mounted the deflector. As the speed rises or falls the deflector is forced into or out of the jet. The spear rod is hollow, and has a hole running through the full length of it, the hole at the cylinder end making a seating for poppet valve 16, so that when the valve is pressed against the hole communication through the rod is closed. Pressure water is brought through valve 32 to the back end of the cylinder. When valve 16 is pressed against the seating the pressure on both sides of the piston 14 is equal, and pressure on the spear-head

is constantly endeavouring to pull the spear into the nozzle. The deflector is connected by means of rods and levers to bell-crank lever 20, one end of which presses against the poppet valve 16. If the load be thrown off, the deflector is forced into the jet and the poppet valve pushed hard up against the spear rod. Pressure accumulates behind the piston, and the spear is slowly forced into the nozzle, reducing the area of jet. As the area of jet is reduced, the

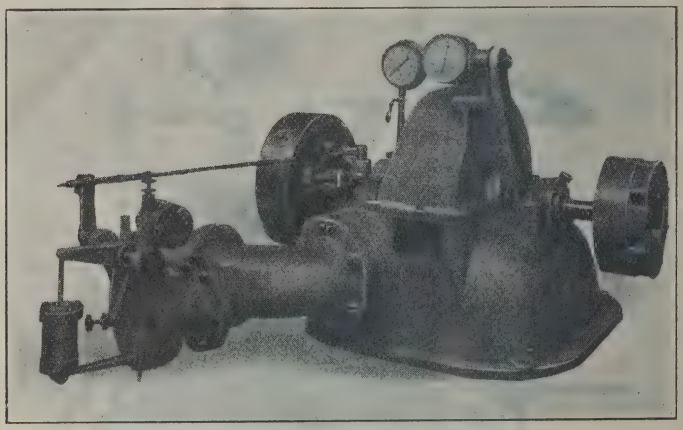

FIG. 31.

deflector is lifted out of the jet, until finally deflector and spear come to rest in a position where the deflector is just clearing the jet. If the load is thrown on, the deflector is raised, the bell-crank lever 20 is drawn away from the poppet valve, and the pressure in the cylinder forces

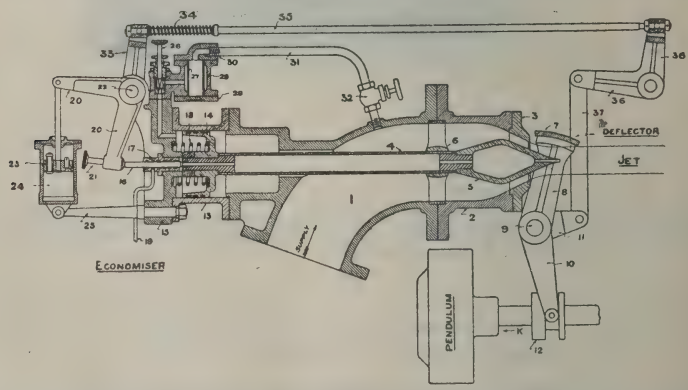

FIG. 32.

the valve outwards away from its seating. The pressure behind the cylinder is now relieved, and a superior pressure in front of the piston forces the spear back, thus forming a larger jet.

In order to prevent undue rise of pressure in the pipe line, the inward movement of the spear must be slow; but in order to prevent rise in speed, the cutting off of the jet must be extremely rapid; this is allowed for by the connection of rod 35 to lever 33 being through the spring 34; the rapid movement of the deflector compresses the spring 34, which keeps the poppet valve

ST. JÉRÔME HYDRO-ELECTRIC PLANT, NORTH RIVER, CANADA.

(Designed by Messrs. Surveyer & Frigon.)

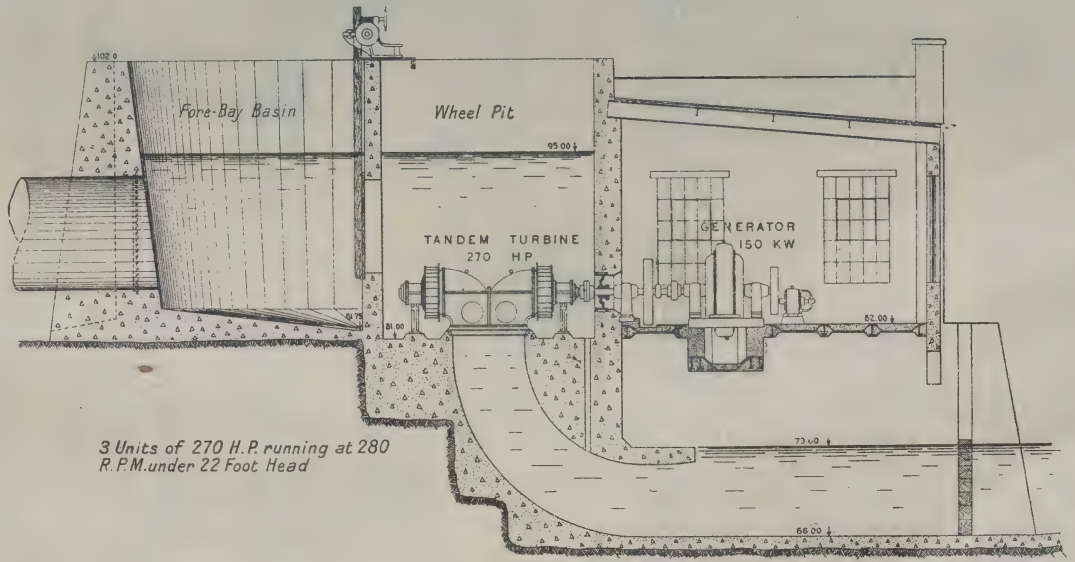

FIG. 33.—Three Units of 270 h.p. running at 280 r.p.m. under 22-foot head.

up against the end of the spear rod. Pressure accumulating behind the piston forces the piston, and with it the spear, inwards, the rate of closing being regulated by means of a by-pass valve in piston 23 moving in the oil dashpot 24. A non-return valve is arranged in 23, allowing the oil to pass rapidly from the upper to the lower side of the piston, and thus permitting lever 20, and with it the poppet valve, to be rapidly moved. The spear rod, following the movement of the poppet valve, is rapidly drawn back. A regulating valve, 26, is provided; but this is not intended to regulate the movement of the spear, but only to ensure that there is not more water passing into the cylinder than can be carried through the hole in the spear.

TYPICAL HYDRO-ELECTRIC PLANTS.

St. Jérôme Hydro-Electric Municipal Plant on the North River, Canada.

This plant (fig. 33) was constructed in 1913 by the town of St. Jérôme to supply electricity to its population of 3,500; it is built on the North River, which carries the waters from the Laurentian Mountains to the Ottawa River and thence to the St. Lawrence River.

The chief features of this plant are a concrete weir, a needle dam with three openings, and a reinforced concrete pipe 8½ ft. in diameter bringing down the water to a power house 1,000 ft. distant from the head gate. The power house consists of a semi-circular forebay of reinforced concrete communicating, by means of sluices, to the three turbine pits. These turbines are of the twin open flume type, designed to have each a maximum output of 270 h.p. at 277 r.p.m. and operating under 20-foot head. The setting of the wheels is horizontal, and they are provided each with a concrete draft tube discharging under the power house proper. The building contains the generators, which are directly connected to the turbines through a cast iron wall plate provided with a stuffing box. Two of the generating units are now installed, and their electrical equipment consists of two 150 kw., 3-phase, 60-cycle, 6,600-volt alternators. The exciters are two 10 kw. units, 120 volts, 1,150 r.p.m. belt connected to the end of the generator shaft. The power is transmitted at 6,600 volts over a transmission line 4 miles long, to a sub-station in St. Jérôme and distributed through the town on a 2,200-volt primary circuit and a 110-volt secondary circuit.

The plant (fig. 34) of the Cedars Rapids Manufacturing and Power Co. is situated on the St. Lawrence River about 27 miles from the city of Montreal. The low water flow of the river at that point is about 170,000 cub. ft. per second, and the company has been authorised by the Government to utilise 56,000 cub. ft. per second.

The Cedars Rapids have a fall of 32 ft. in two miles, and the river is approximately 3,000 ft. wide at that point. The development consists of a head-race canal about two miles in length, formed by an outer embankment built up in the river, parallel to the flow, and an inner bank placed back from the original shore line. This head-race is from 700 to 1,200 ft. wide, and is dammed at the lower end by the power house substructure.

The present length of the power house is 667 ft., extending from the outer bank towards the shore and connected to the present shore line by a rock-filled crib dam. This crib is 48 ft. high, and so placed that the work of extending the power house for the remaining 513 ft. to the new shore line for the final development may be carried on without disturbing the crib. When the power house is ready for the final development the crib and fill may be removed by dredging.

The turbines for this development have the largest dimensions of any in the world to date (although not the highest capacity output). In the design are seen all the features of recent advances, such as (1) volute casing and draft tube moulded in the concrete substructure, (2) cast iron speed ring with the vanes serving as columns to support the concrete floor, generator and thrust-bearing loads from above, (3) lignum vitæ guide bearing, (4) Kingsbury thrust bearing located above the generator, and (5) pneumatic brakes acting on the generator rotor to bring the revolving parts quickly to a standstill.

The present construction provides for ten units of 10,000 h.p. each, but 160,000 h.p. will ultimately be developed.

Each generating unit consists of a vertical American turbine guaranteed to have a maximum efficiency of at least 87 per cent. when operating under an effective head of 30 ft. running at a speed of 55·6 and developing between 10,000 h.p., and the maximum figure corresponding to wide open gate, provided, however, that the maximum power does not exceed 10,800 h.p. by more than 5 per cent. To each of the main turbines is connected a 10,000 kv.-a. 3-phase 6,600-volt 60-cycle generator of revolving field type.

In the transformer house on shore are the high-tension switches and feeders between transformers and transmission lines. Provision has been made for four transformer banks, two to be of 24,000 kv.-a. capacity and made up of 8,000 kv.-a. single-phase 6,600/110,000-volt units; the other two banks will be of 15,000 kv.-a. capacity, each bank having three 5,000 kv.-a. single-phase 6,600/66,000-volt units. The 110,000-volt banks feed transmission lines running to Messina, N.Y., where 60,000 h.p. will be taken by the Aluminium Co. of America. The remainder of the power is transmitted at 66,000 to Montreal, from the 15,000 kv.-a. bank.

The Grand'Mère Municipal Hydro-Electric Plant on the Shawenegan River, Canada.

This plant (fig. 35) was built in 1913 by the town of Grand'Mère to supply electricity to its 5,000 inhabitants. It is located at eight miles from Grand'Mère, on the Shawenegan River.

The fall utilised is a hundred feet high, and the water is carried to the power house through a four-foot wood stave penstock, 1,100 ft. long.

The equipment consists of two 500 h.p. spiral casing water turbines, running at 600 r.p.m and each directly connected to an alternating current generator and a direct current exciter. The generators are of 300 kw. capacity, producing electricity at 60 cycles and 2,200 volts. The current is stepped up, by transformers in the power house, to 10,000 volts, transmitted to a substation in Grand'Mère and distributed through the town on 2,200 volts primary circuit and a 110-volt secondary. The power-house floor is situated very high above the low water elevation of the Shawenegan River on account of the extreme high water level, due to the backing up of the St. Maurice River in the spring.

Jordan River Development of the Vancouver Island Power Company, Ltd.

The Jordan River plant (fig. 36) of the Vancouver Island Power Company, Limited, is situated at the mouth of Jordan River, which flows into the Straits of San Juan de Fuca about 40 miles west of the City of Victoria, Vancouver Island, Canada.

This development is of particular interest on account of the high head utilised, the static head at the power house being 1,145 ft. The power house is situated on the beach near the mouth of the Jordan River, with the main floor 7 ft. 6 ins. above high tide level. Water is conveyed to the water wheels in the power house from a forebay reservoir through steel pipe lines 9,290 ft. long. The forebay, which is a small equalising reservoir formed by two earth fill dams, is about 1,152 ft. above sea level, giving a static head of 1,145 ft. at the nozzles in the power house.

The power house is composed of two buildings. The first one, completed in 1911, contains two generating units of 4,000 kw. Each of these units consists of a 4,000 kw., 2,200-volt,

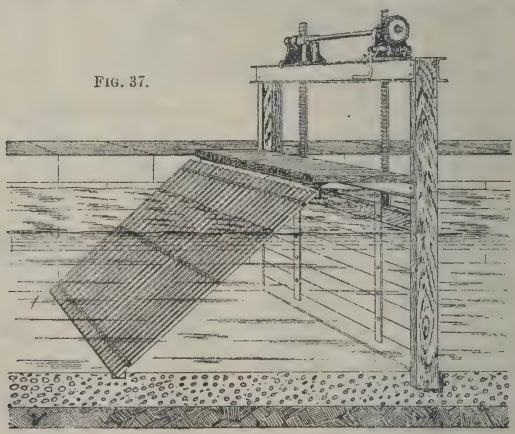
3-phase, 60-cycle Allis-Chalmers-Bullcok generator, driven at 400 r.p.m. by a single Doble tangential water wheel of 6,000 h.p. which is mounted on one end of the shaft and overhangs the bearing at the end of the unit.

Water is conveyed from the terminal end of the pressure pipe through a cast-steel flanged taper pipe, which is bolted to the flanged end of the pipe. This taper pipe decreases in diameter from 30 ins. to 24 ins. at the outlet end, where it is bolted to a hand-operated, 24-in., single disc, steel body, rising stem gate valve, which is provided with a by-pass. The steel nozzle casting is bolted to this valve. The jet of water is projected on to the wheel through a Doble needle regulating nozzle, and the governing is done by a type 'Q' Lombard governor, operating the needle gear by means of an oil pressure cylinder. Surges or rams in the pipe line, caused by the quick closing of the main nozzle, are prevented by the Doble relief nozzle. This nozzle is similar to the main nozzle, but is located below it, and the stream does not hit the buckets on the wheel but discharges freely down the tailrace.

The second power house was completed in 1914; it contains a third generating unit composed of an 8,000 kw., 2,200-volt, 60-cycle, 3-phase Canadian General Electric generator, driven at 400 r.p.m. by two Doble tangential water wheels, one mounted on each end of the shaft and overhanging the bearings. The water wheels are rated at 13,000 h.p.

A separate exciter unit is provided for each main generator unit. No. 1 and No. 2 exciters are 100 kw., 125-volt, direct current generators on the same shaft with a 100-h.p. water wheel and a 150-h.p., 2,200-volt induction motor. No. 3 exciter is a 200 kw. generator direct connected to a 200-h.p. water wheel and a 300-h.p., 2,200-volt induction motor.



The transformer equipment consists of two banks of 1,450 kw. transformers (with one spare) and one bank of 3,000 kw. transformers; all of the oil-insulated, water-cooled type. They step the voltage up from 2,200 to 60,000 volts, at which pressure the current is transmitted to Victoria. The transformers are set in compartments along the back wall of the generator room.

Sluice Gates, Strainer Racks, etc.

(*Contributed by Messrs. James Gordon & Co., Windsor House, Kingsway, London, W.C.* 2.)

The type of sluice-gate shown by fig. 37 is usually adopted for medium or large size head races, and is made with framing and gearing suitable for single gates up to 8 to 10 ft. wide, and for wider races, frames designed for two or more gates, according to the width of the water channel.

FIG. 37.

The frames for these gates are constructed of rolled steel joists or channels, making a very simple, cheap, and extremely strong arrangement. For smaller channels the same design and arrangement can be adopted with somewhat lighter construction, or cast-iron frames fitted with cast-iron gates and suitable lifting screws or racks can be used. Strainer racks are usually constructed of flat wrought-iron bars threaded on to rods with pipe distance-pieces placed between each bar to insure proper spacing, the wider racks being made in small sections to facilitate handling.

The water channel between strainer-rack and turbine-pit should be completely covered in, in order to prevent any possibility of foreign matter getting into the channel on the turbine side of the strainer racks.

In streams which are liable to heavy floods, and contain at times a lot of drift wood and foreign matter, it is usually advisable to put down two strainer racks, the first one protecting the intake to the head race, and being made of heavy bars with wide spaces between so as to stop all the larger material, and a fine one to protect the turbines themselves at the lower end of the race close to turbine pits or pipe intakes.

In designing head and tail races for water-power installation, special attention should be paid to their cross-sectional area, which should be ample for the quantity of water to be carried, in order to guard against loss of head when the water is running at full velocity.

This is extremely important on plants for low falls, where only a few inches of head will make quite a considerable difference to the horse-power available.

The velocity in channels of this kind for low-fall turbine work should not exceed 2 ft. per second, and if possible should be even less than this.

For higher falls, where a slight amount of loss is not very material, velocities as high as 3 ft. or 4 ft. per second can be adopted, but care should then be taken that the banks of the channels are properly protected to prevent erosion.

NIAGARA FALLS INSTALLATION.

The cost of power supplied from the Niagara Falls is 3*l.* 6*s.* per horse-power per annum. The capital outlay on the plant was 45*l.* per horse-power.

Pipe Lines.

(Contributed by Messrs. James Gordon & Co., Windsor House, Kingsway, London, W.C. 2.)

The following table gives thicknesses for different sizes of pipes under varying pressures. The figures are based on a factor of safety of 5, which is a fair average limit to work to for all ordinary work, but in the lower end of high-pressure pipe lines the factor of safety may run up to 8, or even sometimes 9. The working pressures are given in pounds per sq. in., and are for double-riveted or welded steel pipes ; the strength of single-riveted pipes is about 30 per cent. less.

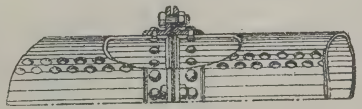
In practically every case with modern hydraulic power plants, steel piping, either riveted or welded, is used. Fig. 38, page 1234, shows types of joints which can be adopted for this class of piping. The slip joint (*a*) is suitable for low head pressures and for pipes constructed of thin plates. The joint is made by one pipe being tapered slightly outwards and the other slightly inwards, the tapers being coated with paint, cement grout, or some similar composition, and driven into each other until they form a water-tight joint.

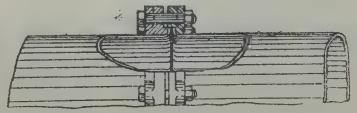
The socket and spigot joint (*b*) for lead and yarn packing is a very useful one for low or medium head pressures, as it has some amount of flexibility, and also allows under all ordinary conditions for any expansion or contraction in the pipes being taken up in the joints.

The collar joint (*c*) is another type of lead joint to which the same conditions practically apply.

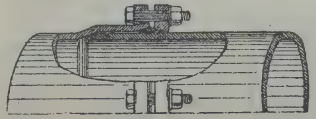
For higher pressures ordinary forms of lead joints do not always prove satisfactory, owing to the danger of the jointing material being blown out by the pressure of the water. In these cases some form of flanged joint must be used, two of which are shown—one (*d*) with the flanges riveted on to the pipes, and the second (*e*) with the pipe ends turned up and fitted with loose flanges bolted together. The patent muff joint (*f*) is of a special type and allows for a large amount of expansion and contraction in the pipe line, and can be constructed to keep perfectly tight under the heaviest pressures which have to be dealt with.



(*a*) Tapered Slip Joint for low pressures.



(*b*) Socket and Spigot Joint, packed with lead and yarn.



(*c*) Loose Collar Joint, packed with lead and yarn.

(*d*) Flanged Joint for riveted pipes.

(*e*) Flanged Joints for welded pipes.

(*f*) Patent Muff Joint for high pressures.

FIG. 38.

Anchorage.—One of the most important points in the design of pipe lines is the provision for anchorage on the line itself, and especially at the foot of the line near to the power house, in order to prevent any possibility of pipe line movement being transmitted to the turbines or Pelton wheels. The pipes can be efficiently anchored in several ways, the more common forms of anchorages being to provide cast iron or steel thrust blocks, forming a foot or base on the pipe itself, which are firmly secured to heavy concrete or rock foundations; or special anchoring pipes can be provided with thrust flanges and solidly set into heavy blocks of masonry or concrete.

Expansion and *Contraction* of long lines of piping also require careful attention, and it is necessary in long straight runs of pipe to provide either a type of joint capable of taking up expansion and contraction, or to fit the pipe line with special expansion joints, which are usually constructed of cast iron or steel and of the sliding socket and spigot type.

Relief Valves.—Where the length of a pipe line is excessive in proportion to the head of water, and the plant has to deal with heavy and sudden load changes, it is necessary for the safety of the plant and pipe line to provide efficient relief valves to prevent serious water-hammer effects. These, however, should be of special design, as the ordinary forms of spring-loaded relief or safety valves are worse than useless under conditions of this kind, as if they are set to open with only a small rise in pressure the reaction of the discharging water will nearly always prevent them closing again, and if they are adjusted in the ordinary manner the pressure rises too high before they open, and the sudden closing of the valve by means of the heavy spring employed often causes worse water-hammer effects than there would be with no relief valve at all.

Relief valves for hydraulic power work should be so designed that they will open immediately with a very small rise in pressure, and in proportion to the pressure increase, the closing being effected by some form of oil cataract or dashpot which can be adjusted so that the time of closing will coincide with the time required for slowing up the moving column of water.

The best form of relief valve, however, is one which is directly connected to the gate or nozzle-operating mechanism of the power unit, and adjusted so that it will open in proportion to the decrease of gate or nozzle opening, and be closed again slowly by means of an oil dashpot or cataract. With a relief valve of this form the pressure rise is anticipated, and therefore very good results can be obtained. With a relief valve independent of the Pelton wheel or turbine rise in pressure must take place before it can come into operation.

Where Pelton wheels fitted with deflecting nozzles are used, no relief valve is generally necessary, as the quantity of water discharged remains the same for any load, or is slowly cut off by hand.

Water Hammer in Pipes.*

In 'The Design of Pipes' (p. 1192), it was pointed out that the penstocks had to be designed to resist the static head plus the head due to water hammer. The magnitude of this extra pressure depends, among other things, upon the length of the penstock and upon the rate of the change of the velocity of the water in the penstock. The rate of change of velocity depends upon the velocity of the wheel gates as they are moved by the governor to suit the variations in the load.

When the gates of a turbine close to suit a drop in the load, the force required to decrease the velocity of the water flowing in the penstock is evidenced by a rise in pressure in the wheel casing, expressed in feet of water by the following formula:

$$h = H \frac{2}{\frac{2 \times T}{T_2} - 1}$$

where

h = water hammer of water in ft.;
H = static head of water in ft.;
T = governor closing time;
$T_2 = \frac{L \times V}{g \times H}$ = penstock time;
L = length of penstock in ft.;
V = maximum velocity of water in ft. per sec.;
$g = 32{\cdot}2$.

Conversely, when the gates are opened to suit an increase in load, the force required to increase the velocity of the water is evidenced by a fall in the pressure in the wheel casing, expressed in feet of water by the following formula

$$h = H \frac{2}{\frac{2 \times -T}{T_2} - 1}$$

* Adapted from *Etude générale du coup de bélier dans une conduite de diamètre constant*, by Comte de Sparre.

These formulæ give the effect at the turbine, of a closure or opening of the gates, but it is often necessary in a long penstock, in order to economise material, to know at several points along the pipe the effect of the movement of the turbine gates. If we call x the distance from the turbine to the point considered, we find that the water hammer at that point is equal to the hammer at the turbine multiplied by $\frac{L-x}{L}$ and that it is therefore proportionate to the distance from the head gate to the point considered.

In practice it is well to so regulate the governor closing time as to keep the maximum water hammer at the turbine not above 25 per cent. of the static head of water.

SECTION XXIV

PART V

HYDROSTATIC PRESS—HYDRAULIC RAM—HYDRAULIC LIFTS—HYDRAULIC BOLT FORCERS—HYDRAULIC RIVETERS.

The Hydrostatic Press.

P = Power or pressure applied.
l = length of lever, in inches or feet.
A = Area of ram, in square inches.
W = the weight or resistance, in lbs.
l' = length of fulcrum, in inches or feet.
a = Area of piston, in square inches.

$$\frac{Pl A}{l' a} = W. \qquad \frac{W l' a}{Pl} = A. \qquad \frac{W l' a}{A l} = P. \qquad \frac{PA l}{W l'} = a.$$

To Compute the Thickness of the Metal to Resist a Given Pressure.

Rule.—Multiply the pressure per square inch in pounds by the diameter of the cylinder in inches, and divide the product by twice the estimated practical tensile resistance or *value* of the metal in pounds per square inch, and the quotient will give the thickness of the metal required.

Example.—The pressure required is 9,000 lbs. per square inch, and the diameter of the cylinder is 5·3 inches: what is the required thickness of the metal or cast iron?

$$\frac{9000 \times 5{\cdot}3}{6000 \times 2} = \frac{47700}{12000} = 3{\cdot}975 \text{ ins.}$$ The *value* of the metal is here taken at 6,000.

The Hydraulic Ram.

The water working the ram is supplied through the pipe S (fig. 1), and escapes through an opening at *o*, until it has gained a velocity sufficient to raise the valve or ball, B, which suddenly stops the current, and causes an excessive pressure in the ram, R, which opens the valve or ball, C; the water is forced into the vessel and air-chamber, A, and finally through the delivery-pipe, *d*, to its destination. When equilibrium of pressure is restored between S and R, the ball, B, falls, and the operation is repeated. The ram can make as many as 200 strokes per minute, depending upon its size.

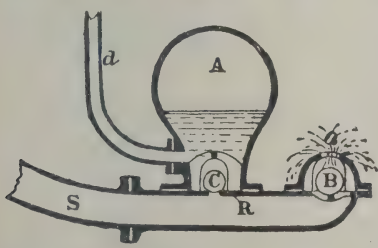


Fig. 1.

The length of the supply-pipe, S, should not be less than 5 times the height of the fall. But the pipe may be made 10 times, or more, the height of the fall.

In ordinary cases the hydraulic ram returns about 50 per cent. of the natural effect. That is, the quantity of water, q, multiplied by the height, h, of the delivery above the ram will be about 50 per cent. of the quantity of water, Q, working the ram, multiplied by the head of fall, H, in the same unit of time.

$$qh = 0{\cdot}5QF. \qquad q = \frac{0{\cdot}5QH}{h}. \qquad Q = \frac{2qh}{H}.$$

Q and q can be expressed in any unit of volume or weight. F and h can be expressed in any unit of length.

If

Q and q = cubic feet per minute,
F and h = fall and height in feet,
L = length in feet, and D = diameter in inches of the supply-pipe, S,
l = length, and d = diameter of the delivery-pipe, d,

$$D = \sqrt[5]{\frac{2Q^2(L + 5D)}{F}}, \qquad d = \sqrt[5]{\frac{4q^2(l + 5d)}{h}}.$$

TABLE OF RESULTS OF OPERATIONS OF HYDRAULIC RAMS.

Number of Strokes.	Height of Fall.	Height of Elevation.	Water Expended.	Water Raised.	Useful Effect.

NOTES ON HYDRAULIC RAMS.

Working Fall.—Any working fall, from, say 18 ins. up to 100 ft., will do to work a ram, but the more working fall obtained up to about one-third of the total height the water has to be raised above the ram, the less the ram will cost to raise a given quantity, and the less driving water will be required to lift that quantity.

In sluggish streams where it is inadmissible to put a dam in the stream it is sometimes necessary to carry the driving water several hundred yards down stream in earthenware pipes, running nearly level, before a few feet fall can be obtained: but where driving water is plentiful it is often less costly to be content with a small working fall and have a more powerful ram, than go to the expense of obtaining the greater fall for the sake of enabling a smaller ram to do the work required.

Height to Force.—The height to force must be estimated from the level of the ram or bottom of the working fall.

Rising Main Pipe.—Rams will force to a distance of several miles. In one case a ram is in use forcing to a distance of three miles and to an elevation of 340 ft., with a working fall of only 10 ft.

Driving Water.—The quantity of driving water required to work a ram depends upon the amount of working fall available, the height to raise the water, and the quantity of water it is desired to raise. Rams can be made to work under favourable conditions with less than one gallon of water per minute.

In giving the quantity of water available to work a ram, it is useless to say there is 'sufficient to fill a pipe of certain size,' unless the gradient of the pipe be given at the same time, in order that the velocity of the water in the pipe may be ascertained. Unless the water be practically unlimited for the purpose required, it is preferable to make a positive measurement of the water. A ready method of measuring the flow of very small streams is to dam up the stream with a little puddle, and insert a pipe in the dam to form a spout. Then let the water flow into a bucket for, say, exactly 15, 30, or 60 seconds, and carefully measure out the contents of the bucket in pints, when the total flow in gallons per minute or hour can be calculated. If the stream be too large to measure with one spout, two or more spouts can be inserted in the dam, and each of them measured separately. If the ram required be a large one, and the volume of driving water available be too great to measure in this way, it should be gauged by means of a weir board.

Hydraulic Lifts.

A speed of 200 to 400 feet per minute is usual.

For packing the ram, hat-shaped packing is preferable to the U-shaped, as it causes less friction and lasts longer. Leather packing is the best, but the most usual form is 'hydraulic' flax or hemp in stuffing boxes.

The cylinder of the lift should be absolutely plumb.

In well-constructed direct-action lifts the total friction should not be more than 5 per cent. In suspended lifts the friction varies from 15 to 20 per cent.

An air-vessel placed between the valve-box and ram cylinder will prevent any shock in the cage from the passing of the water when the valve is opened or closed, or when the water is turned into the waste-pipe.

The gear rod or rope for high-speed lifts should have a range of from 5 to 6 feet (from full pressure to full exhaust), so that the man working the lift may have proper control over it.

The cam motion opening the valve should open the latter very gradually.

The high pressure system of working hydraulic lifts is the most economical in every way, and it enables high working speed to be obtained.

Public supplies of high pressure hydraulic power are available in London, Liverpool, Hull, Manchester, Birmingham, and Glasgow.

Direct acting ram lifts are usually adopted in this country for moderate heights; the machine consists of a hydraulic cylinder having a flange cast on its upper end resting on the foundation at the top of the well bored to receive it, and a simple platform or cage moving between guides firmly screwed to the upper end of the ram working in the cylinder. The valve controlling the action of the lift is worked by a rope, or rod passing through the platform. Tappet gear automatically stops the lift at the top of its stroke, and permanent stops are also fitted to prevent overtravel. Alternative rams can be fitted to meet varying loads.

The suspended type of lift is less expensive than the direct-acting lift when the height of travel is considerable, or where there are difficulties in boring the well for the cylinder. A factor of safety of 10 to 15, to 1, on all ropes (collectively) is ample; very high factors mean, in most ordinary cases, that ropes become too large in diameter to ensure long life. The ram can be placed in the lift shaft or in the roof, or basement, either vertically, horizontally, or on an incline. Safety gear should be fitted to come into immediate action in case the ropes break. The valves are similar to those used for the direct-acting type.

The direct ram lift is becoming usual in America even in the highest buildings on account of its safety. The cylinder consists of a bored well lined with stout Artesian tubing, and failure can hardly occur, for the pipes fit closely in the bored rock. The outlet piece if well made and attached to the lining tube is not apt to fail. Balances are employed so that the long rams when out are under tension.

The guide-bars of lift should preferably be fixed to stone templates with bolts let in and secured by lead, and the bars fixed by nuts. This is preferable to wooden bricks, which are liable to shrink. The V guide-bar is the best form.

Electric push button control of lift and gates can be fitted to either type of lift.

Each elevator shaft of the 'Empire Building,' in New York, is walled up independently as high as the third floor, and is made a close fit for the car, the last 50 feet of the drop of each elevator thus forming an air-cushion. If the car fall, the air is confined in the bottom of the shaft, and, by its gradual escape, lets the elevator down easily without shock. It is stated that a car has been dropped from the twentieth floor of the building without breaking eggs placed in the car. The pressure of the air caused by a fall from the top floor, a height of 290 feet, is calculated to be about 3½ lbs. per sq. in. The estimated proportion between the depth of the air-cushion and the length of the drop is as 1 to 6. The only precaution necessary seems to be to make the doors of the lower-floor entrances air-tight.

In hydraulic lifts trouble sometimes arises owing to water leaking from the ram glands and falling on to the ropes. Where this possibility exists the ropes should be well protected with a coating of tallow and blacklead well mixed together, otherwise the water will find its way into the interior of the rope, and by rusting the wires rapidly weaken them. The danger in such cases lies in the fact that there is often no external evidence to show that the ropes are unsafe. In one instance the two supporting ropes of a lift broke without warning near to their anchorage to the cylinder, causing the lift car to fall the full height of the lift well, wrecking the lift and killing the attendant. On examination of the broken ropes it was found that the internal wires had been damaged by the water to such an extent that they were quite brittle and without strength, but no broken wires were noticeable before the accident at the point of failure. The best way to prevent such failures is to design the lift so that water cannot possibly fall on the ropes, or, if this be not feasible, to fit drip trays or other appliances to keep the water off the ropes if leakage should occur.

Danish Regulations concerning the Arrangement and Working of Lifts and Hoists driven by Machinery.

The lift cage must be closed in all round, except at the entrance, either with solid sides and roof or with trellis-work having openings not exceeding 1 in. It must be lit up inside, and must contain a notice of the number of passengers allowed. From any point in its travel there must be the means of signalling if in difficulty. Except where their adoption would be attended with serious inconvenience, entrance-doors must be fitted inside the cage itself; these must not open outwards, and must be kept locked while travelling. Where they are dispensed with, at every landing the lift well must be fenced to the full height on the entrance side, with no inward projection; and the clearance between the cage and the well must nowhere exceed 2 ins. In ram lifts the cage and ram must be securely joined together. A hanging cage must be suspended

by at least two ropes or chains, each of which must alone be strong enough to carry ten times the weight of the cage fully loaded. Each must also be connected with either a stopping apparatus or a brake, so arranged that the cage shall either be stopped in a fall of not more than 1 ft. or else shall be let down at a speed not exceeding 3 ft. a second. Lifts worked by a winding drum must be provided with a contrivance for preventing the rope from becoming slack in the event of the cage sticking in its descent, and at the same time for stopping the drum. Every counterbalance weight is likewise to be hung by at least two ropes or chains, each having ten times the strength necessary to carry the weight. The counterbalance weights must be securely guided, and the space in which they work must be securely fenced, so as to guard against all possible risk of accident.

See also ' Electric Lifts.'

Hydraulic Bolt Forcers.

Fig. 2 represents Young's Hollow-ram Portable Hydraulic Bolt Forcer, constructed principally for forcing in and out coupling bolts, though it is also suitable for forcing pins, etc., in and out of machines. The apparatus consists of a hollow steel sliding ram, the ends or tails of

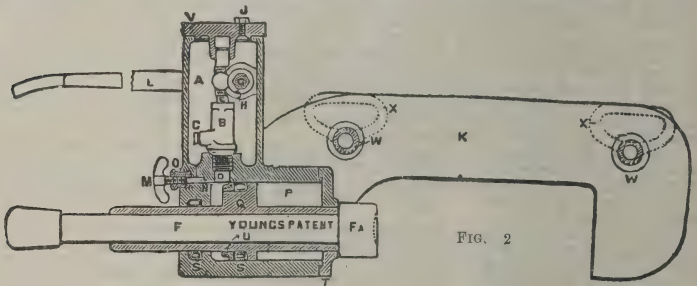

FIG. 2

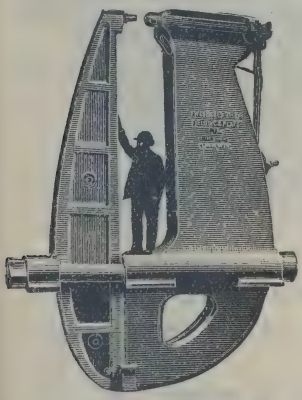
A, cistern ; B, pump ; C, suction valve, spring, stopper, and gauze strainer ; D, delivery valve, spring, and stopper ; E, pump plunger ; F, steel drift ; F A, drift shoe ; G, pump shaft ; H, pump tumbler with set screw : J, air screw ; K, arms ; L, working pump lever ; M, stop and release valve ; N, stop and release seat ; O, stop and release valve gland ; P, cylinder ; Q, hollow ram ; SS, U leather for packing ; T, cylinder cover ; U, packing ring ; V, cistern lid ; W, distance pieces ; X, handles.

which project through the front and back respectively of the cylinder. Inserted in this hollow ram is a steel drift, which passes right through the centre of ram ; a head is forged on one end of the steel drift, and a shoe for the bolt is fitted on the other. The method of working is the same as in any ordinary hydraulic pump, viz. the fluid is forced by the pump from the reservoir into the cylinder, and the ram is gradually forced forward until it presses the shoe, on the end of the steel drift, against the bolt to be forced out. Should the bolt show no sign of moving out of coupling when the maximum hydraulic pressure has been obtained, a sharp blow is given with a hammer on the head of the drift, which transmits a shock or ' jar ' to the bolt and starts it from its position, and it can then be ejected, either by pumping the ram forward or knocking it out by hammering on the head of the steel drift ; this is a valuable feature, as the bolts are generally rusted in their seats, and a sharp blow is very efficacious in starting a bolt or pin under powerful and steady pressure.

This machine fitted with crosshead instead of arms as shown is largely used for forcing winch drums from their shafts.

DETAILS OF HYDRAULIC FORCERS.

Power . . . . . tons	20	20	30	40	50	75
Width of gap . . . . . inches	9	15	12	14	16	18
Run out . . . . . inches	3	3	4	5	5½	6½
Height . . . . . inches	15½	15½	16½	17	18	18½
Suitable for bolts approx. . inches diam.	2	2	2½	3	4	5
Approx. weight . . . . . cwts.	1¾	2	3	4	4½	6¼



The body of the apparatus can be separated from the arms or claws by withdrawing two small sliding bolts, when the machine can then be carried in two separate pieces, the body placed first in position on the shaft, and the claws lifted up afterwards and fixed, without having to screw and unscrew any bolts. A gauge supplied with each machine indicates the pressure.

Hydraulic Riveters.

Fig. 3 represents the Tweddell hydraulic riveter (manufactured by Fielding & Platt, Ltd., Atlas Works, Gloucester), a tool which is very largely used for riveting purposes.

In this machine, by means of two rams, one inside the other, a pressure, in the first place, is brought to bear on the plates by means of an annular tool, A, encasing the moving capping die, B. When the plates are thus brought together, the capping tool heads the rivet; and after this

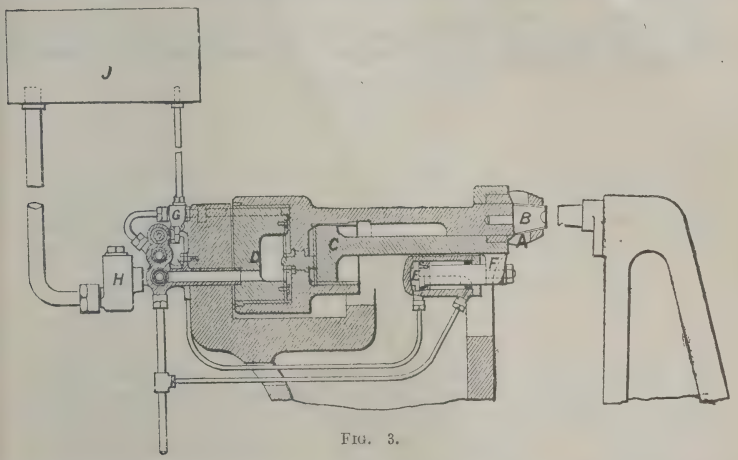

FIG. 3.

operation is performed, the combined power of both rams (C and D) is applied on the head of the rivet, and through the shoulders of same on to the plate surrounding it. The size of work is only limited by the power of the machine, but some very good work in cold riveting, up to 1 inch diameter, has been done by these machines. An advantage of the machine is that by

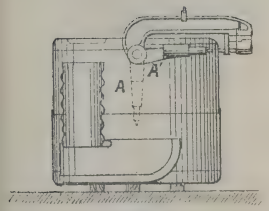

FIG. 4.

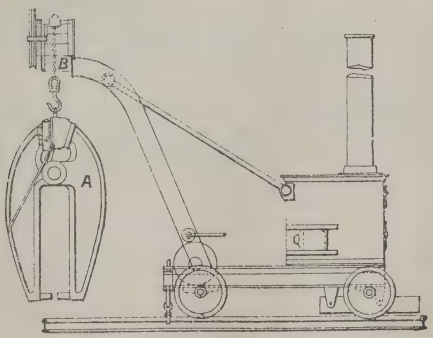

FIG. 5.

substituting a riveting die for the annular closing tool, A, a second and smaller power is available. This adds very much to the general use of the tool, for it is impossible to keep such a powerful machine in constant work. Excellent work had been done by this machine when using plain bolts—i.e., making both heads of the rivet in the act of closing it. This machine is capable of exerting three different powers, which is a great advantage. Although these machines are made

up to 200 tons power, very little more high-pressure water is required, owing to the use of the auxiliary piston, E, which draws forward by means of the lug, F, the two main rams, C and D, the space left behind being filled with low-pressure water through check-valves, G and H, from a tank, J.

In cases where boiler-ends are placed with their flanges inwards, the machine shown by Fig. 4 is used. In this machine there is a hinged arm, A, which is first of all lowered into the boiler and when restored to its proper position, A′, the riveting is proceeded with.

Fig. 5 shows a portable riveter, A, slung from a travelling crane. By means of the iron girder, B, this riveter is moved across the work to be riveted, whilst the crane with its rivet-heating oil or reverberatory furnace is traversed along. Riveters of this type were largely used in the construction of the Forth Bridge.

SEWERS.

Rate at which Rainfall Reaches a Sewer.

C = cubic feet per second per acre reaching sewer: c = average cubic feet of rainfall per second per acre during heaviest fall; S = average slope of ground in feet per 1,000 ft.; a = number of acres drained; K = ·75 for paved streets, ·625 for ordinary cases, ·31 for suburbs with gardens, lawns, and macadamised streets.

$$C = Kc\sqrt[4]{\frac{S}{a}} \qquad \textit{(Burkli-Zeigler.)}$$

(For other formulæ see 'Rainfall,' pp. 1281–2.)

Discharging Capacity of Sewers.

R = hydraulic mean depth in feet; S = sine of angle of inclination; v = velocity in feet per second.

$$v = 124\sqrt[3]{R^2}\sqrt{S} \qquad \textit{(Crimp and Bruges.)}$$

Discharge from the Submerged Orifice of a Culvert.

D = diameter of orifice in inches; L = length of out-fall culvert in feet; W = quantity discharged in cubic feet per minute; H = head in feet.

$$D = \cdot 531\sqrt[5]{\frac{LW^2}{H}} \qquad \textit{(Eytelwein.)}$$

CIRCULAR SEWERS.

x = area of sewer ÷ the wetted perimeter; f = inclination in feet per mile; v = velocity of flow, in feet per minute; a = area of flow, in square feet; V = volume of discharge, in cubic feet per minute.

$$v = 55\sqrt{x \times 2f} \qquad V = va.$$

American Rule.
(Large Sewers.)

The following formula is used by Mr. H. R. Asserson, chief engineer of the Sewer Department of Brooklyn, for proportioning the sizes of large sewers:—

$$D = \frac{3 \log. A + \log. N + 8}{10},$$

where D = diameter of sewer in inches; A = the area drained in acres; N = the distance in feet in which the sewer falls 1 ft.

(Small Sewers.)

For small sewers up to 18 ins. in diameter the formula is—

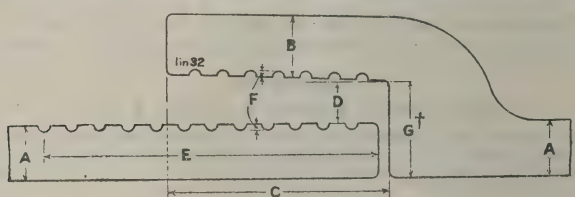
$$D = \frac{3 \log. A + \log. N + 6{\cdot}8}{10}$$

Salt-Glazed Ware Pipes

Salt-glazed ware pipes may be used up to 36 ins. diameter, but above 24 ins. they are difficult to manufacture of a cylindrical shape, and brickwork or concrete is usually adopted.

British Standard Salt-Glazed Ware Pipes.*

(No. 65—1914.) (*Abstract.*)



The specification divides pipes manufactured in accordance with the specification into two classes, viz. :—

British standard pipes. British standard tested pipes.

British standard pipes are pipes subject in every respect to the requirements of the specification, and a percentage are to be subjected to a hydraulic test.

British standard tested pipes are subject in every respect to the requirements of the specification, and every pipe has to withstand a hydraulic test.

The specification provides that the dimensions of pipes shall be not less than those set out in the following table, except as provided in the section dealing with permissible variation.

1	2	3	4	5	6	7
Int. Dia. of Pipe.	Minimum Mean Thickness of Barrel. A.	Minimum Mean Thickness of Socket. B.	Minimum Internal Depth of Socket. C.	Minimum Jointing Space. D.	Length of Grooving on Spigot. E=1½C.	Minimum Depth of Grooving. F.
Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	In.
3	7/16	7/16	2	5/16	3	1/16
4	1/2	1/2	2	3/8	3	1/16
5	9/16	9/16	2¼	7/16	3⅜	1/16
6	5/8	5/8	2¼	7/16	3⅜	1/16
7	11/16	11/16	2½	7/16	3¾	1/16
8	11/16	11/16	2½	1/2	3¾	1/16
9	3/4	3/4	2¼	1/2	3¾	1/16
10	13/16	13/16	2¾	5/8	4⅛	1/16

21	1⅝	1⅝	3¼	¾	4⅞	1/16
24	1¾	1¾	3¼	¾	5¼	1/16
27	1⅞	1⅞	3¼	¾	5¼	1/16
30	2	2	3¼	¾	5¼	1/16
36	2½	2½	3¼	1	5¼	1/16

† Width of shoulder of socket, which must exceed the mean thickness of the barrel of the pipe by not less than the values for D given in column 5.

The sockets of pipes shall be conical, having a taper of one-sixteenth of an inch measured on the diameter per inch of length.

The length of the barrels of straight pipes shall be as follows :—

Up to and including 6 ins., 2 ft.

7 ins. to 10 ins. inclusive, 2 ft. and 2 ft. 6 ins.

12 ins. to 36 ins. inclusive, 2 ft., 2 ft. 6 ins., and 3 ft.

* By permission of the British Engineering Standards Association.

The interior of the sockets and exterior of the spigots shall have groove one-sixteenth inch deep for a length equalling one and a half times depth of socket.

The glazing shall be attained by the action of the fumes of volatilised common salt on the material of the pipes during the process of burning.

Subject to the mean thickness of the barrel and socket of a pipe being not less than that specified in columns 2 and 3 of the above table, a variation in the thickness of the barrel or socket may be allowed at any two points not exceeding the following :—

Diameter of Pipe.	Permissible Variation of Thickness.
Not exceeding 12 ins.	$\frac{1}{16}$ in.
13 ins. to 18 ins. inclusive	$\frac{3}{32}$ in.
28 ins. to 36 ins. inclusive	$\frac{1}{8}$ in.

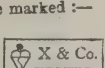
The internal diameter of the barrel shall nowhere deviate from the standard diameter by more than the figure given in the following table :—

Standard Internal Diameter of Pipe.	Permissible Variation from Diameter.	Standard Internal Diameter of Pipe.	Permissible Variation from Diameter.
3 ins. and 4 ins.	$\frac{1}{8}$ in.	15 ins. and 18 ins.	$\frac{5}{16}$ in.
5 „ to 7 „	$\frac{3}{16}$ in.	21 „ and 24 „	$\frac{3}{8}$ in.
8 „ and 9 „	$\frac{1}{4}$ in.	27 „	$\frac{7}{16}$ in.
10 „ to 14 „	$\frac{5}{16}$ in.	30 „ and 36 ins.	1 in.

The permissible deviation of straightness of the barrels measured on the inside of the curve for all diameters of pipes shall be as follows :—

Length of Pipe.	Permissible Deviation from Straightness.
2 ft.	$\frac{3}{16}$ in.
2 ft. 6 ins.	$\frac{1}{4}$ in.
3 ft.	$\frac{5}{16}$ in.

The hydraulic test shall be an internal pressure of 20 lbs. per square inch without showing signs of injury or leakage.



The pipes shall also be tested for absorption by testing pieces of the body of the pipe taken at more than 6 ins. from the end of the pipe. The test pieces shall be of whole thickness of pipe, and shall have two glazed surfaces each of which shall be not less than 8 ins. super or more than 20 ins. super. The test pieces shall be thoroughly dried at a temperature of 150°C., and shall then be immersed in cold water which shall be raised to boiling point and there maintained for one hour. The percentage of increase of weight shall not exceed the following :—

Thickness of Pipe.	Percentage of Increase of Weight.
$\frac{3}{4}$ in. and under	5 per cent.
Over $\frac{3}{4}$ in. and up to 1 in.	6 „

Hydraulic radius . . ·2897 d	·3325 d	·3157 d	·269 d	·2066 d	·1685 d

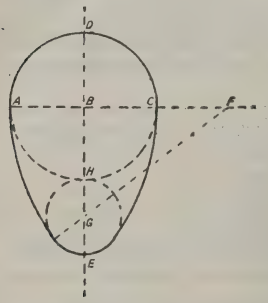

Fig. 1.

This form of sewer gives a fair hydraulic mean depth for flows varying greatly in volume. In a town sewered upon the combined system this is an advantage over the circular section, especially in the case of sewers laid in undeveloped areas where it is frequently necessary to make provision largely in excess of present requirements.

Diameter of Upper Circle = AC = d.
Conjugate Diameter = DE = $1\frac{1}{2}d$.
Radius of Invert = $\frac{1}{4}d$.
Radius of Side = FA = $1\frac{1}{2}d$.

Another advantage possessed by egg-shaped sewers is that for equal sectional areas this form is more easily entered by workmen than the circular section.

On the other hand, the egg-shaped section is not so strong to resist external pressure as the circular, and consequently if used in bad ground special precautions must be taken.

In ordinary practice, egg-shaped sewers are used for those sizes of culvert which fall between the largest circular stoneware-pipe sewers and the smallest size of circular brick culvert in which men can conveniently work.

These limits fix the maximum and minimum sizes of egg-shaped sewers at 3 ft. 6 ins. × 2 ft. 4 ins. and 2 ft. 3 ins. × 1 ft. 6 ins., respectively.

For ordinary depths the smaller sizes of egg-shaped sewers are constructed of one ring of brickwork half-a-brick thick; for the large sizes a second ring of brickwork may be introduced or, preferably, the sewer may be strengthened by placing concrete outside the brickwork.

The following table gives particulars of the ordinary sizes of egg-shaped sewers :—

Dimensions.	Sectional Area in Square Feet.		Wetted Perimeter. Lineal Feet.		Brickwork in superficial yards of half-brick thick per Lineal Yard of Culvert.	
	Total.	Up to ⅔rds of top circle.	When full.	When full to ⅔rds top circle.	One half-brick ring.	Two half-brick rings.

The last table is applicable to sewers and drains by taking the same proportion of the tabular numbers that the cross-section of the water in the sewer or drain bears to the area of the whole area of the sewer or drain.

The formula upon which the table is constructed is :—

$$Q = 2356 \frac{\sqrt{d^5}}{\sqrt{\frac{l}{h}}},$$

where,

Q = volume of discharge, in cubic feet per minute;
d = diameter of pipe in feet;
h = height of fall of the water in feet;
l = length of pipe in feet.

Application of the Table.

To compute the volume of fluid discharged, the length of the pipe or sewer, the height or fall, and the diameter being given.

Rule.—Divide the tabular number opposite the diameter of the pipe by the square root of the rate of inclination (length ÷ height); and the quotient will give the volume required.

Example.—A pipe has a diameter of 9 ins. and a length of 4,750 feet; what is its discharge under a head of 17·5 feet?

Tabular number for 9 ins = 1147·6, and

$$\sqrt{\frac{4750}{17{\cdot}5}} = \sqrt{271{\cdot}4} = 16{\cdot}47;$$

then

$$\text{Discharge} = \frac{1147{\cdot}6}{16{\cdot}47} = 69{\cdot}67 \text{ cubic ft. per minute.}$$

Sewerage Systems.

There are two principal systems of sewerage, known respectively as the 'combined' and the 'separate,' systems. In the former, one set of sewers is provided for the removal of both the sewage proper, and also the rainwater; in the separate system two sewers are provided in every street, one for sewage and the other for rainwater. Both systems have their advantages, but these are counterbalanced by certain disadvantages.

The combined system has the advantage of simplicity, but it involves large and deep sewers with small volumes of sewage flowing in them in dry weather, and where the sewage has to be pumped and purified this system produces a larger volume of sewage than the separate system.

On the other hand, a separate system of sewers becomes very complicated, especially in large towns, and there is great risk of sewage drains being connected to the surface water sewers. The latter discharge direct into the nearest river or stream, and can therefore be made of smaller size than in the combined sewerage system, which concentrates all liquid upon one point. The drainage of all streets and yards is taken direct into the surface-water sewers. As the first washings of these surfaces are very foul, there is danger of pollution of the streams into which the surface-water sewers discharge.

In most cases neither system is carried out in its entirety, but a combination is effected with a view to adopting the best points of both.

The quantity of sewage in a strictly separate system should, if the sewers were watertight, be measured by the water consumed, and it is usually taken at from 20 to 40 gallons per head of the population draining, and the rate of flow in the middle of the day is from one and a half times to twice the mean.

Where a partially-separate system is adopted, the back roofs and back yards of the houses are usually drained to the sewage sewers, and the impervious area per head of the population varies from 10 square yards to 20 square yards.

The rainfall on this area, at the rate of from $\frac{1}{4}$ in. to 1 in. per hour, depending upon the area of the district (being smaller for large areas than for small), must be added to the sewage, to find the discharging capacity of the sewers.

In a combined system of sewers the main factor is rainfall, and the rate of fall and proportion of impervious area and size of district must be taken into consideration in determining the dimensions of the sewers.

The proportion of rainfall flowing off an urban area probably never exceeds 75 per cent. of the gross fall, and usually 30 per cent. to 50 per cent. is sufficient to provide for in ordinary circumstances.

(For discharges of catchments, including sewreed areas, see 'Rainfall,' page 1279.)

As an example of practical working, the following table may be quoted, giving the basis on which sewers have for many years been designed in a North Country city with an average rainfall of 36 ins., and nearly all streets being covered with impervious paving:—

Drainage Area in Acres.	Inches of Rainfall per Hour.	Drainage Area in Acres.	Inches of Rainfall per Hour.	Drainage Area in Acres.	Inches of Rainfall per Hour.
20	1·00	75	0·47	350	0·35
23	0·95	100	0·45	375	0·34
26	0·90	125	0·44	400	0·33
29	0·85	150	0·43	425	0·32
32	0·80	175	0·42	450	0·31
35	0·75	200	0·41	475	0·30
38	0·70	225	0·40	500	0·29
41	0·65	250	0·39	525	0·28
44	0·60	275	0·38	550	0·27
47	0·55	300	0·37	575	0·26
50	0·50	325	0·36	600	0·25

Flushing Sewers and Drains.

All sewers and house drains should be laid at sufficiently good gradients to secure self-cleansing To prevent deposit, 4-inch diameter drains should have a fall of not less than 1 in 40, 6-inch drains 1 in 60, and 9-inch drains 1 in 100. Whenever these gradients cannot be obtained special facilities should be provided for flushing, and this operation should be regularly attended to once or twice per week.

The water supply to closets, slop-sinks, etc., should be obtained from cisterns specially provided for the purpose, and not direct from the water-main, nor yet from cisterns in which the water for other domestic uses, such as cooking and drinking, is stored.

The best material for the cisterns is galvanised wrought-iron of No. 14 s.w.g. thickness.

The following table gives the capacities of flushing chambers for drains:—

CAPACITY OF FLUSHING CHAMBER REQUIRED FOR PIPES OF DIFFERENT SIZES.

Size of Pipe. Diameter in Inches.	Gradient of Pipe.	Capacity of Chamber in Gallons.
4	1 in 40	30
	,, 50	40
6	,, 60	60
	,, 100	100
	,, 200	160
9	,, 100	200
	,, 150	250
	,, 200	300
	,, 300	400
12	,, 100	300
	,, 200	400
	,, 300	500
	,, 400	750
	,, 500	1,000
	,, 600	1,500

Sewers as distinguished from drains may be laid at flatter gradients than those quoted without special flushing arrangements, but this depends upon the quantity of sewage flowing down the pipe. A sewer flowing half full will maintain itself in good order at a much flatter gradient than one flowing quarter full. It is usually found that a velocity of 2 feet to 2½ feet per second will produce self-cleansing conditions.

In practical sewage works sewers with a small flow should have the following minimum gradients:—

8 ins. diam. 1 in 75. 12 ins. diam. 1 in 150. 18 ins. diam. 1 in 250.
9 ins. diam. 1 in 100. 15 ins. diam. 1 in 200.

Where, however, the sewers have a goodly flow of sewage the following gradients will be found to be self-cleansing:—

8 ins. diam. 1 in 175. 12 ins. diam. 1 in 400. 18 ins. diam. 1 in 800.
9 ins. diam. 1 in 250. 15 ins. diam. 1 in 600. 21 ins. diam. 1 in 1,000.

Ventilation of Sewers.

The object of the ventilation of sewers is to remove the foul emanations arising from the sewage and the fouled surfaces of the sewers above the actual liquid and to discharge them at points where they will easily become diluted with fresh air and not cause a nuisance.

Until comparatively recently it was thought that sewer air was harmful in itself and was likely, not only to impair the vitality of the subject, but also to be the direct cause of infectious disease.

Now, however, it is more generally conceded that sewer air is at least as free from bacteria as the air near the surface of a road, and that apart from any offensiveness to the sense of smell it is not dangerous to persons breathing it. The degree of offensiveness of sewer air depends more largely upon the condition of the sewer than upon the effectiveness of the ventilation.

Fresh sewage does not produce a bad smell, and modern sewers constructed with the best materials and gradients and regularly flushed do not give off foul emanations. On the other hand, sewers constructed of absorbent materials, laid to bad gradients, containing deposits of sewage solids, and in which flushing is absent or carried on at very long intervals, the sewer air becomes very foul and is liable to produce nuisance.

Formerly, the generally accepted theory was that 'sewer gas,' being lighter than air, would tend to rise up the gradient of the sewer and would be discharged at its summit.

This idea has now been demonstrated to be erroneous: there are many factors which affect the motion of air in sewers such as temperature, humidity, ebb and flow of sewage, the drag of the flowing sewage, the natural diffusion of gases, friction on the periphery of the sewer, and the action of the wind.

Of all these, by far the most important is the latter, and it dominates the other factors except on very calm days.

The system of ventilation of sewers introduced on the advice of the late Sir Robert Rawlinson many years ago, was to relieve the pressure of sewer air by means of gratings in manhole covers at ground level.

These open ventilators were fixed at intervals of about 100 yds., and if it was found that some of the ventilators were a nuisance, additional openings were to be made at shorter intervals.

It has been the almost universal experience in most towns that at certain times these surface grids caused nuisance by allowing the sewer air to escape and bad smells resulted.

A modification of the system has been effected by the introduction of tall shafts connected with the sewers alternating with openings at street level.

The tall shafts theoretically act as outlets and the openings at ground level as fresh-air inlets. It is found, however, in practice, that this order is under varying conditions reversed and it is never certain which will be the inlet and which the outlet.

The general practice now is to have all manhole covers sealed where they are situated in narrow streets near the doors and windows of houses or in other situations likely to cause nuisance, and to have vertical steel or iron columns 20 to 25 ft. in height and 6 ins. to 12 ins. diameter, fixed in the line of curb and connected to the manholes to act either as inlets or outlets: the tops of the columns are fitted with wire guards.

In some cases the shafts consist of iron socketed pipes fixed against a building and carried up above the eaves or roof ridges in such a way as to be clear of all windows, skylights, or chimneys.

In broad suburban roads or where the sewers cross agricultural land, the manhole covers are still left open for ventilation purposes.

Connecting the sewers to the flues of factory chimneys has been tried but the draught is confined to a very small area and is not nearly so effective as one would anticipate. Numerous proprietary systems of sewer ventilation by means of fans, special cowls, gas destructors, antiseptic sprays and deodorants have been put on the market from time to time, but these are generally successful only in very favourable circumstances and cannot be recommended for general use.

SEWAGE TREATMENT.

Quantity of Sewage to be dealt with.

The quantity of sewage per head of the population drained, and the effect of the admission of rainwater, have been dealt with in the preceding matter dealing with sewers.

It has now become fairly well established in practice that in towns where the sewers are upon the combined system, and where the sewage is purified, the works shall be capable of providing full treatment for a quantity equal to three times the mean dry weather flow, and that in addition to this there shall be means of partially treating a further quantity equal to three times the mean dry weather flow, any surplus beyond this to be discharged untreated into the streams.

In towns sewered on the separate system the full treatment can be restricted to a volume of twice the mean dry weather flow, and partial treatment must in that case be provided for four times the dry weather flow.

Apart from the fluctuations in volume due to the admission of storm water, the quantity varies from hour to hour during the day, and in different days of the week, owing to the greater or lesser discharge of liquid from the houses in the district.

The following diagram represents the rate at which sewage is received on an average day in dry weather at the Leeds Sewage Purification Works :—

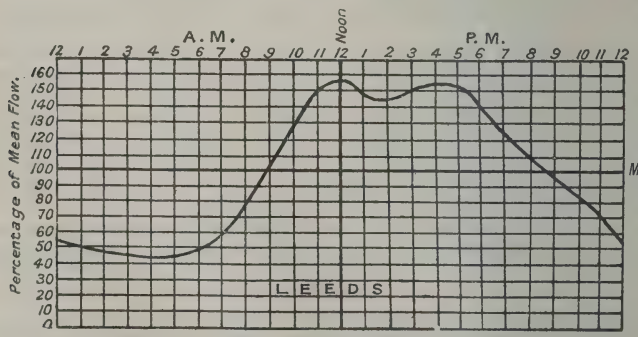

Fig. 2.

It will follow from what has been said that there are continual fluctuations in the volume of liquid to be dealt with at a sewage purification works, and such works must therefore be capable of adapting themselves to all the conditions under which they may be called upon to act.

General Outline of Treatment.

The object of all sewage purification processes is to convert the organic substances in the sewage into harmless inorganic matter. The organic matter may be in suspension or in solution, and it is not sufficient to eliminate the former, as was the case in some of the older processes, and leave the matters in solution, as these will subsequently putrefy and cause nuisance.

In average sewage of a domestic character—i.e. free from trade refuse—there are usually about 100 grains of solid matter per gallon, of which 40 grains are organic.

Grains per Gallon.	Organic.	Mineral.	Total.
Solid matter in suspension . . .	20	10	30
Solid matter in solution. . . .	20	50	70
Total	40	60	100

The solids in suspension can be reduced by subsidence, but the matter in solution must be oxidised, and this is effected by the action of bacteria.

In all cases the first step is to remove the largest and heaviest of the suspended matters, and this is done in detritus and screening tanks.

Such tanks should have a capacity of from 2 per cent. to 5 per cent. of the daily sewage flow and should contain iron gratings for the removal of floating matters, scum boards to arrest the scum; and they should be so designed as to reduce the velocity of flow of sewage sufficiently to allow the heaviest of the road grit, etc., to settle to the bottom of the tank.

The next step is usually to remove the lighter matters in suspension, and this is generally effected by providing tanks of suitable design: (*a*) to allow the particles to settle by gravity; (*b*) this process is sometimes expedited by the addition of chemicals known as precipitants; (*c*) for liquefaction of the solids in suspension by bacterial action and settlement combined, as in septic tanks; (*d*) assisting the action by presenting large surfaces to attract floating matter, as in the Travis tank or Dibdin slate filter.

Having freed the liquid as far as possible of the suspended solids with their organic contents, the effluent from the first part of the process must be subjected to a further treatment, which has for its object the oxidisation of the matters in solution and their conversion into harmless inorganic compounds which will not putrefy or take up oxygen from the stream into which it may be intended to discharge them.

This part of the process may be effected by application to land or to some form of bacterial filter; but if the latter it is usually necessary to have a further process for the removal of the solids in suspension which are evacuated by the filter. This can be effected either by land treatment, filtration, or settlement in tanks or lagoons.

The capacity of the tanks necessary for the removal of the suspended solids depends upon the strength of the sewage and a variety of circumstances.

If the tank can be used for quiescent settlement—i.e. filled with sewage, allowed to stand, and then emptied by decanting—a capacity of two hours to four hours' sewage flow will usually be sufficient provision. The usual method of using such tanks, however, is to use them continuously by drawing off over a long weir in a thin film at the same rate as the filling; in such a case the tanks should have from six to twelve hours' capacity.

If, however, the settlement be assisted by the addition of precipitants, and the tanks are used for continuous precipitation, their capacity may be reduced by one-half.

Septic tanks vary in capacity from fifteen hours to twenty-four hours' flow, and there is a tendency towards the smaller limit in present practice.

Precipitation by the use of chemicals has some effect upon the organic matter in solution as well as that in suspension, and by a sufficiently large expenditure it is possible to reduce the impurity in solution by as much as 50 per cent. The cost of doing this, however, would be prohibitive in actual practice. (See table, pages 1256 and 1257.)

The precipitants chiefly used are lime in a caustic state, 10 to 12 grains per gallon of sewage; lime and sulphate of iron or green copperas in the proportion of 6 grains to 3 grains of lime with 3 grains to 1 grain of copperas; lime and alumina in the proportion of 2 of the former to 1 of the latter, usually about 8 and 4 grains respectively; alumino-ferric, either with or without lime, proportion 10 to 7 grains lime and 5 to 3 grains alumino-ferric—if used without lime, up to 8½ grains per gallon.

Sludge.

The solid matters precipitated in the tanks produce what is known as sewage sludge, containing about 90 per cent. of water.

The final disposal of the sludge resulting from sewage purification has always been one of the chief difficulties of the problem of sewage treatment. The manurial value of the material is small, and it is a waste product of the process which must be got rid of as cheaply and as expeditiously as possible.

The methods of doing this may be briefly summarised as :—

1. Removal to sea.
2. Earth burial.
3. Cremation.
4. Drying in lagoons.
5. Drying in prepared beds.
6. Filter pressing.

The quantity of sludge per million gallons of sewage varies with the quality of the sewage, and the process adopted for the separation of the solid matter therein.

The method of estimating the quantity of sludge from a given process is as follows ;—

To the average number of grains per gallon of solids in suspension in the sewage add the grains of precipitant applied, and deduct from the total the grains of solids in suspension in the tank effluent ; this gives the grains of solid matter deposited from each gallon of sewage.

If
G = grains per gallon as above determined,
M = sewage per day in million gallons,
T = tons of wet sludge per day (90 per cent. water),
P = percentage of water in pressed cake,
C = tons of cake containing P per cent. water,

then $$T = \frac{100\,M \times G}{154}\ ;\ C = \frac{T}{100 - P}.$$

Pressed sludge cake containing 50 to 55 per cent. of water weighs about 14 cwts. per cubic yard.

Land Treatment.

The effluent from the various tank processes described may be suitably oxidised by application to land.

There are two distinct methods of using land. Where a suitable light friable soil can be obtained, filtration is the process adopted, the sewage passing downward through the soil to underdrains. If, on the other hand, the available land be all of a retentive character, which will not allow of the easy passage of water, the method adopted is to pass the tank effluent over the surface of the land by irrigation and to pick it up again in suitable catchwaters and reapply it to a fresh plot, and subsequently to a third or even a fourth plot before final discharge into the stream ; such land should not be underdrained, or only to a very slight extent.

The quantity of liquid which can be dealt with per acre of land will depend upon the character of the land, the strength of the sewage, and the degree of excellence of the preliminary treatment.

The following table gives a scale of quantities for various soils and average sewage, but great care must be exercised in applying the table :—

Soil.	Crude Sewage.		Settled Sewage.		Efficient Preliminary Treatment. Land Secondary.	
	Gallons.	Population.	Gallons.	Population.	Gallons.	Population.
Light sandy loam on gravel and sand	15,000	375	20,000	500	30,000	1,000
Sandy loam on gravel and sand	12,000	300	17,000	400	30,000	1,000
Peaty soil on gravel and sand	10,000	250	13,500	325	30,000	1,000
Sand and gravel	8,000	200	10,000	250	30,000	1,000
Gravelly loam on gravel and sand	6,000	150	8,000	200	20,000	666
Loam getting more clayey	4,500	125	6,000	150	15,000	500
Heavy loam on marl	3,000	75	5,000	130	12,000	400
Clay soil on clay	1,500	50	4,000	120	10,000	333
Stiff clay soil on dense clay	1,000	33	3,000	100	10,000	333

Artificial Bacterial Methods.

The alternative to land treatment for the final or oxidising process in sewage treatment is the use of bacteria beds. These are divided into two main classes :—

(*a*) Contact beds.
(*b*) Percolating or continuous filters.

Contact beds consist of tanks filled with material such as broken clinker, and used by filling them up with tank effluent until the filtering medium is just charged with liquid, allowing it to stand for a given period, draining off, and standing empty. The usual cycle of these operations is as follows :—

Filling	1 hour.
Standing	2 hours.
Draining	1 hour.
Aerating	4 hours.
	8 hours.

With this cycle three fillings per day are possible, and as the liquid capacity of a bed is 33 per cent. of its gross capacity, it follows that a bed is capable of treating each day a quantity of tank effluent equal to its gross capacity—i.e. when containing no filtering medium. The operations of filling and emptying may be done by hand valves or by automatic valves worked by floats. The depth of contact beds should not exceed 4 ft.

The second class of bacteria beds consists of masses of hard rough material, such as broken stone or slag of gauges varying from 3 ins. to ¼ in., over which the tank effluent is distributed in the form of spray and through which it percolates. The bed may or may not be enclosed by means of side walls, but it must have a good substantial floor, efficient means of drainage, and a proper system of distribution if good results are to be obtained. The depth of the beds varies from 4 ft. to 10 ft., depending upon the fall available and the size of the filtering medium.

The quantity of tank effluent which can be applied per square yard of surface of the bed depends upon the strength of the sewage and size of the material employed for filtering, and varies from 100 gallons per square yard per day to as much as 400 gallons, but this quantity cannot be maintained for long. A good average quantity is 150 gallons per square yard per day for a filter 6 ft. deep composed of materials averaging 2 ins. diameter ; this will allow the bed to take the hourly fluctuations in the rate of flow of sewage, and for short periods it will take storm-water up to three times the figure named.

The sprinkling process can be effected by a variety of arrangements, most of which have revolving arms operating in different ways, but there are also fixed jets and reciprocating travellers for rectangular beds.

The relative merits of contact beds and percolating beds are as follows :—

1. Where there is not much fall available, single contact beds can be constructed with about 3 ft. 6 ins. of fall ; double contact beds require 7 ft.

A continuous filter may be constructed with a fall of about 5 ft. 3 ins., but if a coarse filtering material is to be used this must be increased by 2 ft., or possibly more.

2. The tanks used for contact beds must be watertight, and therefore the facilities of the site for making watertight beds must be taken into consideration.

3. The weight of the material used in a continuous filter is greater than that of a contact bed, and therefore the stability of the ground must be taken into consideration.

4. Double contact beds must be provided if an equivalent degree of purification is required to that produced by a continuous filter.

5. Contact beds must be worked by automatic gear if three fillings per day are required, but may be operated by hand if two fillings are sufficient.

6. Generally speaking the gear for operating continuous filters is less liable to get out of order than that for contact beds.

7. Where the facilities for reducing suspended solids are limited, contact beds will sludge up and deteriorate much more quickly than continuous beds.

8. Percolating beds are more adaptable to fluctuating rates of flow than contact beds.

9. The first cost of percolating filters is less than that of contact beds for equal quantities of sewage.

10. Generally speaking, continuous filters give better results than contact beds.

Volume of sewage taken at 156,800,000 gallons per day. (*W. J. Dibdin.*)

Local Government Board's Requirements.

The following are believed to be the requirements of the Local Government Board with regard to sewage purification plants :—

Quantity of Sewage.

Quantity of sewage per head is usually reckoned at the rate of 30 gallons per day for dry-weather flow, for domestic purposes. In some cases this figure is modified to 20 gallons. If there be trade refuse to be dealt with, this must be added.

The quantity of sewage and rainwater to be fully treated at the works is :—

(*a*) Where the sewers are on the combined system, three times the domestic average plus $1\frac{1}{10}$ trade refuse.

(*b*) Where the sewers are on the separate system, twice the domestic sewage plus $1\frac{1}{10}$ trade refuse.

The quantity of sewage and rainwater to be partially treated is :—

(*a*) Where the sewers are on the combined system, three times the domestic sewage plus $1\frac{1}{10}$ trade refuse.

(*b*) Where the sewers are on the separate system, four times the domestic sewage plus $1\frac{1}{10}$ trade refuse.

Any excess over these quantities may be discharged over the stormwater overflows.

The above degrees of dilution are to be calculated on the average rate of flow throughout the 24 hours. The effect of this is that during the daytime when the average rate of flow is exceeded, the degrees of dilution will be less than those stated above, and on the other hand during the night the degree of dilution will be largely exceeded.

Storm Overflows.

Storm overflows on sewers should as far as is reasonably practicable be avoided, but where they are necessary they should be placed in such positions and with the weirs so fixed that no nuisance is likely to result. In any district where there is an active river authority the Board will desire to be informed of the opinion of such authority in respect of any proposed overflows. In the absence of any special circumstances overflow weirs should be fixed so as not to come into operation until the flow exceeds six times that of the average dry-weather flow.

There should be no overflow for untreated sewage or stormwater at or near the disposal works.

Screens.

All liquid delivered at the disposal works should as a rule be passed through a screening chamber.

Storm-water Treatment.

A weir set at three times the dry-weather flow should be placed *below the screens*, and any volume passing over this weir should be dealt with in storm tanks. The tanks should be two or more in number and their total capacity should not be less than a quarter of the dry-weather flow. They should be so arranged that when they are full they will act as 'continuous flow' tanks, and that they can be readily emptied and kept empty when no liquid is passing into them.

The liquor from the tanks can be discharged without further treatment except in special cases, and the sludge should be dealt with by any of the usual methods which may be most suitable in the particular circumstances.

In cases where a sufficient area of suitable land is available for the purpose, detritus tanks followed by irrigation may be substituted for the storm tanks.

Sewage Treatment.

Detritus Tanks.—There should be two or more detritus tanks below the screening chamber. The capacity of each tank should be about $\frac{1}{10}$th of the dry-weather flow.

Septic Tanks.—Septic tanks should not be less than two in number, and their total capacity should be about equal to the dry-weather flow.

Chemical Preparation Tanks.—For *quiescent* treatment there should not be less than eight tanks, each of which should have a capacity equal to about two hours' dry-weather flow.

For *continuous flow* treatment there should not be less than two tanks, with a total capacity of at least eight hours' dry-weather flow, and in most cases a greater number of tanks will be desirable.

Settling Tanks.—For *quiescent* treatment—same as chemical precipitation tanks.

For *continuous flow* treatment there should not be less than two tanks with a total capacity of from ten to fifteen hours' dry-weather flow.

Filters.—In determining the sizes of percolating filters and contact beds, the Board have, in order to allow for the strength of the sewage to be treated, adopted the division into 'strong,' 'average' and 'weak' sewages recommended by the Royal Commission.

The strength of sewage should, when possible, be ascertained by analysing average samples of crude sewage taken in dry weather at frequent and regular intervals throughout seven days, and in proportion to the flow. Possibly, in the case of small works, the period for taking samples for analysis might be somewhat shorter, but the period should not be less than forty-eight hours, and Saturday and Sunday should be avoided. In every case, the daily rainfall during the period when the samples were being taken and during the preceding days should be ascertained.

The analysis should in all cases include the following items :—

In parts per 100,000 *by weight.*

(1) Ammoniacal nitrogen.
(2) Albuminoid nitrogen.
(3) Total nitrogen.
(4) Oxygen absorbed from strong permanganate in three minutes at 80 degrees Fahr.
(5) Oxygen absorbed from strong permanganate in four hours at 80 degrees Fahr.
(6) Suspended solids.
(7) Soluble solids.
(8) Chlorine.

It is also desirable that the amount of dissolved oxygen taken up during the oxidation of the ammoniacal and organic matter of the sewage should be given.

The results of analysis would of course require to be properly interpreted ; but as a rough guide it may be taken that from the figure for 'Oxygen absorbed from strong permanganate in four hours at 80 degrees Fahr.' the strength of the sewage may be very roughly classified as follows :—

'Strong' sewage	17 to 25 parts per 100,000
'Average' „	10 to 12 „ „
'Weak' „	7 to 8 „ „

In cases where the sewage cannot be analysed its strength should be estimated according to the water consumption, the flow per head, the kind of sewage system, whether water-closets are in general use, the volume and nature of trade waste, the amount of dilution by subsoil or surface water, etc.

Failing satisfactory evidence to the contrary it will be desirable to assume that the sewage is 'strong,' for the purpose of estimating the required capacity for the disposal works.

For the purpose of showing the *minimum* total cubic contents of filters required for treating three times the dry-weather flow in different cases, the tables A and B have been prepared on the data given in the Commission's Report.

The rates of filtration given by the Commission are rates which can generally be *doubled* in wet weather. Where it is proposed to deal with *three* times the dry-weather flow, the Commission say that it would generally only be necessary to provide 1½ times the capacity of filter required for the dry-weather flow. This basis has been adopted in arriving at the figure in the Tables A and B.

TABLE A.—CONSTANTS FOR CALCULATING THE MINIMUM CUBICAL CONTENTS OF PERCOLATING FILTERS.

Preliminary Treatment.	Strong Sewage.		Sewage of Average Strength.		Weak Sewage.	
	Coarse or Medium Material.	Fine Material.	Coarse or Medium Material.	Fine Material.	Coarse or Medium Material.	Fine Material.
Detritus tanks .	15	*	25	*	40	*
Septic tanks. . . .	45 †	*	70	*	100	100
Settlement tanks (continuous flow) . .	45 †	*	70	*	100	100
Settlement tanks (quiescent) + . . .	50 †	25	100	70	130	130
Precipitation tanks (continuous flow) . .	65	50	100	80	150	175
Precipitation tanks (quiescent). . . .	100	65	130	130	170	200

Notes as to Filtering Material.

(*a*) A filter may be regarded as *coarse* if the material will not pass through a 1-in. sieve; as *medium* if it will pass through a 1-in. but not through a ½-in. sieve; and as *fine* if it will pass through a ½-inch sieve.

(*b*) *Coarse* material will be desirable in all cases where the liquid to be treated contains much suspended matter.

(*c*) In the cases marked * the use of fine material would not be desirable unless the circumstances were exceptional.

† If *medium* sized material were used in these cases the figures should be reduced by about 10.

TABLE B.—CONSTANTS FOR CALCULATING THE MINIMUM CUBICAL CONTENTS OF CONTACT BEDS.

Preliminary treatment.	Strong Sewage.			Sewage of Average Strength.			Weak Sewage.		
	Single Contact.	Double Contact.	Triple Contact.	Single Contact.	Double Contact.	Triple Contact.	Single Contact.	Double Contact.	Triple Contact.
Detritus tanks	—	—	25 *	—	25	†	—	38	†
Septic tanks	—	—	33	—	38	†	75	66 ‡	†
Settlement tanks (continuous flow)	—	—	33	—	38	†	75 *	66 ‡	†
Settlement tanks (quiescent)	—	—	44	—	50	†	100	†	†
Precipitation tanks (continuous flow)	—	33	†	—	50	†	133 ‡	†	†
Precipitation tanks (quiescent)	—	43	†	—	66 *	†	133 ‡	†	†

Notes to Table B.

(*a*) The beds should not be less than 2 feet 6 inches nor more than 6 feet in depth.

(*b*) The different series of beds, in double and triple contacts, should have an equal cubic contents, failing any evidence to the contrary.

(*c*) Where a blank is left in the table the particular treatment indicated would only be desirable in exceptional circumstances, as the method would not generally be economical.

(*d*) In the cases marked thus †, the particular treatment indicated would only be necessary in exceptional circumstances (e.g. where an unusually good effluent is required).

(*e*) Where three times the d.w.f. has to be dealt with in wet weather, the individual beds, in the cases marked thus ‡, should be small (to facilitate rapid filling and emptying), or the total cubic contents of the filters should be increased.

(*f*) The average liquid capacity of a cubic yard of contact bed is about 50 gallons.

* There are no data in the Commission's Report with regard to these cases.

In order to ascertain the minimum total cubic contents of the filters required, divide the dry-weather flow by the *appropriate figure* (having regard to the strength of the sewage and the kind of treatment proposed), in the tables above, and the result will be the number of cubic yards which the filters should contain for treating up to three times dry-weather flow.

In cases where a sufficient area of suitable land is used for irrigating the filtrate it will probably suffice if the total cubic contents of the filters is half that provided for by the tables, but where the filter capacity is so reduced it may be necessary in wet weather to restrict the flow to the filters to about 1½ times the dry-weather flow and to pass the remainder of tank liquor direct to the land.

Effluent Tanks or Filters.—Where the effluent from filters is not irrigated on land, tanks (with a capacity equal to about two hours' dry-weather flow and with provision for removing the sludge), or shallow straining filters, will in most cases be necessary for the purpose of preventing the suspended matters in the filtrate from passing into the river.

When the sewage, after previous sedimentation, is applied to land filtration the quantity per acre of the most suitable land shall not exceed 15,000 gallons of dry-weather flow per acre per day or the sewage from 500 persons, and surplus land up to 25 per cent. is usually required to enable the land to be rested. This area will be increased, if the land be not of the first quality.

When the sewage, after previous sedimentation, is applied to land by broad irrigation, the quantity is not allowed to exceed 4,500 gallons of dry-weather flow per acre per day, or the dry,

Activated Sludge Process
for the Purification of Sewage and Trades Waste.

Protected at home and abroad by many Patents. Adopted by seven Government Departments and many Municipal Authorities.

WRITE FOR BOOKLET No. K.Y.B.1.

Address all enquiries to

ACTIVATED SLUDGE, LTD.

14 Howick Place, Victoria Street, Westminster, London, S.W. 1.

F. 1260

Introduced in 1914-15 to the Cities of Milwaukee, U.S.A., Worcester, Eng., &c.

The Activated Sludge Process —of— Sewage Treatment

is now being adopted in all parts of the world

Because :—

1. It is hygienic, aerobic throughout, without smell.
2. Tanks are self cleansing, surplus sludge ejected periodically.
3. Existing tanks may be converted for the treatment of sewage, thus saving heavy expenditure in the building of new tanks.
4. It dispenses with filters and secondary treatment.
5. It reduces area and dimensions of tanks required.
6. It involves practically no loss of fall and often saves pumping.
7. It converts the sludge into a valuable fertiliser.

Ask for Booklet No. K.Y.B. 1.

Address all enquiries to:—

ACTIVATED SLUDGE, LTD.

weather sewage from 150 persons. Surplus land must also be provided in such cases from 25 per cent. to 50 per cent. for resting purposes. Where the land is less suitable, the quantity per acre may be reduced to as little as 3,000 gallons per day.

When sewage is treated by precipitation or bacterial processes and the final purification is effected by land, the tank or filter effluent may be applied at the rate of 30,000 gallons per acre per day or the sewage from 1,000 persons as a maximum on the best land.

In all cases where land of sufficient area and of a not unsuitable character can be obtained at a reasonable cost the final purification must be by land.

Activated Sludge Process.

(*Communicated.*)

The latest development of the sewage problem is that known as the 'Activated Sludge Process,' by which purification is carried out by oxidation of the organic matter present in the sewage by means of air blown through the liquid in the presence of an accumulation of sludge.

Experiments carried out at Manchester during 1913–14 demonstrated that by continually blowing air through successive quantities of sewage, decanting the liquid, and retaining the sludge, the latter became charged with micro-organisms which had the property of increasing enormously the purification effected by the simple aeration of the sewage. The deposit obtained in this manner has now become known as 'Activated Sludge.'

The addition of activated sludge to sewage, when combined with further blowing of fine bubbles of air through the mixture in such a manner as to create and maintain a circulation of air, sludge and liquid, sufficient to prevent settlement of the sludge and keep the sludge and air bubbles equally diffused throughout the liquid, produces a very marked change in the composition of the sewage; first a clotting or clarifying action takes place, then a rapid carbon oxidation process and finally nitrification.

Upon standing, the sludge rapidly settles and separates from the liquid, which when drawn off is not liable to putrefaction and is practically free from bacteria, whilst the sludge is also rendered innocuous and is found to contain a large proportion of nitrogen in a very available form for fertilising purposes.

It will be seen from the following table, which gives the composition of the sludge, that it has a large nitrogen content, so that its value as a fertiliser is extremely high; it contains, in fact, three to four times as much nitrogen as the average septic tank sludge:—

Organic and volatile matter . . .	64·70–70·40 per cent.
Minerals	35·30–29·60 ,,
Nitrogen	3·75– 7·09 ,,
Phosphoric acid	2·10– 4·20 ,,

One of the main difficulties has been to secure a complete diffusion of the air through the body of the sewage. This has been successfully overcome by appliances supplied by *Activated Sludge Ltd.*, 14 Howick Place, Victoria Street, Westminster, S.W. 1.

A further difficulty until recently was in obtaining a satisfactory settlement with a continuous flow, but due to the researches of Mr. W. Clifford, A.M.I.C.E., of Wolverhampton, this problem has been solved by a form of tank inlet which destroys the energy of the inlet current and eddies.

The Activated Sludge Process has many advantages; the chief of these are as follows:—

(1) The purification is rapid and perfect, and the effluent fully oxidised.
(2) Putrefaction stops at once, and the system is free from smells and flies.
(3) The plant can be installed close to buildings, so that long outfall sewers are often unnecessary.
(4) An inoffensive sludge which is a valuable manure is obtained.
(5) Only a small area of land is required.
(6) There is practically no loss of head (4 ins. to 10 ins.), and the sludge is raised automatically.
(7) Trade wastes which are alkaline, or of constant but low acidity, give no difficulty.
(8) A very small staff is needed, but it requires at least one skilled attendant.
(9) Capital costs are low owing to the simplicity of the plant, the small tank area needed (less than for sedimentation or septic tanks), and the absence of filter beds. Further, by installing the plant near a town, there may be a saving in the cost of outfall sewers.
(10) Maintenance costs are low owing to the revenue which may be obtained by the sale of manure.

Taken all round, the cost of installing and maintaining a plant is generally about two-thirds of the cost of septic tanks and filter beds. It should be mentioned that existing tanks can usually be converted, and in many places this has been done quite successfully at small cost.

The plants work well either with a large or small population, and would appear to be well suited for military stations. There are no real disadvantages in the system except possibly the production of compressed air, which is so essential for the working. In many places, compressed air is required for raising the sewage by means of ejectors, and no further compressing plant is needed.

The amount of purification of the liquid sewage depends upon the period of aeration allowed, and hence it is capable of dealing with very foul sewage which would be difficult of treatment by other processes.

The entire patents for the process are held by Messrs. Activated Sludge, Ltd., of 14 Howick Place, Victoria Street, Westminster.

The plants which have now been installed upon this process number twenty-three, a list of which, showing population served and volume of sewage treated, is set out below.

Standard of Purity for Sewage Effluents.

The Royal Commission on Sewage Disposal appointed in 1898 put forward the following provisional standard of purity for sewage effluents for the guidance of Local Authorities.

1. That it should not contain more than three parts per 100,000 of suspended matter; and
2. That after being filtered through filter paper it should not absorb more than
   (*a*) 0·5 part by weight per 100,000 of dissolved or atmospheric oxygen in 24 hours.
   (*b*) 1·0 „ „ „ „ „ 48 hours; or
   (*c*) 1·5 „ „ „ „ „ 5 days.

In 1913 the Royal Commission issued their 8th Report, in which they summarised their conclusions as follows:

(*a*) The law should be altered so that a person discharging sewage matter into a stream shall not be deemed to have committed an offence under the Rivers Pollution Prevention Act, 1876, if the sewage matter is discharged in a form which satisfies the requirements of the prescribed standard.

(*b*) The standard should be either the general standard or a special standard which will be higher or lower than the general standard as local circumstances require or permit.

(*c*) An effluent in order to comply with the general standard must not contain as discharged more than 3 parts per 100,000 of suspended matter, and with its suspended matters included must not take up at 65° F.' (18·3° C.) more than 2·0 parts per 100,000 of dissolved oxygen in five days. This general standard should be prescribed either by Statute or by Order of the Central Authority, and should be subject to modifications by that Authority after an interval of not less than ten years.

(*d*) In fixing any special standard the dilution afforded by the stream is the chief factor to be considered. If the dilution is very low it may be necessary for the Central Authority, either on their own initiative or on application by the Rivers Board, to prescribe a specially stringent standard, which should also remain in force for a period of not less than ten years.

(*e*) If the dilution is very great the standard may, with the approval of the Central Authority, be relaxed or suspended altogether. Our experience leads us to think that as a general rule, if the dilution, while not falling below 150 volumes, does not exceed 300, the dissolved oxygen absorption test may be omitted, and the standard for suspended solids fixed at 6 parts per 100,000. To comply with this test no treatment beyond chemical precipitation would ordinarily be needed. If the dilution while not falling below 300 volumes does not exceed 500 the standard for suspended solids may be further relaxed to 15 parts per 100,000. For this purpose tank treatment without chemicals would generally suffice if the tanks were properly worked and regularly cleansed

These relaxed standards should be subject to revision at periods to be fixed by the Central Authority, and the periods should be shorter than those prescribed for the general or for the more stringent standards.

(*f*) With a dilution of over 500 volumes all tests might be dispensed with, and crude sewage discharged, subject to such conditions as to the provision of screens or detritus tanks as might appear necessary to the Central Authority.

EDITORIAL NOTE.—The standards mentioned in (*e*) and (*f*) are not intended to apply to effluents discharged into streams which are used for drinking water or to streams the water of which, at the point of discharge of the sewage effluent, normally takes up more than 0·2 parts per 100,000 of dissolved oxygen in five days at 60° F. Up to the present time the proposals contained in the Report have not been embodied in any Act of Parliament, and have therefore no official authority, and must be treated as suggestions only.

HOUSE DRAINAGE.

House drains are usually made of salt glazed ware pipes varying from 3 ins. to 6 ins. diameter. Drains taking the discharge of water-closets should not be less than 4 ins. diameter.

Wherever possible all house drains should be laid outside the building; they should be laid as far as practicable in straight lines with easy bends, furnished with inspection chambers, and should be arranged so that they may be easily got at in case of necessity.

When it becomes imperative that drains should pass under the buildings, cast-iron pipes should be used and they should be laid in a straight line between two inspection chambers outside the building.

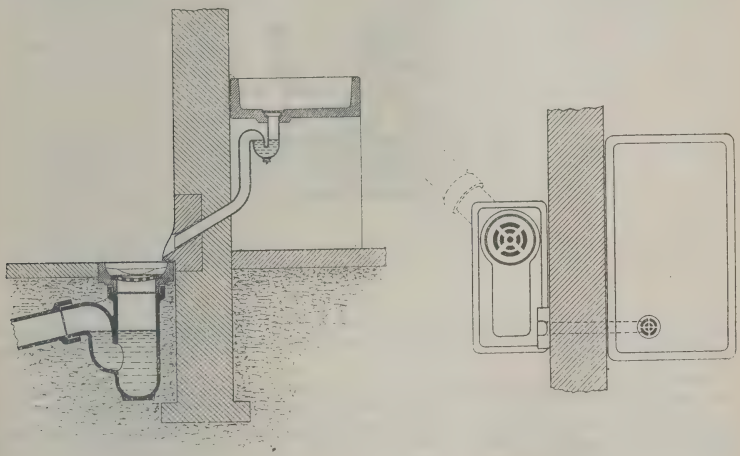

FIG. 3.—Section and Plan of Scullery Sink, with connection to Gully.

The size of drain-pipes should be sufficient to carry off sewage at the rate of forty gallons per head of the maximum population drained in six hours, and in addition rainfall at the rate of ½ in. per hour upon the area of roofs and paved yard surfaces draining to the sewers.

It was formerly considered essential that all private drains should be trapped from the sewer at a point as near as possible to the junction with the sewer and that an inspection chamber should be built at the trap and should be provided with a fresh-air inlet.

The Local Government Board appointed a Departmental Committee to advise upon the desirability of fixing these intercepting traps near the sewers. In 1912 the Committee made their report, and stated that the case for the necessity of the intercepting trap had broken down, and that it is not only unnecessary but in many cases is harmful. It is probable, therefore, that there will be an early modification of building regulations in most towns, deleting the byelaws requiring intercepting traps between sewer and drain.

The recommendation of the Committee must not be understood to imply the uselessness of traps other than the main intercepting trap : it is just as important as ever that all inlets to drains should be trapped between the drain and the house.

The general scheme of drain trapping should be based upon the following lines :—The main drain to each house or building should be carried from the sewer without a trap or air inlet to the furthest point where a branch connection is to be made, and there a ventilating shaft should be erected and carried up well above the eaves of the house and clear of all windows, dormers, skylights, and chimneys. The end of the pipe should be fitted with a wire guard ; most cowls are useless.

Branch drains for sink wastes, bath wastes, and rain-water pipes should terminate with trapped glazed stoneware gullies placed at ground-level and paved round with a containing curb of blue brick on edge on three sides and a short paved channel at least 18 ins. long on the other on to which the waste etc. pipes should discharge. Bath wastes etc. from upper floors should be made to discharge in the open air into the cistern heads of down-pipes which are themselves cut off from the gully as above described.

Branch drains for soil pipes should be untrapped at the foot of soil pipes and the latter should be carried up outside the external walls of the building in a straight line to above the eaves to form a ventilating column, the same precautions being adopted as in the case of the ventilation column for the end of the drain. Where there is only one soil-pipe connection it can often be arranged at the end of the main drain and so avoid the provision of more than one ventilation shaft.

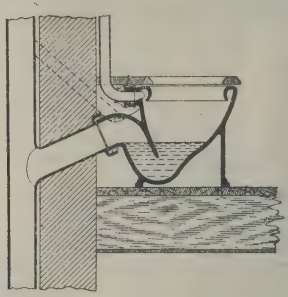

FIG. 4.—Section of Water-closet.

When it is found inevitable that soil-pipes should be fixed inside buildings they should be of drawn lead throughout their entire length and should be carried up through the roof to give thorough ventilation.

Sinks and water-closets should, whenever practicable, be placed against external walls so that they may discharge at once into a drain outside the main wall, as shown in figs. 3 and 4.

Water-closets are best placed where they can be thoroughly ventilated directly from the external air with windows extending to the ceilings, and they should be arranged to be entered from a well-ventilated ante-room or passage with doors to shut off communication with the other portions of the house.

LONDON COUNTY COUNCIL REGULATIONS FOR WATER-CLOSETS (*Abridged*).

Building (for closet) must have one external wall abutting on a space 100 ft. square super (or if in a basement approached directly from an opening at least 5 ft. wide and 40 ft. square super) and must not be directly approached from a room used for habitation, work, storage, or preparation for food. Walls abutting on such rooms must be of brick from floor to ceiling.

A window opening directly into the external air at least 2 ft. square, and in addition at least one ventilating air brick, air shaft, or other effectual means of ventilation must be provided.

Floor of closets approached from the external air to be of hard impervious material, having a fall to the door of half inch to the foot.

Door with proper fastening to be provided.

Cisterns giving an adequate and effectual flush must be fitted to all closets. Closet cisterns must be entirely separate from cisterns containing drinking water. A proper supply of water to the cistern must be supplied. No service pipe may be allowed to be connected in any way with any part of the closet apparatus except the cistern. Downpipe and union between closet and cistern must have internal diameter of not less than 1¼ in.

Closet Basin and Trap.—The basin must be of non-absorbent material of such shape that a sufficient quantity of water is held in such a manner that the soil falls direct into the water clear of the sides.

No container to be fitted under basin.

An efficient syphon trap must be fitted immediately behind or in connection with the basin. The trap must be constructed to always provide a sufficient water-seal between the basin and the drain. Traps must be ventilated where more than one closet is connected with the same soil pipe. Ventilating pipe must not be less than 2 ins. internally, and connect with the arm of soil pipe not less than 3 ins. nor more than 12 ins. from the highest part of the trap. Ventilation must be on the drain side of the water-seal, and the ventilation pipe must be carried either to the open air at a point as high as the top of the soil pipe or to the soil pipe above the highest closet.

No D trap or similar trap must be fitted.

Soil pipes must be outside buildings wherever practicable. Soil pipes inside buildings must be drawn head with wiped joints, or heavy cast iron with molten lead joints, properly caulked. Pipe to be continued without diminution and as straight as possible to a height to allow of safe outlet by open end for foul air. Height must be above highest part of roof of building, and where practicable 3 ft. above any window that lies within 20 ft. measured in a straight line from open end. Wire guard to be fitted to open end, the area of the opening in which must be equal to not less than size of pipe.

Soil pipe must not directly connect with waste of bath, rain-water pipe, or to a sink, and soil pipe must have no trap in it nor between it and the drain.

JOINTS.

Lead Pipe to Iron.—A brass thimble to be used—the lead wiped to open end and the other connected with the iron by a joint of molten lead, properly caulked.

Stoneware to Lead.—Brass socket or thimble wiped to lead and connected to stoneware with Portland cement.

Stoneware to Iron.—Stoneware to be inserted into socket in iron and connected with joint made with Portland cement.

DIMENSIONS AND WEIGHTS OF SOIL PIPES.

Internal diameter must not be less than 3½ inches.

Diameter.	Lead. Weight per 10 feet Length not less than	Iron. Weight per 6 feet Length not less than
3½ inches	65 lbs.	48 lbs.
4 „	74 „	54 „
5 „	92 „	69 „
6 „	110 „	84 „

Water-closet basins are all made with traps attached, and this is sufficient protection against sewer air coming into the house from the soil pipe. To ensure proper ventilation of the branch pipe from the w.c. trap to the soil pipe and to prevent unsealing by syphonic action where closets are placed over one another and are connected to the same soil pipe, a small auxiliary ventilation pipe should be connected near the trap and be carried upwards at an angle of about 45° into the soil pipe, as shown in fig. 4.

Water-closet basins should be so designed as to present as large a surface of water as possible into which the excreta may fall when the closet is in use; they should have flushing appliances which effectually wash the whole of the internal surface of the basin with the minimum of water,

and they should have all parts easily accessible for cleansing by hand. Closets with a syphonic action are most effectual and much to be preferred to any type of valve closets. The pedestal type of closet with lift-up lid so that it can be used as a urinal is the one most in favour.

Water-closets should be fitted with waste-preventing water-cisterns of not less than 2-gall. capacity and a 3-gall. cistern if allowed by the local waterworks regulations is preferable.

Flush pipes should be of lead or copper and should be 2 ins. diameter with a head of 6 ft. to give efficient flushing.

Urinals should not be provided at all inside private houses, and whenever they are fixed inside a building they should be made throughout of glazed stoneware with curved surfaces and as few joints as possible so as to avoid any angles in which the urine can lodge. They should be fitted with lead or copper sparge pipes capable of thoroughly washing all the surfaces liable to be soiled with urine.

Slate urinals may with advantage be painted with a mixture of common coal tar and naphtha; they should be thoroughly washed out at least once a day. Slate is not a material to be recommended for the construction of urinals; all stalls and basins should be of glazed stoneware.

The usual allowance of water for each stall in a public urinal is half a gallon per minute. The waste pipes for each stall should be 2 ins. in diameter.

White glazed bricks are preferable for facing the walls of public urinals; ordinary brick walls cemented over and painted are decidedly objectionable. The joints in the brickwork must not be thick under any circumstances, as they would present an absorbent surface.

Baths and housemaids' sinks should be of glazed porcelain fitted with trapped waste pipes which should be carried through the nearest external wall and be made to discharge in the open air over the cistern head of a downpipe: the top of the cistern head should be covered with a copper wire guard to keep out the birds, dead leaves, etc.

Kitchen and pantry sinks should be of glazed stoneware and should be fixed against an external wall, and their trapped lead waste-pipes should be carried through the wall and be made to discharge in the open air upon a paved channel leading to a trapped gully.

SECTION XXV

PART II

IRRIGATION — AVAILABLE SUPPLY — EVAPORATION — ABSORPTION—EVAPORATION FROM SOILS—LOSSES FROM IRRIGATION CANALS — MEAN VELOCITIES — CRITICAL VELOCITY—DUTY OF WATER.

Contributed by Reginald Ryves, Assoc.M.Inst.C.E., M.Cons.E.

(Author of 'A Note on Mass Dams and Dams of Arches,' etc.)

IRRIGATION.

Available Supply of Water.

Irrigation from Large Rivers.—The discharges of the river during the seasons when the water will be required are calculated from the observed depths over weirs, from differences of water level above and below bridge openings, and by the methods hereafter to be described under 'Capacities of Canals.' Whether these supplies will be fully available or not may depend upon the water levels which can be maintained above the weir, and upon what cultivable areas are commanded by the water at these levels. In this respect the scheme must be considered as a whole, and by making suitable regulations as to the crops which may be grown on certain areas and at certain seasons the availability of the supply may be increased.

Supplies from Defined Catchments.—In the case of a supply from a defined catchment the estimates of run-off may be made by the methods described under 'Rainfall,' the necessary deductions being made when the whole of the water stored cannot be directly utilised. Out of the whole recorded range of annual or seasonal rainfalls, and corresponding runs-off, one will be chosen as that suitable as a basis for the project, and the capacity of the reservoir designed accordingly. A table drawn up for catchment areas in Nagpur, Central Provinces, India (*Strange*), gives estimated yields for monsoon rainfalls ranging from 1 in. to 60 ins., and from this table the following examples are taken.

MONSOON RAINFALLS AND ESTIMATED RUNS-OFF FOR NAGPUR.

Evaporation from a Water Surface.

The actual rate of evaporation from the surface of a pool of water depends mainly on four factors: the temperature of the water itself; the velocity of the wind; the degree of humidity of the air; and the temperature of the air. As regards the first, this is more or less proportional to the air temperatures if we are measuring evaporation over considerable periods of time in different places. As regards the second, the velocity of the wind, this factor does not as a rule vary so much as others if we take a period such as a year; but it sometimes varies a great deal within areas of moderate extent, and it should be taken into consideration in making estimates of evaporation. The degree of humidity varies very greatly, not only in different countries or different districts, but also in proportion to the distance from the sea and, in some cases, with

elevation. There may be a marked decrease in the humidity of the air in a distance of a few miles from a long, straight coast line, the decrease being more gradual as we pass farther inland. There are also sharp differences between places just within and those just without the path of a monsoon current. The relation between water temperature and the rate of evaporation was studied at four stations in California (*Fortier*) with the following results, the evaporation being in sixty-fourths of an inch per day. The tanks used were of galvanised iron, 22 ins. in diameter and 28 ins. deep sunk in the ground.

Water Temperature and Evaporation.—53°F., 6; 62°F., 12; 73°F., 23; 80°F., 31; 88°F., 39.

The following were the results of experiments to test the rates of evaporation in air currents of different velocities, that in still air being taken as unity. (*Russell.*)

Wind Velocity and Evaporation.—Velocity 0, evaporation 1·00; velocity 5 miles an hour, evaporation 2·2; velocity 15, evaporation 4·9; velocity 20, evaporation 5·7; velocity 25, evaporation 6·1; velocity 30, evaporation 6·3. Observations taken at the Assuan reservoir show the relative importance of average month's temperatures and average month's wind velocities. The results do not, of course, aid in the establishment of a relation between actual wind velocities, actual temperatures, and rates of evaporation, but they are of practical use for purposes of comparison.

AVERAGE VELOCITIES OF WIND, AVERAGE TEMPERATURES, AND RATES OF EVAPORATION, ASSUAN, EGYPT. LATITUDE, 24°. YEAR 1912.

Evaporation, ins. per day	0·12	0·17	0·24	0·31	0·35	0·45	0·43	0·44	0·32	0·29	0·21	0·15

Humidity and Evaporation.

By taking a sufficient number of observations of rates of evaporation, it is possible to establish at the same time the relation between evaporation and air temperature and that between evaporation and humidity. Experiments of this kind with water at a constant temperature seem to be lacking, nor have observers, as a rule, noted the actual temperatures of the water. Results are, however, comparable in groups, such as those with small experimental tanks, and those with floating tanks in deep and shallow waters, respectively.

The following table gives the results of observations at Vehar reservoir, near Bombay, latitude 19° (*Conybeare*), and in Nagpur, 21° (*Binnie*). The values seem to be low, but this hardly affects their application in practice, as the engineer would draw the curves and fix his own zero line on the result of monthly or annual evaporations for the locality.

APPROXIMATE MONTHLY EVAPORATIONS IN FEET WITH GIVEN TEMPERATURES AND RELATIVE HUMIDITIES.

Percentage of Saturation.	Mean Temperatures, Fahr.						
	65°	70°	75°	80°	85°	90°	93°
88	0·14	0 17	0·19	0·21	0·24	0·27	0·30
85	0·19	0·22	0·22	0·23	0·27	0·30	0·33
80	0·22	0·27	0·29	0·30	0·32	0·36	0·38
75	0·24	0·29	0·33	0·35	0·37	0·40	0·42
70	0·26	0.30	0·34	0·35	0·38	0·42	0·44
65	0·28	0.31	0·34	0·36	0·40	0·44	0·46
60	0·30	0·35	0·38	0·40	0·42	0·47	0·49
55	0·32	0·37	0·42	0·46	0·50	0·52	0·54
50	0·35	0·40	0·45	0·50	0·55	0·60	0·62
45	0·45	0·50	0·57	0·67	0·71	0·75	0·78
40	0·61	0·66	0·70	0·72	0·77	0·82	0·84

The figures in the following table are taken from results of observations by the Egyptian Public Works Survey Department (*Cay*). It is clear that the rate of evaporation depends considerably upon the mean altitude of the sun, since, for air temperatures which are nearly the same, the rate of evaporation is affected by the latitude and the month. This is shown by the small tables, and the evaporation at latitude 24° in October with air temperature 83° and humidity 41 may be compared with that at latitude 27° in August, with nearly the same humidity.

The effect of altitude upon evaporation was tested at four stations on the same mountain in California with the following results :—

Evaporation at Different Altitudes.—4,500 ft., 2·69 ins. ; 7,100 ft., 2·04 ins. ; 10,000 ft., 1·63 in. ; 12,000 ft., 1·61 in.

Annual Evaporation.

At stations selected as representing the chief irrigation districts of California the following were evaporations for a year (*Fortier*). At Berkeley, the cooler coast area with relatively high rainfall, 41 ins. ; at Chico, the bottom of the Sacramento Valley, 53 ins. ; at Pomona, representing Southern California, 66 ins. ; at Tulare, the San Joachin Valley, 68 ins. ; at Calexico, the Imperial Valley, 71 ins.

The evaporation at a number of representative stations is given in the following table, but the methods adopted in measuring evaporation varied considerably. At Croydon, the evaporation from a 5-in. vessel in air was more than 50 per cent. greater than that from the 12-in. vessel floating in water.

EVAPORATION AT REPRESENTATIVE STATIONS.

Locality.	Approximate Latitude.	Evaporation in Inches.	Remarks.
Whitehaven, England	54½°	29·91	Elevation 90 ft. near coast.
Bolton-le-Moors, England	53½°	25·65	Average of 10 years. Elevation 320 ft.

Seasonal and Monthly Losses by Evaporation.

It is often necessary to be able to estimate the losses by evaporation during particular seasons, and monthly rates of evaporation, or daily rates in individual months, are frequently recorded. For considerable areas in India the seasonal losses may roughly be reckoned as: In the cold weather 12 ins., in the hot weather 32 ins., during the monsoon 16 ins.; total, 60 ins.

In the following table, some of the rates of evaporation are comparable, but the table has been drawn up chiefly in order to show the relative rates of evaporation in different months at the same station.

Losses by Evaporation and Absorption taken together.

In a great many cases the available data of losses from reservoirs are those for evaporation and absorption, or percolation, taken together. The more nearly the engineer can estimate what proportion of the total loss is due to evaporation alone, the more easily will he be able to decide as to the necessity or expediency of taking measures to reduce percolation. Fairly high losses may be tolerated from reservoirs where a considerable proportion of the percolating water reaches wells from which it can be lifted and used; and this may in some cases be an advantage when the level of the water in the reservoir is very low, or, at least, a mitigation of the disadvantage. Actual losses by percolation can be estimated when the rate of evaporation is obviously very small. Conversely, the proportion lost by evaporation may be estimated when the losses by percolation are known to be small. The losses may be measured as depths on the maximum waterspread, or as actual depths on the mean of the waterspreads at the beginning and end of each short period of observation. Thus, there are often apparent discrepancies between really similar cases, especially when the reservoirs are very shallow in parts, and when, as often happens, the maximum rate of evaporation occurs when the tank is very low.

Losses by percolation are sometimes very large. The losses from four irrigation reservoirs in the United States were as follows, measured in acre-inches or acre-feet referred to the *maximum* waterspread in acres:—(1) one year, 50·4 ins., all attributed to evaporation; (2) maximum of 2 years, 53·8 ins.; (3) maximum of 4 years, 132 ins.; (4) maximum of 2 years, 17·3 ft., ⅞ of which was attributed to percolation.

At Red Hills tank, Madras, a total loss of about 7·5 ft. seems to have been indicated by one set of tests, and 8·39 by another series. An allowance of 9 ft. is now made, and is considered to be ample, a fairly liberal estimate being desirable as the water is used for the supply of the city. Tanks in Rajputana were found to lose 9·77 ft. per annum, of which 3·66 ft. was attributed to absorption.

The reservoirs of the Sheffield waterworks are estimated to have lost only about 15 to 15½ inches by evaporation and absorption, the loss at Rotherham in a neighbouring area being 22 ins.

The following were the results of observations at Red Hills Tank, Madras, the year being roughly divided into seasons which do not, however, begin and end at even approximately the same dates every year.

SEASONAL LOSSES (INCHES PER DAY) BY EVAPORATION AND ABSORPTION, RED HILLS TANK, MADRAS.

Evaporation from the Soil.

A study of rates of evaporation from the soil is of practical importance as bearing upon estimates of the actual amounts of water required by crops under varying conditions, and the probable losses from the ground when the water is applied some time before cultivation. The importance of the subject is the greater in proportion to the extent to which the cultivation has the character of fruit growing or gardening, as distinct from the growth of large areas of grain crops. In orchards especially, it is possible so to apply the water that the loss by evaporation is considerably reduced. It is often an advantage to keep the water in distinct channels as long as possible.

CALIFORNIAN EXPERIMENTS ON EVAPORATION FROM THE SOIL.

Important series of tests have been carried out during recent years in California, and have been reported by Mr. S. Fortier, Chief of Irrigation Investigations, United States Department of Agriculture.

The experiments were carried out with tanks about 47 ins. deep and 23½ ins. diameter, sunk into the soil and filled nearly to the brim. These tanks were weighed in order to measure losses. The following tabular statement gives the results of experiments made in July and August on the evaporation from soils containing different proportions of water, measured as inches depth over the area of the surface. In the case of the initial free moisture this represented about 4½ to 6 per cent. The amounts of irrigation water added represented, respectively, very light, light, and ordinary irrigation.

WATER CONTENTS IN SOIL AND EVAPORATION (IN INCHES).

Initial moisture	2·8	2·7	2·7	4·1
Irrigation water	0	2·6	4·8	6·3
10 days' evaporation . . .	0·4	0·9	1·2	1·5

Evaporation from the soil may be much reduced by beating or crumbling the dry surface to a powder, by spreading a layer of finely divided soil over the surface, or by irrigating by means of furrows, afterwards spreading the dry soil from between the furrows by some means which will tend to crumble or powder it. In small-scale irrigation and where the cost of the water is high these considerations may be of importance. The following results were obtained in California with experimental tanks containing sandy loam, the evaporation from which when it was left uncovered after the water had been applied was compared with the evaporation after coverings of different depths of finely divided sandy loam had been added. The result of the experiment with the thinnest layer is, of course, the most important generally. During the fourteen days of the experiment the shade temperature of the air at noon was often more than 100°, while the soil temperature in the sun, at noon, varied from 120° to 140°. The figures were :—

Evaporation in hundredths of an inch per day : from uncovered soil, 72·5 ; from soil protected by a 4-inch layer, 20·6 ; 8-inch layer, 10·0 ; 10-inch layer, 2·0.

The following were the results of a twenty-one days' test.

SOIL EVAPORATION IN PERCENTAGE OF WATER APPLIED.

Days	2½	6½	10	14	17	21
Bare soil . . .	11	18	21	25	28	32
3-inch cover . .	2	5	7	9½	11½	14

A further series of experiments was carried out with tanks 47 inches deep and 23½ inches diameter.*

* See *Engineering News*, Sept. 5, 1912, but note that in figs. 2 and 3 the diagrams of evaporation in inches have been accidentally transposed.

In one set of tests the tanks were nearly filled with soil, leaving room for the covering of loose soil in each case, spread after the application of the water, while in another set of tests the tanks were nearly filled and the water applied at the bottoms of furrows of corresponding depths, the soil being afterwards spread. The following table gives the results of both experiments :

EVAPORATION AND SOIL COVERINGS.

Period after water was applied: days		7	14	21	28	21	28
		Evaporation in percentage of water applied.				Evaporation in inches.	
Surface irrigated and left		17·5	25	31·5 (29)		1·75	
Surfaces irrigated and covered with loose soil (inches)	3 ins.	4·8	9·5	13·7 (12·5)		0·75	
	6 ins.	1·5	3·2	6·0 (5·7)		0·34	
	9 ins.	1·5	1·3	4·1 (3·3)		0·22	
Surface irrigated and left		13·2	16·4	18·6	20·8		1·25
Water applied at the bottoms of furrows, depths in inches	3 ins.	9·2	12·0	14·9	16·5		0·99
	6 ins.	7·0	9·6	12·3	14·3		0·86
	9 ins.	6·1	7·5	9·9	12·0		0·72

In the column for the 21st day, the figures in brackets are calculated from the evaporation in inches, and possibly correspond to earlier readings. The other figures in the column are taken from the curve.

Relation between Evaporation from Soil and Evaporation from Water

The experiments, on the results of which the table below is based, showed what were the evaporations from soils containing different proportions of water, and from a water surface.

Percentage of Free Water.	Temperatures, Fahrenheit.				Weekly Evaporation in Inches.	
	Air in Shade.	Soil in Shade.	Soil in Sun.	Surface of Water.	Soil.	Water.
Saturated.	71°	76°	95°	77°	4·75	1·88
17·5%	76°	78°	106°	80°	1·33	1·94
11·9%	76°	78°	106°	80°	1·13	1·94
8·9%	76°	78°	108°	80°	0·88	1·94
4·8%	76°	78°	108°	80°	0·25	1·94

ANNUAL EVAPORATIONS IN INCHES DURING TWELVE YEARS, LEA BRIDGE, ENGLAND.

Water : max., 26·93 ; min., 17·33 ; mean, 22·2.
Soil : max., 25·14 ; min., 12·07 ; mean, 19·53.

Evaporation from Ice

At Boston waterworks, U.S.A., the evaporation from ice was about 0·06 inch per day, or 7 ins. for the cold season.

Water Losses from Irrigation Canals.

No general rules can be given for estimating the rate at which water is lost from irrigation canals. Some are practically watertight, and only lose water by evaporation, while others lose large proportions of their supply by leakage.

On the Ganges Canal, at one period the water sent down was accounted for as follows :—Irrigation, 56 per cent. ; loss in canal, 15 per cent. ; in distributaries, 7 per cent. ; in village water-courses, 22 per cent.

In the Punjab, a loss of 8 cusecs per million square feet of wetted surface has been allowed, and larger amounts in some cases. Certain canals with discharges from 400 to 450 cusecs were

found to lose about one cusec per mile. The Bari Doab Canal, when eighteen years old, lost about 12 to 14 per cent. of its discharge in a length of fifty miles.

Many canals lose a great deal of water for some time after their construction, and afterwards become reasonably watertight. The deposit of silt at a reasonable rate for some time after the canal is in service may be facilitated by suitable designing of the cross-sections and temporary adjustments of levels at the falls; but no general rules can be given as to this difficult problem.

When L is the loss from a canal, measured in the first mile, the loss up to a further distance of D miles is $L\,D^x$, where x varies from $\frac{5}{6}$ to $\frac{9}{9}$.

Capacities of Canals: Mean Velocity.

The discharge or capacity of a canal or river is the product of the cross-sectional area and the mean velocity. The mean velocity is usually found from Kütter's formula (see p. 1298), a coefficient of roughness, n, being chosen with regard to the nature of the soil and the probable behaviour of the canal with respect to silting and erosion. Since the formula takes account of the water slope or fall, and of the hydraulic mean radius,

$$\frac{\text{area}}{\text{wetted perimeter}}$$

every measurement or calculation of discharge by other means tends to fix the value of n for the particular conditions of the bed of the canal or stream. Small discharges may sometimes be measured directly in basins or symmetrical pools, and at notches or specially prepared weirs (pp. 1178–1181), but calculations for discharge over large weirs are themselves subject to disturbing factors and their value in the determination of n is limited.

For irrigation canals in favourable soils and working under favourable conditions the value $n = 0{\cdot}0225$ is considered suitable, and this value has been adopted in the design of very important works. For canals in less favourable conditions the value 0·025 is often adopted, and for canals distinctly below average conditions n may be taken as 0·0275. The value 0·030 may be applied to some rivers and to canals in 'defective condition,' whilst for channels which are much obstructed n may be taken as 0·035. The first two values above are those of most importance in irrigation engineering. For aqueducts of rubble masonry n may be taken about 0·017 to 0·020, and for ashlar and brickwork, 0·013.

Bazin's Formula.

Bazin's new formula is often used for channels, especially for those which, in irrigation systems, are relatively small. It is derived from the general formula

$$V = c\sqrt{RS},$$

by making

$$c = \frac{157{\cdot}6}{1 + \frac{m}{\sqrt{R}}},$$

where c is the coefficient, and V, R, and S have the values given on page 1298.

$m = 0{\cdot}109$ for smooth cemented surfaces.
$= 0{\cdot}29$ for ashlar and brickwork.
$= 0{\cdot}83$ for rubble masonry.
$= 1{\cdot}54$ for very smooth earthen channels, pitched, or partly pitched.
$= 2{\cdot}36$ for ordinary earthen channels.
$= 3{\cdot}17$ for canals encumbered with weeds or boulders.

Direct Measurement of Mean Velocities.

The Use of Floats.—Floats of various kinds have been employed for the measurement of the velocities of canals and rivers, being sent down the reach so as to maintain as far as possible their proper positions in the cross-sections, the average velocity being calculated from float speeds and depths in each strip of the reach. Double floats are often used, the lower and larger float which is a little heavier than water, being held at a determined depth below the surface by a smaller surface float to which it is attached by a cord. Thus the velocities at different depths and at different distances from the centre-line of the stream can be measured. The essential difficulty in using these floats is that if the lower float has a specific gravity considerably greater than that of the water the surface float must be relatively large, and affect the result appreciably, while if the specific gravity of the lower float be but little greater than that of the water it is liable to be lifted towards the surface by small upward currents.

For the lower floats both cylinders and spheres have been employed; for instance, cylinders 6 ins. in diameter and 12 ins. long, or 6 to 8 ins. in diameter and 9 to 12 ins. long; and spheres 2 ins. and 3 ins. in diameter.

Various forms of surface floats have been used, including very thin discs of considerable area, intended to slip easily along the surface without seriously affecting the speed of the lower float. This form seems to be suitable in calm weather, while a deeper float of smaller surface area may be preferable when there is a breeze. Calm days are best for float observations of any kind, but if a river or canal flows with or against prevailing winds of considerable velocity observations on calm days may be to a small extent misleading.

Rod Floats.—For canals, and for reaches of rivers in which the water varies but little in depth, a good form is the rod float, which may be a tube weighted at the bottom so as to float upright, or a wooden pole similarly weighted. In the Ganges canal experiments both one-inch poles and one-inch tubes were used, the latter proving to be the better. The rods should float with their bottom ends just clear of the bed of the canal.

Current Meters.—Current meters are often used for measuring the velocity of streams and canals, and must be preferred to floats when there is no reach of sufficient regularity and length for the successful use of the latter. With a current meter the velocity at a particular cross-section may be found, and the measurement of that cross-section will then suffice, instead of the number which the irregularity of a reach may render necessary. It is not always easy in practice to keep the current meter at the desired depth, but in some cases it is held there by a rod. In a sluggish stream, the meter may be towed behind a boat, the speed of which is measured. Current meters should be calibrated, and from time to time tested, by towing them at a measured speed in still water, or, failing that, up and down the same reach of the canal or river. The mechanism of the meter can be stopped and started by a brake, on the stop-watch principle, this brake being worked by a cord from the boat. But some meters are fitted with an electrical apparatus, the wires of which form part of the tow line, and record the revolutions visibly in the boat.

The Pitot Tube.—If a tube be partly immersed, vertically, in a current of water, the lower end being suitably bent and remaining open, the water in the tube rises above the surface of the flowing water. The Pitot tube, designed on this principle, gives approximately the relation, $V = \mu \sqrt{2gh}$, where V = the velocity of the current, and h is the height of the water in the tube above the surface of the stream. Instruments which have been employed have given the results $V = 1{\cdot}7 \sqrt{h}$. A much more elaborate instrument on the same principle (*Darcy*) has also been employed, and has given good results in small channels with fairly high velocities.

Perrodil's Hydrodynamometer.—This instrument is a device for measuring the velocity of a current, by the torsion which is produced in a wire by the pressure of the water against a disc mounted on an arm at right angles to the wire. The velocity is found by the equation $V = c \sqrt{a}$, where a is the angle of torsion, and c a coefficient found by experiment, or calculated from the coefficient of torsion of the material of the wire. The instrument is very sensitive and can be used for very slow currents.

Mean Velocity in a Vertical.—The mean velocity of the water in a given vertical in the cross-section of a stream is also the actual velocity at some proportion of the total depth in that vertical. What this proportion is will depend upon the nature of the stream, and will not be the same for all the verticals. For streams of considerable width and not very variable depth at the cross-section, measurements, by means of a current meter, of the velocities at the assumed depth of mean velocity may yield a fair approximation to the mean velocity of the stream, and a closer approximation may be obtained by making preliminary tests, with rod floats for instance, to determine the depth of mean velocity in the particular case. Values given usually lie between 0·60 and 0·75, or 0·60 and 0·70 of the depth.

Relation between Mean and Maximum Velocities.—For a rough estimation of the velocity of a stream the maximum surface velocity may be measured and the mean velocity deduced from it. If V be the maximum velocity, the mean velocity is KV, where K is a coefficient usually ranging from 0·60 to 0·80. In the following table values of K are given for earth channels and rubble masonry channels.

VALUES OF 'K' IN THE EQUATION 'V MEAN = KV MAXIMUM.'

Hydraulic mean depth (feet)	1	2	3	4	5	6	7	10	15	20
Rubble masonry channels	·77	·79	·80	·81	·81	·81	·81	·82	·82	·82
Earthen channels	·65	·71	·73	·75	·76	·77	·78	·78	·79	·80

CRITICAL VELOCITY.

The 'critical velocity' is that mean velocity at which, for a canal of given depth, the current will neither deposit much silt nor unduly erode its bed. A determination of the critical velocity, the theory of which was evolved by R. G. Kennedy (see Min. Proc. Civil Engineers, vol. cxix.), is of great importance in the design of irrigation canals. The removal of silt from the canals is costly, and the loss of valuable fertilising material is a serious matter to the cultivators. A large amount of silting of the canals and distributaries is often inevitable, but attempts are made to lessen it by designing the canals in accordance with the principle of critical velocity.

The equation for determining the critical velocity for a given depth of water in the canal is

$$V_o = cd_m.$$

The values of c and m vary somewhat according to the nature of the silt. For fine sand-silt brought down from the hills usual values are, $c = 0{\cdot}84$ and $m = 0{\cdot}64$. The following table gives the critical velocities calculated on this basis, for different depths, and the observed critical velocities on the Shwebo and Mandalay canals, Burma. With the latter velocities there was, on the whole, a slight tendency to scour.

CRITICAL VELOCITIES.

Depths in feet . . .	1	2	3	4	5	6	7	8	9	10	12	15	20
$V = 0{\cdot}84\ d^m$, suitable for the Punjab . . .	0·84	1·30	1·70	2·04	2·35	2·64	2·92	3·18	3·43	3·67	4·12	4·75	5·71
Observed in Shwebo and Mandalay Canals . .	—	—	1·72	1·98	2·24	2·48	2·75	—	3·09	—	—	—	—

A canal which would be non-silting on a slope of 1 in 7,600 if drawn from the Indus in Sind, would require to have a slope of 1 in 4,200 to be non-silting if carrying the silt usually found in the Punjab (*Buckley*).

If the theory of critical velocity be accepted as regards silting and erosion up to the old limits of velocity for different soils, but be rejected when those velocities are reached, the maximum depths allowed for large canals will be correspondingly restricted. If, for instance, a maximum velocity of 3·5 ft. per sec. be prescribed, the depth will be limited to about 9 ft. On the old theory, a higher velocity would cause scour, while on the theory of critical velocity, greater depths with a limit of 3 to 5 ft. per sec. would cause silting. There is, however, no sudden change in the physical conditions, and if the theory of critical velocity holds up to 9 ft. depth it doubtless holds for considerably greater depths; and it has been accepted in the design of very important irrigation systems.

VALUE OF c IN $V = c\sqrt{RS}$, $n = 0{\cdot}0250$.

Duty of Irrigation Water.

The duty of irrigation water, or the area irrigated by a given rate of flow during the season, depends upon the nature of the crop, the initial proportion of moisture in the soil, the rate of evaporation, and the rainfall during the irrigation season. It may also depend upon custom and acquired rights and is often affected by the degree of care or of carelessness exercised by the cultivators. All figures relating to duty are, therefore, to be accepted with due reserve for purposes of estimates. The duty reckoned on the amount passing the headworks is, of course, less than that reckoned on amounts measured out to the cultivators, and the former figures will be affected by the length of the main canal and principal branches, and the rate of loss therefrom. The duty of irrigation water may be measured in cusecs continuously for the crop; in acre-ft.; or in acres per million cub. ft. stored.

On the Jamrao Canal system, India, the duty of one cusec per 50 acres has been allowed for during the inundation season, and 100 acres during the cool season. The duty has been as high as 83 acres in the inundation season, for 'dry crops' such as millet and cotton. In the Punjab, 100 acres has been allowed for in the rains, and 200 acres in the cool season.

The following duties, in acres per cusec, may be noted:—

Palked canal, Bengal Deccan, 63; Ekrak tank project, Bombay, 123. Pahakarpur canal, Bombay, 165; Kabul river canal, Bombay, 114; Lower Swat river canal, Bombay, 175; Letabo canal project, Transvaal, 145; Mool river, Transvaal, 145.

By amounts: in Kathiawar, jowari, a grain crop, requires 100,000 cub. ft. per acre, and in Jeypore State the same crop requires about 120,000 cub. ft., including losses and contingencies. In the Madras Presidency, where large areas are irrigated from numerous shallow reservoirs, the quantity, including all losses, which is stored per acre is, roughly, about 216,000 cubic ft., or nearly 5 ft. depth, for the 5 months' 'monsoon' rice crop, and 175,000 cubic ft., nearly 4 ft. depth, for a cool weather rice crop. In Central India, the storage is about 200,000 to 250,000 cubic ft. per acre. Wheat requires only about half as much water as rice.

DUTY OF IRRIGATION WATER: AVERAGES OR ESTIMATED AVERAGES: ACRES PER CUSEC.

Southern California, surface irrigation, 150 to 300; S. California, sub-irrigation, 300 to 500; Southern Arizona, 100 to 150; New Mexico, 60 to 80; Utah, 60 to 120; Colorado, 80 to 120; Northern Italy, 60 to 150; Madras Presidency, rice 66, 'dry crops' 132.

The average duty of five canal irrigation systems in the Bombay Deccan, from 1894–1895 to 1900–1901, excluding two famine years, was, successively:

For *Kharif*, 70, 52, 74, 111, and 138, with a mean of 89; and for *rabi*, 60, 68, 90, 75, 85, with a mean of 76.

Costs of Irrigation Projects.

The costs of irrigation projects in India do not admit of comparison unless the nature and purpose of the project in each case be described in considerable detail. Some projects are highly productive, others are protective, and many are of an intermediate character. The conditions are very different in the United States, and, on the assumption that the works have been carried out on the narrower economic basis, the following costs may be worth noting.

COSTS OF IRRIGATION PROJECTS OF THE UNITED STATES RECLAMATION SERVICE.

Area in Thousands of Acres	216	206	164	131	129	118	103	100	72	60
Cost of water rights in dollars per acre	30 to 36	22 to 30	45 to 50	55 to 66	45 to 55	22 to 30	52	30 to 35	30	45

COST OF IRRIGATION WITH PUMPED WATER, S. AFRICA.

On the total cost of 63 pumping projects, the cost per acre was 6*l.* 17*s.* Near the coast, the cost of putting two feet per acre on to the land may be taken as between 1*l.* and 2*l.* for a 50-ft. lift, and between 1*l.* 10*s.* and 2*l.* 10*s.* for a 150-ft. lift. Up country, the costs would be about 2*l.* 10*s.* and 3*l.* respectively. (*Legg.*)

Waste Weir Capacities.

For rates of rainfall and calculations for run-off, see 'Rainfall,' pp. 1280, 1281. For discharges of weirs, see pp. 1178–1181. The following formula is used in India for the discharges of the overflow weirs of storage tanks and reservoirs.

Discharge of clear overfall weirs:—

$$D = c\,b\,\sqrt{H^3}.$$

D = discharge in cusecs; b = width of the crest in feet; H = total height above the weir crest in feet, allowing for afflux; c is a coefficient usually about 3·333, or as low as 3·25.

In ordinary practice in the Bombay Presidency, India, it is usual to assume a general rainfall over the whole of a small catchment, and to calculate the run-off accordingly, thus :—

Catchment in Sq. Miles . . .	Up to 5.	5 to 10.	10 to 25.	25 to 75.	75 to 150.	Over 150.
Run-off in ins. of rain per hour .	2·00	1·50	1·25	1·00	0·75	0·50

In using this table special circumstances have to be considered; mountain catchments would be given larger runs-off, and for catchments wholly in the plains smaller runs-off would be assigned. (*Strange.*)

RAINFALL.

(Contributed by Reginald Ryves, A.M.Inst.C.E., M.Cons.E., F.R.Met.Soc.)

Rainfall in the British Isles.

For valuable data and studies relating to rainfall in the British Isles reference may be made to a paper on 'The Distribution of Mean and Extreme Annual Rainfall over the British Isles,' by H. R. Mill (Min. Proceedings Civil Engineers, vol. clv., 1903–1904); also to 'Variations in the English Climate during the Thirty Years 1881–1910,' by W. Marriott (Quarterly Journal R. Met. Soc. July 1911). The former paper is accompanied by useful maps of rainfall distribution, and the latter by diagrams showing deviations from the mean values, month by month, for temperature, rainfall, number of 'rain-days,' and atmospheric pressure. Temperature and the number of rain-days have a considerable bearing upon water-supply and sewerage schemes. Reference may also be made to a paper on 'The Abnormal Summer of 1911,' by C. Harding (Quart. Journal R. Met. Soc., January 1912).

The rainfall of each of the three divisions of the British Isles decreases from 100, 80, or 60 inches in the mountains and moorlands near the Western coasts to about 25 inches (over a few areas down to 20 inches) near the Eastern coasts of Scotland and England, and in the Midlands, and to about 35 inches on the East coast of Ireland. Over more than a third of England the rainfall ranges from 25 to 30 inches, and over a considerable total of smaller areas the fall is from 30 to 40 inches. There is a similar range, 30 to 40 inches, over about half Scotland, and a large area in the Western Highlands has a rainfall ranging from 60 to 100 inches. Over the Eastern half of Ireland the fall is from 35 to 40 inches, and over most of the Western half from 40 to 50 inches. For the period 1870–1899 the average annual falls were as follows: England, 31·62; Wales, 49·53; Scotland, 46·85; Ireland, 42·28; British Isles, 39·25. For the period 1881–1910 the average for England was 31·90.

Average, Maximum and Minimum Rainfalls.

It is generally agreed that a period of 30 to 35 years (*Binnie*) is long enough to establish for the average annual rainfall a value which will be nearly the true average, if such there be, and anyhow will be the mean of probabilities. For reasons, some of which are theoretical and others practical, many engineers prefer a period of 35 or 30 years to the longer periods for which records are in some cases available.

In the British Isles for the period 1870–1899 the rainfall of the 'wettest' year exceeded the average fall by 43 per cent., and that for the 'driest' year was 29 per cent. below the average (*Mill*). The following, expressed in percentages of the averages, are the figures for the different parts of the British Isles and for the whole area, taking in every case the wettest and driest years for the area referred to, period 1870–1899:—

England, 146 and 70; Wales, 147 and 75; Scotland, 147 and 72; Ireland, 133 and 69; British Isles, 143 and 70.

For the period 1881–1910 (*Marriott*) the percentage figures for England are 131 and 76·7. This period seems, however, to have been somewhat abnormal. The actual rainfalls compare thus:

England.	Maximum.	Average.	Minimum.
Period 1870–1899	46·98	31·62	22·83
Period 1881–1899	41·78	31·90	24·45

This suggests that although the 30 years' period may be satisfactory as regards the average annual rainfall it may not include a fall approximating to the maximum, nor one approximating to the minimum. Probability would, indeed, seem to be against such a result, but it is interesting to note the differences of nearly 5 inches and 1½ inch above.

At stations in the British Isles the following annual rainfalls in percentages of the average have been recorded : 58·8, 59·8, 61, 60·5, 63·6 and 64·5, showing defects from 35½ to 41 per cent. of the averages.

Sir Alexander Binnie considered the true mean rainfall to lie between the period of 33 and 35 years. From 14 stations scattered over the world he arrived at the following results :—

1. The percentage of years, in which the rainfall is above the mean rainfall, is 45·8.
2. The percentage of years, in which the rainfall is below the mean rainfall, is 54·2.
3. The average fall of wet years is 1·19 of the mean rainfall.
4. The average fall of dry years is 0·83 of the mean rainfall.
5. The average fall of the three consecutive dry years is 0·76 of the mean rainfall.
6. The maximum rainfall is 1·52 of the mean.
7. The minimum rainfall is 0·59 of the mean.
8. The proportional number of periods of three consecutive dry years in 100 years is 20·3.

Rainfall in Foreign Countries.

The following figures are maximum annual rainfalls (for whole countries) expressed as a percentage of the average annual fall in each case (*Binnie*) :

Norway, Denmark, Holland and Belgium, 148 per cent. ; France, 161 ; Italy, 159 ; Switzerland, 147 ; Germany, 139 ; Bavaria and Austria, 144 ; Russia, 166 ; India, 162 ; Australia, 156 ; North America and Canada, 141 ; typical observations for the world, 151.

The following are actual inches of annual rainfall, maximum, average and minimum, for a period of 24 years, in the Madras Presidency, 7 stations :—

70, 47, 31—78, 40, 17—48, 29, 9—60, 50, 17—43, 28, 17—165, 117, 87—182, 131, 95.

The probable figures for a given area, when they cannot be based on records fairly covering the area itself, may be estimated partly from station records and partly from averages for a larger area, the probable range of maximum and minimum values being studied from both points of view, and depending to a considerable extent upon the size of the area under consideration.

The Driest Group of Three Years Running.

Experience has shown that the most serious shortage in water-supplies usually occurs as the result of the defect of rainfall in the driest group of three years running, and this consideration is usually one of the factors in the design of water supplies and irrigation works. It must not be assumed, however, that there are no cases in which the worst single dry year is not the governing factor, and on the other hand, the worst period may in some countries be more than three years. The principle is, however, to be accepted in all cases, inasmuch as there is, for every place, some period which is that towards the end of which the effects of a drought will probably be most severely felt. The rainfall records will go far towards disclosing the critical period, but the nature of the soil, and the extent and nature of natural storage facilities, may also have to be taken into consideration.

The estimated average annual rainfall for the three years' period is sometimes put at 80 per cent. of the general average, though it is doubtful whether so high a percentage could be relied upon in any country. Sometimes it is put at 75 per cent. At Cape Town the average rainfall for the driest three years is 73 per cent. of the general average. In any case it must be remembered that the available run-off in the three years, as will be shown later, may be a much smaller percentage of the average available run-off. If, out of 50 inches of rain, 15 are lost by evaporation and absorption, we have 35 inches available. With a 40 inch, or 80 per cent. fall, we should have 25 inches available, or about 71 per cent., and the loss in the dry year might be greater than the average.

Run-off and Losses.

The available supply and the losses by evaporation and absorption are often expressed as percentages of the rainfall, but the amount of run-off or of loss bears no definite relation to the amount received by the catchment. The yield of a catchment area may better be reckoned as proportionate to the rainfall less some constant quantity which may be called the 'handicap' (*Lapworth*). This method is not, however, applicable to all cases, though in most cases it is suitable for the purposes of preliminary plans and may often give quite accurate results. The following are 'handicaps' for different areas (*Lapworth*) :

Average in Great Britain, 10 to 12 inches ; Thames Valley, 16 inches ; parts of Dartmoor, nearly 18 inches ; North-Eastern and Eastern parts of the United States, about 16 to 20 inches ; in California, 23 inches or more ; in India, up to 30 inches ; in South Africa, about 25 inches.

It is necessary to find the particular 'handicap' in every case, since its amount necessarily depends upon topographical and geological features, upon the area of the catchment and the manner in which the water is collected. Further, it must be noted that the method is by no means generally applicable, and notably fails when the effect of one year upon the next is strongly marked. In the Ajamenta Valley, Gold Coast Colony, the following, in inches, were year's falls and the corresponding yields (*Hunter*) :—

38·8, 1·800—59·9, 8·280—47·7, 2·540—42·4, 0·140—30·8, 0·560—29·6, 0·004—40·2, 0·006.

Again, if we take the figures for the Sweetwater catchment basin, California, we find that the following comparisons may be made (*Folwell*) :—

A year's rainfall of 21 inches yielded 12 per cent., but a fall of 23·4 inches yielded only 9 per cent., while another year's fall of over 23 inches yielded less than 0·4 per cent. A fall of 17·2 inches yielded 4 per cent., but falls of 18 to 19 inches yielded less than a quarter per cent. The average fall of nearly 21 inches yielded less than 6 per cent., but an actual year's fall of 20 inches yielded 8 per cent.

The yield from the Coolgardie catchment, in a period of six years (*Palmer*) ranged from 0·20 per cent. to 3·5 per cent., while the rainfall ranged only from 19 to 33¼ inches.

In a period of 10 years the worst discharge of the Guadalquiver (Spain) was 9 per cent. of the rainfall, and in the best year it was 50 per cent. In the Karroo, S. Africa, a yield of 2 or 3 per cent. would be expected from a year's fall of 8 to 10 inches, and from a fall of 20 inches the yield would be about 8 or 10 per cent. (*Legg*).

Generally, in dry countries with a small rainfall the ratio of evaporation to the rainfall, or to a part of the rainfall, increases rapidly with a decrease in the actual amount of the fall. Conversely, in wet countries with a fairly large proportion of rainy or cloudy days the effect of relatively dry conditions or of scanty rainfall is not felt to nearly the same extent. In some cases it is found that the rainfall to be considered is that of only a part of the year, and it is then necessary to study maximum and minimum rainfalls, and the worst three years, as applying only to this season. In Natal about $\frac{7}{12}$ of the rainfall occurs in the wet season, September to April. In Southern Rhodesia, about $\frac{11}{12}$ from November to March. In other cases, especially when the area does not feel the full effects of any of the seasonal rains, it is necessary to examine the rainfall records in detail for the worst three years, and to eliminate all falls of less than some predetermined amount (single falls or day's rain). Next, the yield from each of a series of falls should be estimated as, in each case, a proportion depending partly upon the amount of the fall and partly upon the interval which had elapsed since the previous fall. The maximum percentage yield will be assigned to continuous rain on soaked ground and soaked subsoil. In dry areas it may be necessary to adopt such a method of estimating the yield, when, owing to the nature and distribution of the rains, no general rule can be applied to the whole rainfall of the year, or to that of a season. For a rough estimate it may be sufficient to eliminate small or isolated falls and to calculate the yield of the remainder as a diminishing proportion of the remaining rainfall, less some constant. In some conditions the proportion need not be a diminishing one.

Absorption and Evaporation.

While it is possible, by the exercise of judgment, to form some idea as to the extent of losses by absorption for a particular area, it is clear that the large number of factors involved makes it impossible to lay down any general rules. Under some circumstances all the rain runs off, under other circumstances it is all absorbed, and there is every conceivable intermediate condition.

A few points are, however, worth noting. Clay soils, after the surface is wet, absorb water only very slowly. Some light soils are absorbent up to a given rate of absorption and rainfall in excess of that rate runs off. If the water absorbed by the soil percolates to places where it is available for use, the loss by evaporation from the soil will largely depend upon the average depth of the subsoil water. A dusty surface to a great extent prevents evaporation from the soil.

In practice, the loss from evaporation and percolation taken together is found by gaugings of the streams from the catchment, or, provisionally, is based upon data obtained from similar catchments, with such modifications as seem to be desirable owing to differences in the conditions. The estimate of the loss by evaporation and absorption, obtained from one set of data, should agree with the estimate of total yield based upon another set of data, or upon general considerations. References to evaporation from free water surfaces and from soils will be found under ' Irrigation,' pp. 1267, etc.

Dr. Walter Leather gives the following formula for estimating evaporation from water surfaces :—

$$E = 2{\cdot}0 (\log t - 1{\cdot}74) + 0{\cdot}33 (\log D - 1{\cdot}00) + 0{\cdot}36 (\log W - 0{\cdot}125).$$

where,

E = Evaporation in millimetres for 24 hours ; D = Dryness = 100 − (humidity at 8 A.M.) ; W = Mean wind velocity for the 24 hours in miles per hour ; t = Mean temperature in degrees F. for the 24 hours.

Rainfall : Quantities and Rates.

One inch of rain is equal to :—

2,323,200 cubic feet per square mile; 14,485,000 gallons per square mile;
3,630 cubic feet per acre; 22,633 gallons per acre.

One inch of rain per hour is at the rate of :—

645 cubic feet per second on a square mile, nearly 1 (1·01) cubic feet per second on an acre ;
241,419 gallons per minute on a square mile ;
377 gallons per minute on an acre.

Cubic feet per minute $= A_2 r \times 1613{\cdot}7$.

Flood Discharges.

For every area, however small or however large, there is some period of time at the end of which the effect of continuous rain reaches the maximum. What this period is depends upon all the circumstances, the size of the area in question, the nature of the rainfall, the physical character of the catchment, and the nature of the vegetation or of artificial works all affect the result.

The maximum rate of rainfall for the period in question is therefore a leading factor in the calculation of the flood discharge of the area. For some small areas the maximum discharge may be that which occurs when natural storage on the catchment has reached the maximum, and the rate of run-off is then equal to the rate of rainfall, or to some proportion of it, allowing for underground escape of a part of the water. In most cases, however, the maximum capacity of the catchment for surface water is reached only for short periods after the heaviest rushes of rain, and the amount of such storage affecting the result is the average over a relatively long period, and cannot be estimated with any degree of accuracy. A period longer than the critical period will give a lower rate of discharge because the rate of rainfall will be less, and a period shorter than the critical period will give a discharge lower than the maximum because the water from the more distant parts of the catchment will not have time to reach the outlet. If we knew the rate of flow over the ground and along the watercourses we could find the time required for water to arrive at the outlet from the part of the area most distant in time, in many cases the farthest point in distance. But we seldom know these average speeds, except sometimes in the case of a sewerage system. It is usually necessary to have recourse to empirical formulæ, or formulæ partly empirical and partly rational, and the engineer has to exercise judgment in choosing one coefficient affecting the whole quantity or several coefficients affecting different factors. In some large river basins the effects of short storms over several tributary valleys may, by the simultaneous arrival of the resulting floods, yield a larger discharge than that due to the lower rate of rainfall for the critical period corresponding to the whole area. In such cases the purely empirical formula may be better than the rational formula, because the engineer makes a note of every real coefficient established by experience, and all these coefficients are strictly comparable.

Further, in the case of a steep, rocky valley, the river of which drains flat uplands, or glens under dense jungle, the heavier rainfall for the shorter 'period of total contribution, for the main valley may give a larger flood discharge than the smaller rainfall for the longer period of total contribution for the whole catchment. Even in normal river basins, areas projecting beyond the average distance of the watershed of the distant parts of the catchment may be eliminated, the loss in area being more than made up for by the gain in rate of rainfall for the reduced period of total contribution (*Ryves*).

The following formulæ are used in calculating flood discharges of rivers and, in some cases are also employed for quite small catchments.

Ryves' formula—

$$Q = CM^{\frac{2}{3}}.$$

Q = discharge in cu. ft. per sec.; M = area in square miles, C is a coefficient usually ranging from 450 to 1,000, according to the nature and situation of the catchment; rainfall data are also taken into consideration, by comparisons with established results.

This formula is largely used in Southern India.

Dickens' formula—

$$Q = 825\ M^{\frac{3}{4}}.$$

This is the form in which the equation is usually presented, but it is doubtless advisable to vary the coefficient as in the case of the Ryves' formula.

The Dickens' formula is probably more particularly suited to the conditions of Bengal and other parts of Northern India, but both formulæ may be usefully employed in other countries.

The formula $Q = CM^{\frac{3}{4}}$ has been found to apply, for *ordinary floods* in the New England and Appalachian catchments, with a coefficient C = 130 to 200; in Eastern Middle State river basins, with a coefficient from 60 to 100; and for Western tributaries of the Mississippi, with coefficients from 12 to 50 (*Fanning*).

Chamier's formula—

$$Q = 640 \times R \times C \times \frac{M}{\overline{M}}.$$

R = average rate of greatest rainfall in inches per hour for such duration as will allow of the flood-water flowing to the outlet from the farthest extremity of the catchment. C = coefficient of surface discharge, giving the proportion of rainfall that may be expected to flow off the surface, M = area of catchment in square miles.

This formula seems to have given good results, and by comparing the calculated discharges for many catchments with those actually observed it should be possible to arrive at some idea of the figures for the rates of flow, from watershed to outlet, upon which the period of total contribution depends and from which, therefore, the rate of rainfall is derived. Since this factor cannot, in comparison of results, be disentangled from the factor C, it will take longer to extend the use of the formula than it does in those cases in which the exercise of judgment and the results of practice focus on to a single coefficient.

In order that the length of the catchment might be taken into consideration the following formula was proposed:

Burge's formula—

$$Q = C \cdot \frac{M}{(L)^{\frac{1}{2}}}.$$

Where L is the length of the main river or stream in miles; C is usually taken as 1,300.

A modification of this formula has been proposed, as follows (*Jackson*).

$$Q = C \times \frac{B}{L} 100\ M^{\frac{3}{4}}$$

Where L is the extreme length and B the extreme breadth of the catchment area.

It may be suggested that when it is possible to make a fair estimate of the period of total contribution, and, therefore, of the maximum rate of rainfall, such an estimate should form the basis of the calculation for maximum flood discharge, and when no such estimate can be made an empirical formula with a single coefficient should be used.

Storm-water Discharge of Sewers.

The same principles that govern the discharges of large river basins hold in the case of the storm-water discharge of sewers, but it is usually much easier to estimate the average rate of flow from the most distant parts of the catchment (measured in time) and, therefore, to estimate the period of total contribution, the rainfall for which can be found from local records.

The following are formulæ employed:

Bürkli-Ziegler's formula—

$$Q = R \times C \times \sqrt[4]{\frac{S}{A}}.$$

Q = discharge in cubic feet per second per acre.
R = average rainfall in cubic feet per second per acre 'during heaviest rainfall.'
C = 0·75 for paved streets; 0·31 for rural districts; average 0·625.
A = area of district drained in acres.
S = general fall of area per thousand.

It is clear that R will depend upon the period of total contribution which will have to be found in each case in order that the formula may be applied. The factor C would, as regards unpaved areas at any rate, also depend upon the period of total contribution.

Kuichling's formula—

$$Q = A \times a \times t \times (b - c \times t).$$

A = area drained, in acres; a, b, c, empirical constants which vary for different localities; t = time required for the concentration of storm water at the outlet.

This formula seems needlessly complicated since, if t be known the rainfall can be found and a single modifying coefficient could be applied to it, as well as one to be applied to the quantity as a whole, if considered necessary.

Lloyd-Davis' formula—

$$Q = \left(60{\cdot}5 \times \frac{60}{Tc} \times R\right) \times Ap.$$

Q = cubic feet per minute; Tc = time of concentration in minutes (time of flow through the ongest sewers); R = rainfall in inches during Tc; Ap = percentage of impermeable area in acres.

In some respects this is a good formula, but the permeable area would also affect the total in most cases. It would seem better to treat permeable and impermeable areas separately, and add the resulting discharges together to get the total discharge, but it would be difficult to do this except where the period of total contribution was the same for both parts of the area.

Having found the period of total contribution, the maximum rate of rainfall for that period must be found from local rainfall records. Thus, a curve drawn for records of heavy falls for a district in Southern India gave the following results (*Ryves*):—

Heaviest fall in 30 mins., 2·0 ins.; in 60 mins., 3·0 ins.; in 85 mins., 3·8 ins.; in 104 mins, 4·2 ins.; in 134 mins., 4·8 ins.; in 150 mins., 4·9 ins. Such curves are not necessarily drawn for the heaviest 'spot' falls, which are usually due to cyclones traversing a very narrow path. The maximum spot rainfall may be much greater than the maximum for the storm-water area of a large town. Even when the maximum rainfall does affect the whole area it is not always worth while to design the works for this fall. For instance, in some places cyclones are rare, and the maximum falls may greatly exceed the largest intervening falls, for periods of many years, being perhaps 4 or 5 times greater. The same principle may hold with respect to large areas, and the cost of works to deal with another fall such as that which occurred in East Anglia in August 1912 or with floods such as those experienced in Paris in 1913, may be so great that it is better to risk the chance of a similar visitation.

Heavy Single Falls of Rain over Considerable Areas in the British Isles.

London, whole area, 2·5 ins. in 24 hours.
Lake District, 714 sq. miles, 5·63 ins.
Eastern Ireland, 1,160 sq. miles, 4·76 ins. } single fall in less than 3 days.

Aug. 1912.

Before 1912 the maximum fall for 24 hours recorded in Norfolk was 4·48 ins.

Heavy Station Rainfalls in the British Isles.

Inches in 24 hours: Seathwaite, 8·03 and 7·00; Ben Nevis, 7·74 and 7·29; Rosthwaite, 6·94; Angerton Hall, 6·70. For shorter periods:—

Banstead, 3·59 ins. in about 90 mins.; Wallington, 2·77 ins. in 65 mins., and 3·50 ins. in 60 mins.; Wimbledon, 1·58 in. in 80 mins.; Croydon, 1·85 in. in 2 hours 48 mins., and 0·8 in. in 15 mins.; Ponders End, 1·05 in. in 19 mins.; Birmingham, 1·04 in. in 27 mins.; Burnham, 1·73 in. in 40 mins.; a fall of 1·2 in. in 15 mins. seems to be the quarter-hour record for the British Isles.

Heavy Station Rainfalls, Canada and United States.

Toronto 0·5 in. in 10 minutes; and 0·6 in. in 15 mins.; New York, 1·2 in. in 10 mins.; Philadelphia, 1·6 in. in 20 mins.; Chicago, 0·97 in. in 7 mins.

Heavy Station Rainfalls in or near the Tropics.

Central America, 0·6 in. in 10 mins. ; 1·1 in. in 30 mins. ; 1·7 in. in 60 mins. Panama Isthmus, 6 ins. in 95 mins. ; 4·9 ins. in 60 mins. ; 5·86 ins. in 60 mins. Philippines, 27 ins. in 24 hours, also (1913) 48 ins. in 48 hours, and 24 ins. in 8 hours (same storm). Manila, 17 ins. in 15 hours. Near Johannesburg, 3·2 ins. in 15 mins. Near Durban, 15·6 ins. in 15 hours ; 17·6 ins. in 24 hours ; 6 ins. in 3 hours. Mauritius, 18 ins. in 24 hours, and the mean of 15 stations 9·86 ins. in 24 hours ; 99 ins. in 6 days ; 24 ins. in 24 hours. Ceylon, 21 ins. in 24 hours ; 8 ins. in 4 hours.

Heavy Station Rainfalls in India.

Madras, 4·95 ins. in 3 hours ; 2 ins. in 18 minutes ; 3 ins. in 60 minutes, 10, 11, 12, 13, 18, and 20 ins. in 24 hours. Madras Presidency (South Arcot), 7, 8, 9, and up to 11·3 ins. in 24 hours. Central Provinces (Talgaon), 7·75 ins. in 6 hours. West Coast, Bombay Presidency, 8 ins. in 2 hours. Bombay Town, 7 to 9 ins. in 24 hours. Sholapur, 10 ins. in 7 hours.

Forests and Rainfall.

In a considerable number of cases it has been shown that the removal of forests has been followed by a diminution in the rainfall, and in other cases the rainfall has increased with the extension and growth of the forests. The extent of the difference probably depends upon whether the coolness of the forest area just turns the scale in favour of rain at critical times, the resulting increased coolness and dampness causing further falls of rain ; or whether, on the other hand, the forests merely present the best conditions in areas where the conditions generally are favourable to steady rainfall at frequent intervals. A point which is often overlooked is the effect of trees in increasing the total precipitation considerably beyond that recorded by rain gauges. A large proportion of the rime which collects on the twigs of trees in frosts afterwards reaches the ground as water, and, in climates such as those of the British Isles, the total amount of water deposited on the twigs from fogs and drifting clouds is considerable, and most of it reaches the streams or underground storage, or at least replaces losses from subsequent rainfall.

Of more importance, however, to hydraulic engineers is the effect of woodlands in modifying the run-off. The rush of water from bare hillsides is exchanged for the slower delivery from the matted carpet of the woodland, losses by evaporation may be much diminished and the melting of snow usefully retarded. In catchments from which flood waters are largely lost, woodlands may increase the available run-off by extending the period of surface flow. The maximum floods of rivers are reduced, and the lowest summer flow increased. Woodlands are usually much more effective than minor vegetation, such as gorse and heather, in preventing the soil from being carried from the land into an open reservoir.

To protect a reservoir from silting, it may be unnecessary to plant large areas, the silt being arrested by suitable planting of narrow belts of woodland, or by the protection of natural growth, along the margins of the streams.

Some engineers consider that in the case of small reservoirs the shelter afforded by a belt of trees along the margins is of value in reducing the amount of scour of the banks caused by wave action. Afforestation over considerable areas in large river basins would, in many cases, reduce the amount of silting in navigable rivers and estuaries.

A matter which does not receive sufficient attention in connection with hydraulic engineering is the effect of judicious planting or woodland conservation over small areas. A narrow belt of woodland along the foot of a slope will arrest the soil brought down by rains from the hillside. The encouragement of dense vegetation along the bottom of a narrow valley or glen may check the rate of flood discharge to a useful extent. The planting of suitable trees along ridges, and for a little way down the slope facing the rain bearing and damp winds, will produce the maximum of certain desired effects, in proportion to the area occupied. Suitable tree and bush growths in swampy areas and around their margins will increase their effect in checking flood discharge, and may prevent these areas from contributing large quantities of silt to the streams during very heavy rains. Areas of soft, cultivable soil liable to denudation may similarly be protected. Generally, a country which is, in the ordinary English sense of the words, ' well-timbered ' is, from the point of view of the hydraulic engineer, a favourable country ; and in the development of new lands the future effects of a proposed agricultural policy should be considered from this point of view, and in consultation with hydraulic engineers.

Rain Gauges.

The smallest diameter for a serviceable rain gauge is 5 ins., and is the size generally used. Trials with gauges of various diameter ranging from 1 in. to 2 ft. have shown that if they are set perfectly level, and observed with great care, exactly the same rainfall has been registered by all of them.

The standard height above ground for rain gauges is 1 ft.

The higher a gauge is fixed above the ground the smaller is the quantity of rain caught

owing to the eddies carried by the wind about any prominent upstanding object. The curve diagram (fig. 1), given in Beardmore's Hydrology, gives the divisor to be used for increasing the

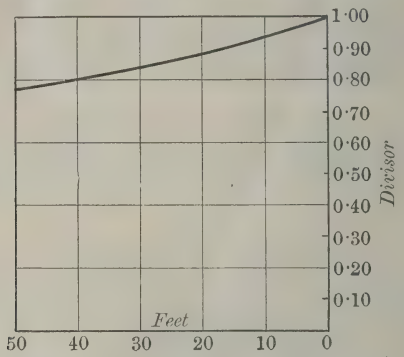

FIG. 1.

quantity of rain observed at any given height above ground level, so as to make the observation equal to that at ground level.

It is more important to have rain gauges placed at a uniform height above the ground than to have them of uniform diameter.

WELLS.

(Contributed by W. H. Booth, F.G.S., M.Am.Soc.C.E.)

The back of the steining should be puddled to a depth of 12 or 15 feet, so as to make the water pass through a considerable amount of soil before entering the well.

The ground around should be puddled, sloped away from the well, and paved, and the lining carried up about 2 feet above the ground level, to keep all dirty water out of the well. The mouth should be covered over, and the water drawn by a pump rather than a bucket.

Form of Wells.—Generally circular, but when there is no steining or a large water-yielding surface is required, as in headings driven from the shaft, a rectangular, elliptical, or other form may be used. Ordinary wells have a clear diameter of from 4 to 5 feet, but when very deep may require to be made large enough at the top to allow of reductions as the depth increases, still leaving room enough below for any pumping machinery.

Temperature in deep wells increases about 1° F. for every 55 feet in depth below 60 feet, at which depth it is pretty uniform at 50°.

Tubing for bore-holes is sometimes of cast iron, the lengths being held together by wrought-iron collars fitting over the ends and flush with the outside of the tubes.

The approximate average cost (pre-war prices) in England may be taken at 1*s.* 3*d.* per foot for the first 30 feet, 2*s.* 6*d.* per foot for the second 30 feet, and so on, advancing 1*s.* 3*d.* per foot for every additional 30 feet in depth. This does not include cost of tubing, conveyance of plant and tools, or working in rock of unusual hardness. (See also Artesian Wells, page 1288).

STEINING.

This is lining the well, chiefly to keep the sides from falling in. Where bricks are not available stone may be used, and even timber, but the latter soon decays. Iron cylinders are also employed.

Brick Steining.—The bricks should be hard, well burnt, and well shaped. Malm paviors are very good; if stocks are used, they should be very carefully picked. The bricks are either laid dry, called 'dry steining,' or in cement, or good hydraulic mortar, where strength is required or to keep out water.

In cement work cast-iron curbs are sometimes built in at suitable intervals, to facilitate the execution of the well, and also to strengthen the work.

In dry steining one or two courses set in cement are introduced for strength at intervals varying mostly from 5 to 12 feet.

The bricks are laid flat, breaking joint. The thickness of the steining varies with the depth and diameter of the well and the firmness of the ground; from 9 inches for diameters up to 9 feet, to 14 inches for diameters up to 14 feet, with an extra half-brick in very bad or loose soils. The best method of laying them is in half-brick rings, with headers at intervals, tying them together. Courses of headers are objectionable, unless the diameter of the well is large.

To exclude land or other springs not under very great pressure, concrete or clay puddle is introduced behind the steining; clay puddle is the more certain to be watertight. When the bricks are laid dry, the swelling of the earth behind will gradually fill up the spaces between them. It is very essential that the steining should be well backed up by working as close as possible to the sides of the excavation; and wherever, from any irregularity in the excavation, this is not convenient, the space should be well filled in either with puddle or brickwork; the latter is preferable, especially where a slip of earth has taken place, in which case the brickwork should be laid in cement. The principal object is to prevent the steining failing by being forced in at one part and out at the other by the pressure of the ground.

The ground round a well should be waterproofed for 30-feet radius of a circle about the well. This ensures that no water can even reach the back of the steining, which has not passed through a considerable bulk of earth.

Well-Sinking.

There are two methods of sinking and steining wells, the first adapted to dry or firm, and the second to wet or loose, ground.

First Method.—The excavation being sunk to a safe depth, a curb or ring of timber is placed at the bottom, formed in 2 or more thicknesses and lap-jointed to equalise its strength, cut circular on the inside but not on the out, of a breadth sufficient to receive the brick-lining of the well, and not less than 3 inches thick. On this, truly concentric with a central plumb-line, the brick lining is built up to the surface, the earth or a puddling of clay being punned in hard round the outside as the work rises. The excavation is now resumed in the centre, leaving enough earth undisturbed under the curb to support the work done. When a safe depth is again attained, the earth under the curb also is often removed in four equidistant places, the duty of support devolving temporarily on the intermediate portions left as piers; and from a broad central footing of timber 4 raking struts are set up and firmly fixed, to support the curb in the points from under which the earth was taken. This being done, the piers of earth are dug away, and the bottom is then, as before, made level around as a bed for a second curb; and thus the work proceeds in stages down to the required depth, the projecting angles of the curbs outside, by their penetrating the soil, contributing to the support of the brickwork in its progressive extension downwards. Sometimes the curbs, instead of being propped from below, are suspended by cross-timbers from the mouth of the well by iron rods.

Second or Older Method.—The surface of the ground having been levelled, or an excavation made to a safe depth, an iron curb with a sharp lower edge, or a wood curb shod with iron, with an outer diameter equal to that of the brickwork cylinder, is laid on the surface or in the excavation, and as the brick steining is built upon it, it sinks by its own gravity, the bricklayer continuing building up at the surface, while the digger inside descends, the soil being hoisted out as fast as excavated. When from the swelling of the ground the descending work becomes earth-bound, the process has to be recommenced at its base to a smaller diameter.

Iron Cylinders are sunk as just described for brick cylinders. They are mostly inserted in order to continue the well when the brick steining has been interfered with by running sands of the irruption of water. Until the water-yielding stratum has been passed through, the sinking of the cylinders is carried on with the assistance of the ordinary boring tools. The cylinders are generally of cast iron, made up of 5 or 6 feet lengths, bolted together by means of internal flanges, leaving the exterior surface perfectly smooth. The bottom length has, instead of a lower flange, a cutting edge to facilitate the descent. The joints are made watertight, either with gasket soaked in tallow or by being caulked with iron cement. Wrought-iron cylinders used for steining are jointed with angle and T iron by rivets countersunk on the outside, so as to leave a smooth surface. When the cylinders become earth-bound they are loaded, or else pressed down by jacks, or rammed down by wooden 'dollies.'

To increase the Yield from a Well already Executed.

1. The water-level in the well may be lowered by pumping, etc., by which the hydraulic depth for the inflow is increased.

2. The bore-hole may be deepened, thus probably leading to denser strata, through which there would be less percolation, and thus more yield to the well.

3. Headings may be driven laterally from the well; the best level for them is just above the lowest level to which the water is ordinarily pumped; in plan they should be straight lines through the well.

4. Dynamite or other explosive is lowered down to the bottom of the bore-hole, and then exploded by electricity.

Quantity of Water in Wells.

To ascertain the quantity of water in a well, take half the circumference (in the clear) and multiply by half the diameter; multiply the result by the depth, which gives the cubic measures, then reckon 6 gallons and 1 pint to the foot cube.

Protective Distance from Drains.

A well should not be closer to a drain than 4 feet for every foot in depth; thus a 20-foot well should be at least 80 ft. from any possible source of corruption. Wells 100 ft. deep if with water-tight sides, may be relied upon as safe from leakage contamination, as this depth of soil is capable of removing a greater amount of organic matter that may exist in the water.

Prof. Frankland gives 200 yards from a cesspool, cemeteries, etc., as the nearest safe distance; in Italy, 100 yards; in France and Austria, 200 yards. But much will depend on the dip and nature of the strata.

Artesian Wells.

In the best modern practice, artesian wells are lined with stout steel-socketed wrought-iron or steel pipes, to a point at least lower than the lowest water level. In chalk bores the pipes are lightly driven at least 10 feet into the chalk—or further, if necessary—the projection of the sockets being very effectual in securing the shutting off of the upper, and perhaps undesirable, waters from the lower.

No pipe should be less than ¼ inch thick, from 3 to 6 inches diameter, up to ⅜ inch thick for pipes of 10 to 16 inches.

When the water level is considerably below surface, the yield of a well is measured by the capacity of the largest pump that can be put down the bore tube. Deep-bore pumps consist simply of a plain barrel hung in the water by a wrought-iron rising main pipe of slightly greater diameter. The bucket is hung by rods inside the rising main, and these project through a stuffing-box in an outlet casting on the top of the main, and are actuated by a crank or other means to give a stroke of 18 to 24 inches in ordinary cases. A plunger is added in the outlet casting for forcing to considerable heights above surface, and a balance lever should be connected to the cross-head by links.

The best water-bearing strata in England is the Lincolnshire (Oolitic) limestone, which contains many spouting copious wells; notably one at Sleaford, only 6 inches diameter, which overflows at 30,000 gallons per hour 3 feet above surface. The chalk is very free bearing in many parts, but capricious and occasionally nearly dry. The Keuper marl yields good brewing water at Newark, Burton, Leicester, etc., but not very copiously, and apt to be very small in amount and capricious in character. The Keuper sandstone is a free yielding stratum, and gives good soft water. The Permian sandstone is also a fair and at times a copious water-bearing rock, and so also is the magnesian limestone.

The Lower Greensand sometimes yields copiously, and, as a rule, the more copious the supply, the better the quality. It is at times ferruginous. The Lias clay is apt to produce saline water; so also is the London clay. The Upper Tertiary beds of the London basin below the London clay often yield fair but slightly alkaline supplies.

The carboniferous rocks vary greatly, and often give copious supplies, and but few rocks are quite dry. As a rule, the more copious yields are all within 200 feet of the surface. Deeper boxes yield less and less. Water has been obtained from the Lower Greensand in Windsor Forest at 1,243 feet below surface, the quantity being small, the quality good, and the water rising to about 230 feet above sea level, or overflowing the surface nearly 8 feet.

For borings in rock having a surface outcrop near the site of the boring, the water level will usually be little or nothing above the nearest watercourse crossing such outcrop, but where borings penetrate an impermeable surface, and reach a rock having a distant outcrop the water level will be determined by such outcrop, and, though lower than the receiving surface, will be higher than a distant draining point, if any.

It is by no means unusual for well borers to pass through water and declare it to be absent. They will also continue boring into strata that are hopeless as water-bearing strata under the impression that they have not yet passed through the upper stratum. Thus in places the Gault way rests upon the Kimmeridge clay, and it is difficult to distinguish one clay from the other. Well boring should only be carried out under educated inspection, and regular samples of everything passed through should be kept, and records of the water level every morning and of any change during the day. Small changes in the material and variations of the water level are often very instructive and significant to the hydrogeologist.

Wells in the lower chalk formation are frequently failures owing to failure of the workmen to recognise the evidences about them.

While there can be no good done by carrying wells to excessive depths, it is a common experience to find wells that have been sunk only to their high-water mark horizon, so that when the water level sinks the well is dry. This is a frequent occurrence in the lower chalk, in which there is a very wide difference between the highest and the lowest water levels. Wells sunk in high-water periods invariably run dry when the lower-water period approaches.

For the varying strata of the British Isles, and the usually small depths required, the ordinary system of boring with chisels and rods appears to be as cheap as any other. For depths beyond 500 feet the rope is often used. No one system can be adhered to, but rods, ropes, and the diamond must be employed, according to the requirements of each case.

More recent practice is to bore by means of the rotary chilled steel shot system. A plain thick steel pipe is notched at its lower end and rotated upon the rock to be pierced. A quantity of chilled steel shot is fed down the pipe. This gets under the lower end of the pipe by way of the notches, and, rolling on the rock under heavy pressure, comminutes by the intensity of the rolling crushing action. Water forced down removes the groundaway rock, and good cores are obtained. Several feet per day may be bored in hard limestone. The method involves no loss of costly diamonds.

To calculate the rate of flow of an artesian well, a simple plan is to lower a bottle of aniline fluid to a depth of, say, 500 feet, and then electrically explode a cap to burst the bottle. The time required for the fluid to appear at the surface gives an accurate gauge as to the velocity of flow. It is claimed that this method gives results as accurate as a weir. The diameter of the pipe being known, the rate of flow readily follows. (*W. H. Booth.*)

WATERWORKS.

(Revised by R. Fairfax Middleton, Assoc.M.Inst.C.E.)

MASONRY DAMS.

Rankine gives for low masonry walls to retain water that the thickness at the base should be about $\frac{6}{10}$ of the height either for rectangular walls or for those of trapezoidal form where the thickness at the top is $\frac{1}{3}$ that at the base.

Another rule for low dam walls is: Thickness at bottom 0·7 height; thickness at middle 0·5 height; thickness at top 0·3 height.

For high masonry dams Molesworth gives H = height of dam in ft.; x = any depth below

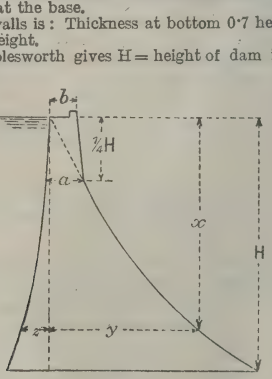

FIG. 1.

the water surface in ft.; y = offset from vertical line to outer face of dam at any depth x; z = ditto ditto to inner face; b = width of dam at top in ft.; a = width of dam at 1/4H from top in ft.; P = limit of pressure on masonry in tons per sq. ft.

$$b = 0{\cdot}4a; \quad y = \sqrt{\frac{{\cdot}05\,x^2}{\mathrm{P} + {\cdot}03\,x}}; \quad z = \left(\frac{{\cdot}09\,x}{\mathrm{P}}\right)^4;$$

y at any section must not be less than 0·6 x.

In modern practice a common typical section is triangular, the inner face being given a slight batter, and the back a batter which will generally approximate to 1 in 1½ but depends upon the weight of the masonry and the exact form of the wall.

The dam must be so proportioned that the resultant thrust acts within the middle third of the base, both with the reservoir full and empty; this provision should also apply to any horizontal section of the dam. The theoretical apex of the triangle must be high enough to allow, if necessary, for the water overtopping the wall, also for wave action.

EARTH DAMS.

The top width may be anything from 6 ft. to 20 ft., depending on the height of the dam and the freeboard.

The inner slope will generally be about 3 to 1 for gravel or other good material, but with clays it may not stand at this and must then be made flatter.

The outer slopes may be as steep as 2 to 1 depending on the angle at which the material will stand; the outer slope should be well drained. The inner slope must be protected from wave action; this is generally done by laying stone pitching or concrete slabs on the surface of the bank.

Water tightness is generally obtained by means of a core of puddled clay in the centre of the bank, the puddle being carried right down through the solid ground below the bank and well bonded into the impervious material on which the reservoir is built.

The puddle wall should generally be about 4 ft. thick at the top and both sides batter outwards about 1 in 40 to ground level, below which the thickness of the puddle should be quickly reduced to about 6 ft. and carried down at this as far as necessary. This applies to good puddle; the thickness must be increased if the puddle is of poor quality.

The puddle is sometimes replaced by a concrete wall; care must, however, be taken to avoid the possibility of unequal strains upon such a wall, as these might lead to cracking and possible failure.

CALLENDER'S SHEETING.

TRADE
'CALLENDRITE'
MARK

For the PERFECT WATERPROOFING of

RESERVOIRS, PONDS, CONDUITS, SWIMMING BATHS, TANKS, AQUEDUCTS, BRIDGES, EJECTOR CHAMBERS, ROOFS, BASEMENTS,
Etc., etc.

'CALLENDRITE' is the ORIGINAL PURE BITUMEN SHEETING invented by CALLENDER'S over 40 years ago, and is guaranteed to be manufactured from the finest Bitumen obtainable for the purpose, properly refined and tempered under **CALLENDER'S ORIGINAL PROCESS.**

25 Victoria St., Westminster, London.

Send for Illustrated Catalogue showing some of the Important Works carried out with 'CALLENDRITE' and the methods adopted.

F. 1291

Another method is to fill the trench in the solid ground with concrete and to build on this a wall of puddle. In this case the puddle must be well tongued into the concrete so as to ensure a watertight joint.

Lining Distribution or Service Reservoirs.

In small reservoirs watertightness may be obtained by covering the whole of the bottom and sides of the reservoir with a layer of puddle. The puddle in this case should be covered with concrete to protect it from damage. In reservoirs of any size, however, the cost of the method would be prohibitive.

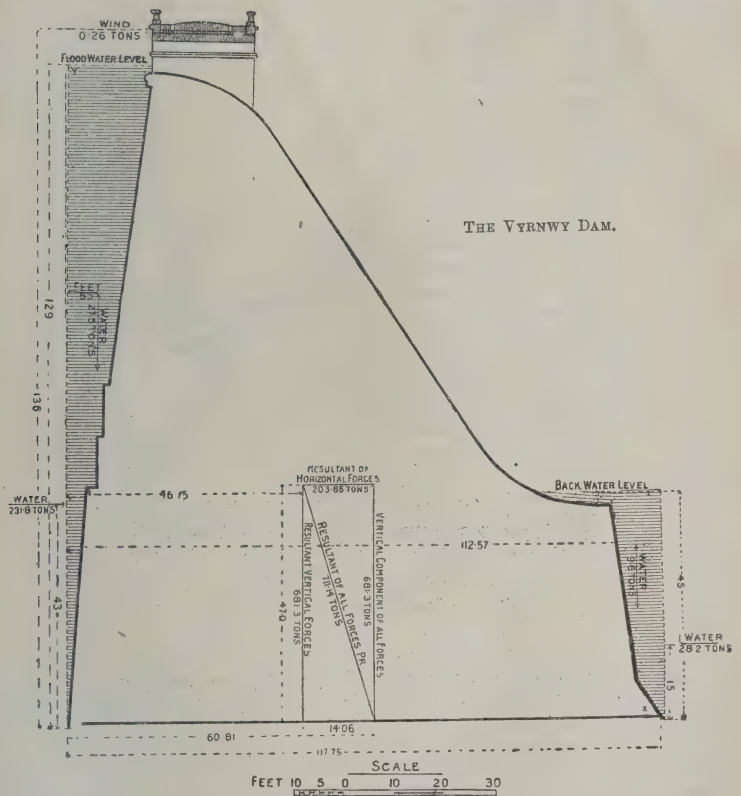

FIG. 2.—Cross-section of Vyrnwy Dam.

CALLENDRITE.

Callender's 'Callendrite' (*Geo. M. Callender & Co. Ltd.*, 25 *Victoria Street, Westminster, S.W.* 1) is the original bitumen damp course (for damp-proofing buildings) and sheeting, for effectively waterproofing old and new reservoirs, tanks, swimming baths, basements, flat roofs, etc., as invented by Callender's over forty years ago. It is used by the Admiralty, the War Office, the Office of Works, the London County Council, and other bodies.

The sheeting—for all engineering work—is made in standard rolls, 24 ft. long, 6 ft. wide.

Damp course in rolls 24 ft. long, to all the usual wall widths. When necessary, Callender's Patent Impervious Wall Ties and Patent Joining Irons should be employed. Price of Callendrite (including free delivery for fair order) averages 4*d.* per foot super for damp course and 6*d.* per foot super for sheeting. Inclusive price given, with guarantee of efficiency, for laying and fixing sheeting by Messrs. Callender's own workmen.

THE CROTON DAM.

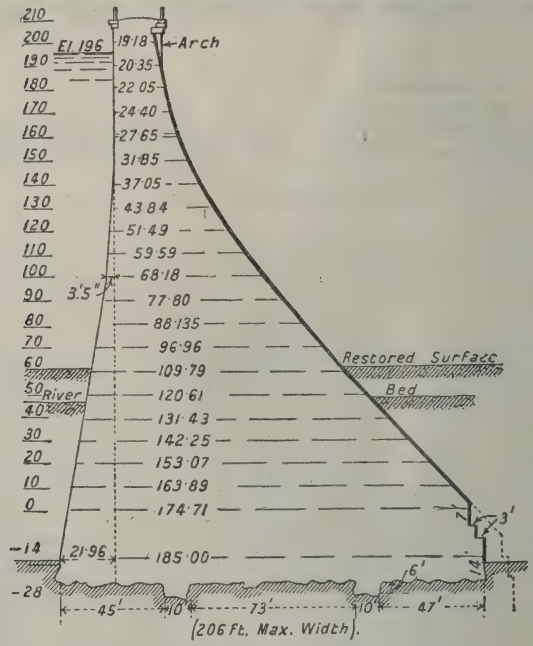

FIG. 3.—Cross-section of Croton Dam.

THE VYRNWY DAM.

The Vyrnwy Dam (fig. 2) is 1,350 feet long on the top, the plan being straight. The maximum height above the foundation is 136 feet. The profile adopted is designed to resist the water pressure and also to form a waste-weir; the front face of the wall is, therefore, made to conform to the curve described by water in overflowing, and to deflect it into the basin in front of the dam. The foundation is laid on a clay slate rock. The dam is built of 'Cyclopean rubble,' the stones varying in weight from 2 to 8 tons. For the lower part of the dam the stones are set in mortar composed of 2 parts washed sand, 1 part Portland cement; in the main portion of the work, instead of plain sand, a mixture of 1 part of the latter with 2 parts pulverised quarry rock was used for making the mortar, 2½ parts of the mixture being mixed with 1 part Portland cement. The area of the section, shown by fig. 2, is 8,972 square feet. With the reservoir full and the wind blowing with a force of 60 lbs. per square foot, the maximum stress on the masonry is 6·36 tons per square foot. Where the bed rock has the lowest elevation there are 26 drains in a length of 198 feet of the wall; these drains are 9 to 12 inches square, and lie on the rock near such places where leakage is apt to occur; they are 25 feet from the front face and 30 feet from the back face, and connect with a central tunnel 4 feet high by 2½ feet wide, which traverses the foundation longitudinally at an elevation of 46·3 feet above the base of the cross-section. By means of a cross-tunnel leading down-stream any water that may filter into the foundation above the elevation of the drains is discharged at the front face of the dam.

The Assuan Dam.

The Assuan Dam (fig. 5, p. 1293) is a granite rubble masonry structure founded on a similar rock which is traversed by dykes of softer igneous material. It is situated at the head of the first cataract of the Nile.

As originally constructed it was just under two kilometres in length, the top level of the structure was RL. 110·00, the water being held up to a level of 106·00.

It is pierced for the greater part of its length by sluices which are closed by steel gates, most of them working on the Stoney principle. There are 180 sluices in all, of which 22 are at a level of 100·00 and 18 at 96·00; these sluices are 3½ metres high by 2 metres wide. Of the others, which are 7 metres high by 2 metres wide, 75 are at RL. 92·00 and 65 at RL. 87·50; 30 of the lowest sluices are lined with cast iron, the rest being smooth-faced granite ashlar.

The original dam was finished in the summer of 1902.

It was found that the rush of water through the sluices was such as to erode what had appeared to be solid rock, and it was therefore necessary to build masonry aprons along practically the whole length of the pierced dam.

Between 1907 and 1912 the dam was raised so as to impound water to a level of 113·00 metres, and it was at the same time thickened by a blanket wall five metres thick on the downstream side.

The original reservoir impounded 980,000,000 cubic metres of water, or 216,000,000,000 gallons.

The heightened reservoir contains 2,420,000,000 cubic metres, or 533,370,000,000 gallons.

The reservoir is used for irrigation purposes.

GENERAL ARRANGEMENT OF RESERVOIRS.

Overflow.

In reservoirs filled by gravity a waste weir must be provided to carry off flood water, and should be so designed that the maximum flood will not cause the water to rise more than 18 inches over the lip of the weir.

The waste weir channel should be built in solid ground: it is generally constructed in a flight

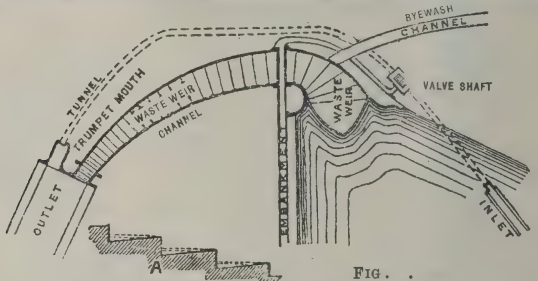

FIG. .

of steps, so as to check the velocity of descent; the risers vary from 1 ft., which is best, to about 5 ft., and the tread should, if possible, be at least double the riser. The best form is a series of weirs and pools, or tumbling bays, or flights of steps with long landings or pools at intervals, the drop into pool being as small as possible. The pools may be formed as shown at A (fig. 6): depth of pool = drop, length of pool = drop × 10.

Fig. 6 shows a tunnel round the flank, also the valve shaft, byewash, and other accessories.

The tunnel and byewash are used for passing storm waters during construction, the former being used afterwards for supply purposes and the latter for passing turbid water in times of storm.

Storage Reservoirs.

The capacity of storage reservoirs is arrived at from the formula

$$C = \frac{500}{\sqrt[3]{R}},$$

where,

C = number of days' storage, = R available rain in inches, as explained under heading 'Gathering Grounds.'

Messrs. W. J. E. Binnie and H. Lapworth have lately suggested the following formula for calculating storage:—

$$s = 15\frac{(n-d)^2}{r^{1\cdot85}},$$

where,

s = inches of storage required to supply (constantly from a stream) n inches per annum; d = the extreme minimum dry-weather flow reduced to inches per annum; r = mean run-off, also in inches per annum.

The storage required in gallons is equal to $s \times$ area of gathering-ground in acres $\times$ 22,610.

The formula is empirical, and was arrived at by a study of the data of seven areas of supply.

GATHERING GROUNDS.

In arriving at the water available from an area the average rainfall on the area must be found from rainfall records; ¼ of this is then generally taken as the average for the three driest consecutive years and then a deduction must be made for evaporation, generally 14 to 16 inches; the remainder, subject to special conditions, will be the available rain; ⅓ of this often has to be given in compensation.

The above applies to ordinary cases in the United Kingdom. For a study of run-off under various climatic conditions, see 'Rainfall' (p. 1279).

On the moorland gathering-grounds supplying Sheffield, rainfall averages 40 ins. a year, two-thirds of which is reckoned on as available; one-third goes as compensation to millowners, etc., and one-third to inhabitants. Every 1,000 acres is said to give an average of 1,250,000 gallons per diem. On the Leeds moorland gathering-grounds ½ cubic feet per second, or 134,600 gallons per diem per 1,000 acres, is the usual minimum dry-weather discharge; the formation is millstone grit, rainfall 26 ins. to 45 ins., of which 14 ins. is allowed for evaporation and 6 ins. as compensation to millowners.

FILTRATION.

(Contributed by H. F. Rutter, M.Inst.C.E.)

Filtration should be preceded by sedimentation. The researches of Dr. A. C. Houston prove that prolonged storage not merely reduces enormously the ordinary and harmless bacterial contents of river waters, but that such storage is a complete protection against danger from pathogenic microbes in the case of water initially infected with such germs.

The area of sand surface needed per million gallons per diem varies considerably, according to the character of the water and the fineness of the filtering medium. Yields of from one million to two million gallons per acre are common values. Modern filters have four feet of water over the sand, two feet nine inches of sand supported by eight inches of graduated shingle. Care should be taken that the uppermost layer of shingle should consist of stones less than half the size of a pea, so as to avoid the danger of the sand being drawn through the shingle. The means of collecting the water should cover the whole floor of the filter and should not consist of transverse pipes placed at intervals. A satisfactory and inexpensive method is to cover the floor with transverse rows of bricks laid dry end to end with a space of 4½ inches between each two rows. These are then completely covered with bricks laid dry at right angles to the rows. A series of 4½ in. by 3 in. channels are thus formed, which lead the filtrate to the central channel made below the floor.

A Deacon meter on the outlet pipe forms a useful means of checking and recording the rate of flow of the filter. Float gauges should be provided to show the relative levels of the water over the sand and in the outlet pipe. The difference between these levels indicates the head under which the filter is working. This head may vary from one inch when the filter is started slowly after cleaning, up to 2 or 3 feet.

Means should be provided for drawing the raw water from above the sand to waste, in case it be required to clean a filter immediately which has become clogged. A quarter to half an inch of sand with the matter arrested thereon is removed by flat shovels. This sand can be washed and spread again either at once, or after the depth of the sand has been reduced by five or six successive cleanings. The cleanings may be at intervals of from one week to four months, according to the character of the water, and the amount of algal growth in the water, which latter condition may materially affect the life of the filter. The removal and cleaning of the main body of the sand is needed at very rare intervals. Filters are in use yielding water of perfectly satisfactory bacteriological character in which the main body of sand has not been changed for forty years.

When a filter is to be cleaned the water should not be drawn down in the sand to a level more than 12 inches below the surface of the sand. This leaves the surface quite hard enough to support the weight of the cleaners, and prevents the sand becoming unduly compacted.

All sensible suspended matter is arrested on the surface of the sand of a filter, and the largest elimination of bacterial life takes place at or near the surface. The bacterial contents are, however, still further reduced progressively in the passage of the water through from five to ten inches of the depth of the sand.

THE 'TORRENT' FILTER.

(The Pulsometer Engineering Co., Ltd., Reading).

In this filter (fig. 7) the filtration is effected by passing the water through a certain thickness of suitable filtering medium, arrangements being made so that the entire filtering medium can be thoroughly cleaned.

The construction is very substantial, all parts are accessible, and the various valves for operating and cleaning the filter are brought together at one place for convenient handling. There are no mechanically moved parts either inside or outside the filter, so that there are no parts to wear or keep in adjustment.

The filter is made either cylindrical or square (the latter when it is necessary to economise space or when the filter has to be brought in parts into an existing building through ordinary doors). A strainer plate is fixed near the bottom of the filter casing, and this plate carries a

layer of filtering medium. The unfiltered water admitted to the upper part of the filter percolates through the filtering medium, where the matter in suspension is retained, and reaches the space below the strainer plate in a clear and bright condition. The bottom of the filter casing is connected to the filtered water main.

The cleaning of the filter is effected by means of air agitation and a reverse flow of filtered water. If there is sufficient pressure in the fitered water main, say equal to 10 to 15 ft. head, a reverse flow from the filtered water main can be used; but if there is not sufficient head in this main, or if the filtered water reservoir is below the level of the filter, it is necessary to employ a centrifugal pump to force the washing water through the filter.

The air agitation (by compressed air) is effected by means of a separate system of air nozzles in the strainer plate, through which the air is equally distributed over the whole area of the

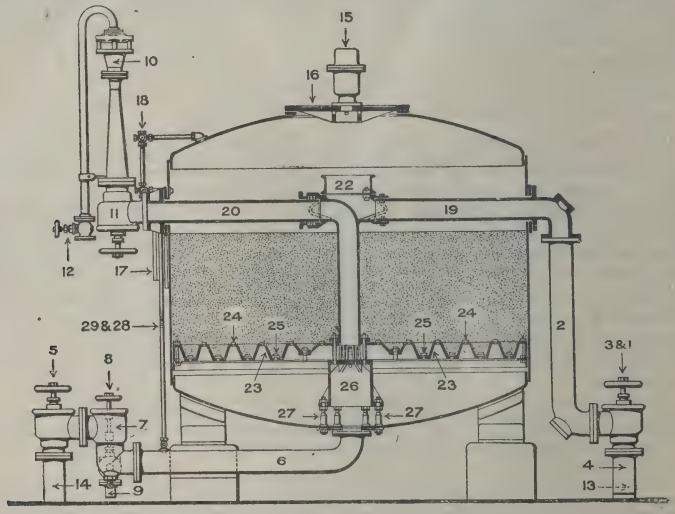

FIG. 7.

LIST OF COMPONENT PARTS.

1. Unfiltered water inlet valve.
2. Unfiltered water inlet wash-out bend.
3. Wash-out valve.
4. Wash-out pipe.
5. Filtered water outlet and wash water inlet valve.
6. Filtered water and wash water bend.
7. Patent wash water regulating valve.
8. Drain valve.
9. Drain pipe.
10. Air blower.
11. Blower valve.
12. Steam stop valve to air blower.
13. Unfiltered water pipe.
14. Filtered water pipe.
15. Automatic air escape valve.
16. Manhole cover.
17. Differential mercury gauge.
18. Water gauge glass.
19. Internal inlet and wash-out pipe.
20. Internal air pipe to strainer plate.
22. Internal wash-out and inlet bell mouth.
23. Strainer plate.
24. Air nozzles.
25. Strainers.
26. Stool for strainer plate.
27. Studs for strainer plate stool.
28. Pressure pipe from underside of filter medium.
29. Pressure pipe from above filter medium.

filter bed. The air nozzles being entirely separate from the strainers makes it possible to use the air simultaneously with the reverse flow of water during the process of cleaning, if found desirable. The air main is carried above the filter, so that there is no risk of its becoming waterlogged, which might cause obstruction to the passage of the air.

A steam blower may be used for supplying the compressed air, but if steam is not available, a small air compressor, with or without an air receiver, can be employed.

The air causes a violent ebullition in the filter and has the effect of raising the filtering

medium, so that the various particles are free to move, and in knocking against one another dislodge all the matter which adheres to their surfaces. Whilst the air agitation is going on an upward flow of water carries away, through the wash-out pipe, the impurities which have been dislodged by the action of the air.

The system of cleaning effects a considerable saving in the amount of wash-water used as compared with that necessary when water only, or water and mechanical agitators, are used.

The time taken to clean the filter may be from 10 to 20 mins.—depending on the nature of the water and the time the filter has been at work since the last cleaning.

A differential gauge is fitted to show the head lost in the filter. This gauge gives an indication of when the filter requires cleaning, because the difference in pressure between the top and bottom of the filter increases as the impurities accumulate on the filtering medium.

MAINTENANCE AND RENEWAL OF WATERWORKS.

In the Metropolitan area, 'pumping' constitutes, on an average, 43 per cent. of the entire maintenance expenditure. During the last thirty years 4,408,846*l.* has been expended out of revenue on pumping operations and on the maintenance and renewals of the pumping-engines and machinery, which during that period have supplied the Metropolis with 1,745,718 million gallons of water for all purposes; thus the cost of pumping alone has been, on the average, 2*l.* 10*s.* 7½*d.* per million gallons, or ·000606*d.* per gallon.

The cost of repairs and renewals of water-mains and pipes amounted to 2,964,127*l.*, or an average of 1*l.* 14*s.* per million gallons.

The average maintenance cost per mile of water-main or pipe-way (adopting the analogy of a railway as a means of conveyance) has been 24*l.* 5*s.* 5*d.*

The cost per million gallons for filtration is 0·37*l.* (*Price-Williams.*)

Standard of Purity of Water.

Total hardness in practice varies from 0 to 30 degrees; 5 degrees is generally considered best.

Water containing more than the following quantities of impurities should be looked upon with suspicion: Chlorine, 1 part per 100,000; Nitrites, 0·2 part per 100,000; Nitrates, 0·3 part per 100,000; Ammonia, 0·1 part per 100,000; Organic Carbon, 2 parts per 100,000; Organic Nitrogen, 3 parts per 100,000; Albumenoid Ammonia, 0·01 part per 100,000.

WATER TESTING.

Simple and ready tests for rough analysis.

For *Sewage.*—Four drops of a solution of potash (Condy's Fluid) to a small glass of water. The colour turns pale or yellow if decomposed organic matter is present.

Lead.—Six drops of sulphuric acid in small glass of water. White precipitate will be found if lead is present.

Zinc.—Six drops of ferro-cyanide of potassium to small glass of water. Green colour if zinc is present.

Copper.—Eight drops of ammonia in small glass of water. Water turns blue if copper is present.

CHEMICAL PURIFICATION OF WATER.

Water is sometimes purified by chemical means: there are several methods, of which the most important are (1) by the addition of chloride of lime and (2) by submitting the water to the action of ozone.

By these methods the impurities are not removed, but the water is sterilised and all the bacteria which it contains are destroyed.

Reservoirs in which vegetable growth or algæ has become profuse have been cured by dragging a bag of sulphate of copper behind a boat to and fro over the area of the reservoir. A very minute fraction of this poisonous salt will effectually destroy all growth, and it is said that the salt cannot be detected in the water after the process is complete. Apparently the organic matter has absorbed it; but as the salt is extremely poisonous great care must be taken that too much is not used.

Action on Lead.

Peaty water from moorlands has a solvent action on lead pipes, due to acidity. It varies, in terms of a sulphuric acid equivalent, from 1 to 44 parts in 100,000. Peaty grounds of small incline are particularly acid, and such water is dangerous on account of its action on lead pipes. According to Mr. Ackroyd the solvent action would not occur if the acidity did not exceed ·5.

Diameter of Pipes.

The diameters of pipes are usually calculated by either Eytelwein's Kütter's or formula.

Eytelwein's formula is

$$V = \sqrt{(11704\,RS) + ·01698} - ·1303$$

where,

V = velocity in feet per sec. ; R = Hydraulic mean radius in feet = Area ÷ wet perimeter = D ÷ 4 for circular section of pipe, where D = diameter of pipe in feet, S = sine of inclination = $h \div l$, where h = head in feet; l = length in feet.

An adaptation of this formula which gives good average results is

$$Q = 4{\cdot}7\ D^2\sqrt{\frac{Dh}{l}}$$

where,

Q = discharge in cub. ft. per min., and D is in inches.

This formula gives rather high results in the case of small pipes with flat gradients, and somewhat low results for large pipes with steep gradients.

Kütter's formula is

$$V = \left[41{\cdot}6 + \frac{1{\cdot}811}{n} + \frac{{\cdot}00281}{S}\right] \div \left[1 + \left(41{\cdot}6 + \frac{{\cdot}00281}{S}\right)\frac{n}{\sqrt{R}}\right]\sqrt{RS}.$$

where V, R, and S have the meanings stated above, and n is Kütter's coefficient for roughness, which varies from ·009 to ·017, ·013 being a value which is frequently taken.

Incrustation and Corrosion of Iron and Steel Pipes.

High-water velocity is favourable to corrosion and incrustation. Cast-iron being taken to rust at the rate of 100, wrought-iron may be taken as 129, and steel at 133. Some waters, as chalk-well waters, treated by Clark's process, will simply cause a clean layer of carbonate of lime inside a pipe. Upland waters, especially if containing peat acid, cause rust. Old red-sandstone water neither rusts nor causes deposit. Greensand water causes rust. Filtered water is better than unfiltered. Angus Smith composition (see Index) is not a permanent protector. Founders do not as a rule exercise proper care in dipping pipes; the pipes ought to be well brushed out, by passing through them a revolving steel brush *from both ends*, so as to get the brushing effect each way, and they should be then at once heated and dipped. Dipping should be vertical, and the pipes ought to again be brushed by the revolving steel brush when immersed in the dip, without which treatment perfect contact may be difficult to secure between the iron and the composition. It is undoubtedly at the pinholes, caused by minute air bubbles, that the first encroachments of corrosion are made upon the pipe

According to H. F. Rutter, pipes of cold-blast iron are far superior to those of hot-blast, as regards resistance to corrosion.

Tracing Leakages.

To identify and trace the source of underground water, such as leakages from canals, reservoirs, pipes, etc. :—

Fluorescin.—Mix fluorescin with the supposed source of the leakage. One grain is sufficient to colour 100 tons of water.

Indigo.—One grain of indigo dissolved in sulphuric acid will colour a ton of water.

The colouration is more easily detected by placing the water in a very long test-tube and looking through the latter endways.

Consumption of Water.

This varies very largely in different parts of the country : in Edinburgh as much as 40 gallons per head per day are consumed, and in Glasgow much more. Where trade requirements are small 25 gallons per head per day should, however, usually be sufficient for domestic consumption, garden, and street watering, and for flushing.

Hardness of Water.

Hardness is termed *Permanent* or *Temporary* according as the hardness is due to the bi-carbonate of lime and magnesia, which cease to be soluble at 212°, or to sulphate of lime, which remains in solution to much higher temperatures. There exist at the present date two methods of removing either or both of these forms of hardness, the first being by treatment with caustic lime and caustic soda, and the second by filtration over zeolites.

(1.)

Treatment by Caustic Lime or Caustic Soda.

Lime sulphate is dealt with by carbonate of soda, and is converted into the mono-carbonate of lime, while sulphate of soda remains in solution as a very soluble salt. Practically these two lime salts, or the magnesia, are the only salts calling for practical treatment. The following are the reactions which take place, from which it is obvious that where caustic soda can be procured cheaply it may be used where both impurities are present, and will perform a double duty and take the place of some or all of the caustic lime.

(*a*) A water containing only bi-carbonate of lime :

Bi-carbonate of Lime	+	Caustic Lime	=	Carbonate of Lime
$CaO+2(CO_2)$	+	CaO	=	$2(CaCO_3)$
$56+88$	+	56	=	$2(100)=200$ of deposit

(*b*) A water containing carbonate of magnesia :

$$MgO+2(CO_2) + CaO = (MgCO_3)+CaCO_3$$
$$40 + 88 + 56 = 84 + 100$$

(*c*) A water containing sulphate of lime :

Sulphate of Lime		Carbonate of Soda	
$CaSO_4$	+	Na_2CO_3	$=CaCO_3+Na_2SO_4$
136	+	106	$= 100 + 142$

or water (*a*) treated by caustic soda :

Bi-carbonate of Lime		Caustic Soda		Carbonate Lime		Soluble Carbonate Soda Water
$CaO+2(CO_2)$	+	$2(NaHO)$	=	$CaCO_3$	+	$Na_2CO_3+H_2O$
144	+	80	=	100	+	$106 + 18$

(*d*) A water with both salts in solution :

$$\left\{\begin{matrix}[CaO+2(CO_2)] \\ 144\end{matrix} + \begin{matrix}CaSO_4 \\ 136\end{matrix}\right\} + 2\left\{\begin{matrix}HNaO\end{matrix}\right\}$$
$$= \text{first reaction } [CaO+2(CO_2)]+CaO+[Na_2SO_4+H_2O]$$
$$= \text{second reaction } \begin{bmatrix}CaCO_3+CaCO_3 \\ \text{insoluble}\end{bmatrix}+\begin{bmatrix}Na_2SO_4+H_2O \\ \text{soluble}\end{bmatrix}$$

Both actions go on simultaneously.

When the bi-carbonate exists in greater proportion than 144 to 136 of the sulphate, the difference in excess must be dealt with by caustic lime as per (*a*). When the sulphate of lime is in excess beyond 136 to 144 of bi-carbonate, the excess is to be dealt with by carbonate of soda as in (*c*). There is no such salt as bi-carbonate of lime except in solution in water containing carbonic acid gas. It is taken as evidence of the existence of the bi-carbonate that the carbonic acid gas is found in the equivalent necessary proportion which would form a bi-carbonate

(2.)

REMOVAL OF PERMANENT OR TEMPORARY HARDNESS BY FILTRATION OVER ZEOLITES.

The exchange which takes place may be represented by the following formulæ which show the reaction, P representing the zeolite or 'Permutit.'

For the softening of temporary hardness :—

$$P - Na_2 + CaH_2(CO_3)_2 = P - Ca + 2NaHCO_3$$
$$P - Na_2 + MgH_2(CO_3)_2 = P - Mg + 2NaHCO_3$$

For the softening of permanent hardness :—

$$P - Na_2 + CaSO_4 = P - Ca + Na_2SO_4$$
$$P - Na_2 + MgSO_4 = P - Mg + Na_2SO_4$$

The reaction continues for so long as any of the base originally existing in the active Permutit remains, after which all action ceases, and the active base has to be restored to its original state by a treatment with a sodium salt.

Thus by a process of exchange to and fro, which is effected without any wastage in the zeolite itself, a softening action is secured, which is continuous and capable of thoroughly and completely removing all hardness in any water supply. The method of softening water by this treatment of filtering through zeolite affords the only means for complete elimination of both temporary and permanent hardness at one and the same time, a water of zero degrees of hardness resulting for so long as the designed capacity of the plant is not exceeded.

By adoption of zeolytic filtration, it has become possible to entirely remove from a water supply all traces of iron in the water, thereby eliminating to a great degree the high corrosive property possessed by certain supplies.

Softening Water.

Dr. Clark's process softens water rendered hard by calcium bi-carbonate. It consists in mixing with it about one-tenth (for spring water from chalk) of water saturated with lime in solution, the lime in which, combining with the free carbonic acid of the bi-carbonate, forms a solid precipitate of chalk. It will soften Thames and New River water down to $3\frac{1}{2}°$, or lower than if boiled for an hour : but it can rarely bring any water below $2\frac{1}{2}°$ of hardness, what is left being termed permanent hardness. Prolonged boiling will drive off the free carbonic acid from the bi-carbonate, precipitating the carbonate. According to Clark's scale, $\frac{1}{4}$ oz. of soap will remove $1°$ of hardness from 10 gallons of water.

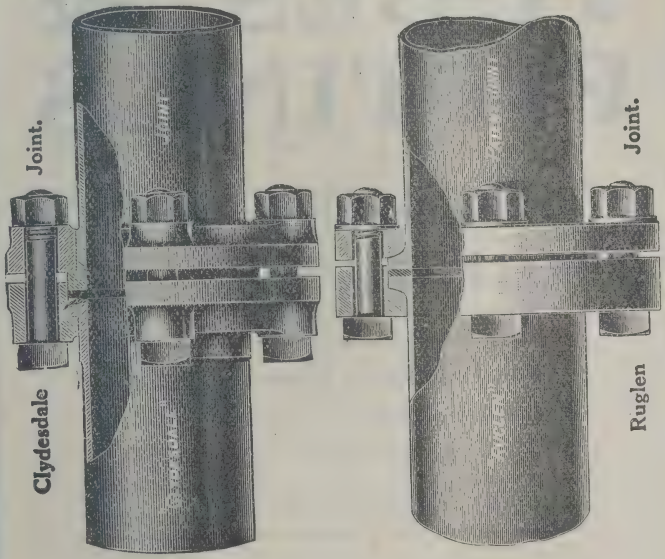
	90·26	165708·0	95·92	176090·0	101·26	185902·0					

The values in the foregoing table are calculated from the formula



$$V = 140\sqrt{rs} - 11\sqrt[3]{rs};$$

where V = velocity in feet per second, r = *hydraulic mean depth* (= area of wet cross section divided by wet perimeter = for full pipes, ¼ diameter) in feet, s = sine of inclination, or total fall divided by total length.

For pipes of greater diameter than above divide the proposed diameter by 4, then twice the velocity opposite to the quotient in the table will be the velocity required, or the corresponding supply multiplied by 32 will be the approximate supply in gallons per minute.

Wrought Iron and Steel
TUBES

With EADIE'S Loose Flange Joints, as illustrated.

Specially adapted for use in Mines for the conveyance of High Pressure Steam, Water and Compressed Air.

To find required head multiply length of pipe in yards by factor in table for given pipe and quantity of water required; the result is the head in feet.

Example.—Head in feet required to pass 1,000 gallons of water per minute through 30 yards of pipe. In table under 8, and in line with 1,000, will be found ·125; then ·125 × 30 = 3·75, which is feet head required.

The figures in the table are true for plain, smooth, straight pipes. Additional head must be allowed if pipes are at all of a rough nature or broken in contour internally. For each right-angle bend having a radius of about twice the diameter of pipe, and passing the average quantities given in table, about 1½ ins. of additional head must be allowed. (*T. Box.*)

Velocity in Feet per Sec. = 8·025 $\sqrt{H}$ (8·025 = $\sqrt{2g}$)	Head in Feet (H)	Lbs. Press. per sq. in.	Diameter of Bore in Inches and Area of Bore in Feet.

(J. & H. Gwynne, Ltd.)

METROPOLITAN WATER BOARD STANDARD SOCKETS (Table, page 1307).

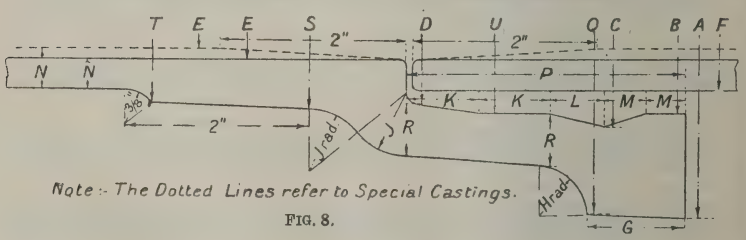

FIG. 8.

The joints of the above standard pipes are made by caulking a ring of lead wire ½ in. in diameter to the bottom of the socket, then running in molten lead for the remainder of the depth, and afterwards caulking or 'setting up.' Alternatively, lead wool may be caulked in for the whole depth.

STANDARD SOCKETS FOR STRAIGHT AND SPECIAL CAST IRON PIPES.

Sizes of Lead Pipe are Internal. 1½ is the usual Minimum Size for Closet Pipe, and 9 lbs. per Yard Minimum Weight.

Comparative Value of Cast-Iron, Wrought-Iron, and Steel Drain Pipes.

Extra heavy cast-iron soil pipes in a number of buildings in nearly all cases had the cast-iron vents evenly pitted on the inside, but in the house drains and branch wastes the lead-caulked joints had opened up more or less. Black steel vents showed scaling to a considerable depth after only ten years' use. Galvanising was observed to be less of a protection against corrosion on steel pipes than on wrought-iron pipes. The galvanised coating does not adhere so firmly to the smooth surface of steel pipes as to the comparatively rougher surface of wrought-iron pipes. The galvanising on steel pipes showed signs of disappearing within ten to twenty years. The investigation furnished ample evidence in favour of genuine wrought-iron pipe as a far more durable material for house drainage purposes than steel pipe.

(*W. P. Gerhard, 'Proceedings' of the American Society of Mechanical Engineers.*)

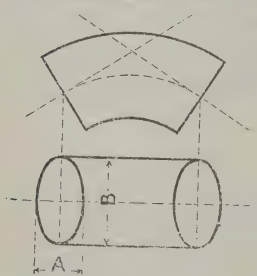

FIG. 9.

Unbalanced Pressures on Bends, etc.

Where any considerable pressure has to be sustained by pipes of large size the unbalanced pressures on bends, etc., must be resisted, horizontally by strutting or tying, vertically by strutting or anchoring. The unbalanced pressure on any bend may be found thus :—

Unbalanced pressure on back of bend = the sum of the areas of the ellipses shown in the elevation × the pressure per unit of area, or A × B × ·7854 × 2P = unbalanced pressure.

WATER TANKS.

Water tanks for house supplies should be covered from the light in order to prevent vegetable growth, but they should be ventilated. A good form of ventilator is an ordinary house sewer air inlet with the mica flaps removed. These should be placed, one or more, according to the size of the tank, at each end of the tank, standing a foot or two above the cover. At one end their openings, which are lateral, should face to, say, the south-west, and at the other end in the opposite direction, so as to set up a flow of air.

The cheapest tanks, to be durable, are excavated partly in the ground, the removed earth being banked against the walls built above ground and rammed at an inward slope so as to afford support against the water pressure. The walls may be of brick or of concrete, rendered internally in good cement mortar. The banks of spoil should be neatly trimmed and sodded or grass sown, and in this way a tank may be almost hidden. Where economy of material is an object, a tank is best circular, since the bank outside can be harder rammed without danger of turning the walls inwards.

These 'tanks' should not be confounded with 'cisterns.'

SECTION XXVI

METERING OF WATER, AIR, GAS, AND STEAM.

(Contributed and revised by J. L. Hodgson, B.Sc., A.M.Inst.C.E.)

The metering of fluids is undertaken to enable running costs to be apportioned, sales to be effected on an equitable basis, to control the mixing of reagents in various chemical processes, or to detect wasteful or inefficient use so that working costs may be reduced and unnecessary additions to plant obviated, etc.

Various efficient and accurate types of water and gas meters have been in use for many years; it is only recently, however, that accurate and reliable air and steam meters have been developed. The first large installation of air meters was made on the Rand in 1911, where now more than 300 million h.p. hours per annum are metered, at an ascertained annual aggregate money saving of 130,000*l.**

The following is a brief summary of the principal classes of fluid and gaseous meters, with notes as to their application, and the names of the leading makers :—

1. Meters Based on Volume or Weight Measurement.

(*a*) Tanks or weighing. [For liquids, condensed steam.]
(*b*) Receivers of known capacity discharging between known pressures and temperatures. [For air and gas.]
(*c*) Piston displacement meters. [For water (Messrs. George Kent, Ltd., Luton; Messrs. Beck & Co. Ltd., Southwark, London; Messrs. Frost, Manchester).]
(*d*) Water-sealed drum meters. [For gas (The Gas Meter Co., London).]
(*e*) Bellows meters. [For gas (The Gas Meter Co. Ltd.).]

2. Meters which Measure the Velocity at a Point or Points in the Cross Section of the Stream.

(*a*) Pitot tube meters. [For water, air and gas (Messrs. George Kent, Ltd.). For air and gas (The Rotary Meter Co. (1905), Ltd.) For steam (The General Electric Co. of Schenectady and the British Thomson Houston Co. of Rugby).]
(*b*) Professor Morris's hot wire velocity indicator. [For air and gas (The Cambridge & Paul Instrument Co. Ltd., Cambridge).]
(*c*) Impact meters. [For measuring air velocity in mine tunnels (Messrs. Davis).]
(*d*) Anemometer meters. [For water in open channels (Messrs. George Kent, Ltd.). For air in conduits and passages (Messrs. Davis).]
(*e*) Floats. [For measuring the velocity of water in open channels.]

3. Meters which Depend on the Drop of Pressure due to an Obstruction Placed in the Stream.

(*a*) Weirs. [For liquids in open channels (The Lea Recorder Co. Ltd., 28 Deansgate, Manchester, and Messrs. George Kent, Ltd.).]
(*b*) Venturi tubes. [For water, air, steam and gas (Messrs. George Kent, Ltd.).]
(*c*) Nozzles. [For gas (Messrs. George Kent, Ltd.). For steam (The General Electric Co. of Schenectady, and Messrs. George Kent, Ltd.).]
(*d*) Circular, cord, or tongue orifices. [For water, air, gas and steam (Messrs. George Kent, Ltd.).]
(*e*) Variable orifices. [For water, air, gas and steam (Messrs. George Kent, Ltd.).]

* See Hodgson, *Proc. Inst. C.E.*, Vol. CCIV, Part 2, and Mavor, *Trans. Inst. Mining Engineers*, Vol. L, Part 4.

ROTARY OR TURBINE METERS.

(*a*) Which measure the whole of the flow passing. [For water (Messrs. Guest & Chrimes Ltd., Rotherham; Messrs. Siemens Bros., Woolwich; Messrs. Hayward Tyler, Luton; Messrs. George Kent, Ltd.; the Self Engineering Co., London). For air and gas (The Rotary Meter Co. (1905) Ltd., Victoria Works, Whitefield, Manchester, and Messrs. George Kent, Ltd.)]

(*b*) Which are placed in a shunt circuit. [For water (Messrs. Siemens Bros.). For air and gas (Messrs. George Kent, Ltd.).]

5. METERS BASED ON THE MOVEMENT OF A SPRING OR WEIGHT CONTROLLED OBSTRUCTION PLACED IN THE PIPE LINE.

(*a*) In which a disc moves axially in a circular chamber with conical or perforated walls. [For water (The Palatine Engineering Co. Ltd., Bootle, Liverpool). For gas or air (The Rotary Meter Co. (1905) Ltd., Victoria Works, Whitefield, Manchester).]

(*b*) In which a shaped plug opens up an orifice. [For steam (The St. John Steam Meter Co., New York).]

(*c*) In which a weighted hinged gate is opened by the flow. [For water and air (Messrs. George Kent, Ltd.).]

6. METERS BASED ON THE DROP OF PRESSURE CAUSED BY FRICTIONAL LOSSES IN A LENGTH OF CHANNEL OR PIPE LINE.

[For measuring irrigation water (Messrs. George Kent, Ltd..])

7. METERS BASED ON THE INTRODUCTION OF A MEASURED AMOUNT OF (*a*) HEAT, OR (*b*) CHEMICAL REAGENT, AND THE CONSEQUENT RISE OF TEMPERATURE OF THE FLUID, OR DILUTION OF THE REAGENT AT SOME POINT FURTHER DOWNSTREAM.

(*a*) The Thomas meter. [For air and gas (Messrs. Humphreys & Glasgow, London).]

(*b*) [A method used for measuring the discharge of rivers and canals.]

8. METERS BASED ON INCREASE OF WEIGHT DUE TO CHEMICAL ABSORPTION.

Notes.

Meters of classes 1 (*c*), (*d*) and (*e*) can be made accurate to within plus or minus 1 per cent. from zero flow up to the maximum flow which they are designed to measure. The chief source of error of meters of class 1 (*d*) is variation in the water level, and in meters of classes 1 (*b*) and 1 (*e*) wear of the valves.

Meters of classes 2 (*a*), (*b*) and (*c*) are usually only accurate down to one-third or one-sixth of the maximum flow for which they are designed, as their indication depends upon the square of the velocity of the fluid. Few anemometers are accurate when working at less than one-tenth of their maximum rated capacity.

Meters of classes 3 (*a*), (*b*), (*c*) and (*d*) are usually accurate down to one-fifth or one-tenth of the maximum flow. If specially sensitive differential pressure-measuring devices are provided, such meters may be made accurate down to one-twentieth or one-thirtieth of the maximum flow. By using a variable orifice, the range over which accurate measurement is possible with any given indicator or recorder is greatly extended. These meters have the very real advantage of having in the pipe line no moving parts which can be deranged by dirt or erosion. The Venturi tube, with its smooth contours which eliminate eddying, is a valuable device when measuring dirty gas. Meters of this class show many ingenious arrangements for obtaining an accurate measurement of the differential pressure over a wide range and for compensating for variations in the specific gravities of the fluids or gases to be measured.

Meters of class 4 are not usually accurate in practice below one-tenth of the maximum flow, though many makers claim much higher ranges of accuracy. Endeavours have been made to increase the range of accurate measurement by opening up additional jets at low flows, or by introducing additional resistance at the high flows. While these devices frequently give excellent results under test conditions, they rapidly get out of adjustment under working conditions. Water meters of this class can often carry considerable overloads, thus greatly increasing the range over which accurate measurements may be obtained.

Meters of classes 5 (*a*), (*b*) and (*c*) are capable of high accuracy over a large range of flow when measuring clean fluids. They rapidly lose their accuracy, however, when measuring dirty fluids, owing to the small clearances becoming choked.

The accuracy of meters of class 6 is dependent upon an accurate knowledge of the area of the channel and its resistance coefficient. These are apt to change owing to silting up and the growth of weeds.

In the following pages the main features of some of the best known, or the most noteworthy, meters are described and illustrated.

Water Meters.

The Kent Mark III Positive Water Meter.

This meter is shown diagrammatically in fig. 1. Its sequence of operations is as follows:—

1. The piston A descends, and the disc P throws over the valve C.
2. The piston B descends, and the disc R throws over the valve D.
3. The piston A descends, and the disc Q throws over the valve C.
4. The piston B descends, and the disc S throws over the valve E; and so on.

Stops M limit the motion so that an exact quantity of water is measured off each stroke.

Projections K enter the outlet passage at the end of the stroke and prevent jar by slightly throttling the flow.

The cylinders are lined with brass, and the valves and valve faces are made of gun-metal. The valves are caused to oscillate slightly each time they are thrown over in order to keep the rubbing surfaces polished. For the same reason the pistons are caused to rotate a slight amount at each stroke.

The valves are held up against the port block by rollers L carried by springs which press inwards towards the valve faces.

The meter body is jointed along the line XY, which enables all parts to be readily accessible (actually the inlet and outlet flanges are at right angles to the positions shown in the diagram).

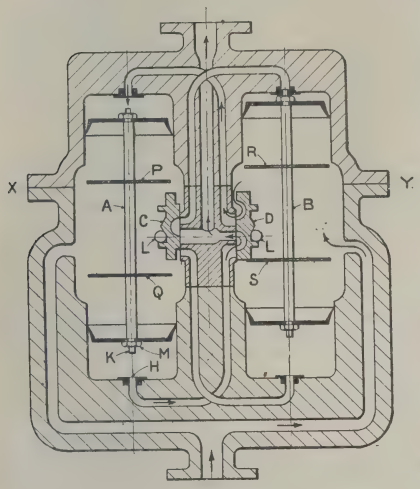

Fig. 1.

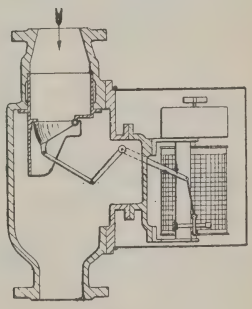

Fig. 2.

The Kent Waste Water Meter.

This meter (fig. 2) consists of a weighted gate pivoted on a horizontal axis and surrounded by a machined shield. The gate opens with increase in the flow, and takes up a definite position at each flow. Its motion is transmitted to the diagram through a stuffing box by means of link mechanism.

It is possible with this meter to measure with accuracy down to very small fractions of the full flow.

Owing to the absence of all sliding parts in this meter, the friction of the mechanism is extremely small.

The bulk of the meter, and the loss of pressure across it, are also reduced to a minimum by its arrangement, which allows of a direct flow between inlet and outlet.

The Beck 'Imperial' Water Meter.

In this meter (figs. 3 and 4) the rotation of the arm A attached to the spindle D, which drives the counter, causes the spherical valve cap V to rock on its seating S, thus opening the lower parts of each of the three cylinders C successively to the inlet and discharge sides of the meter.

The valve cap V is prevented from turning round on its own axis by the projections Q, which engage in recesses left in the valve seat S. The length of the stroke of the pistons is limited by the flange P on the valve cap V, which comes into rolling contact with a machined surface on the valve seat S.

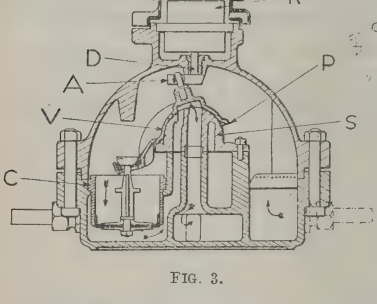

Fig. 3.

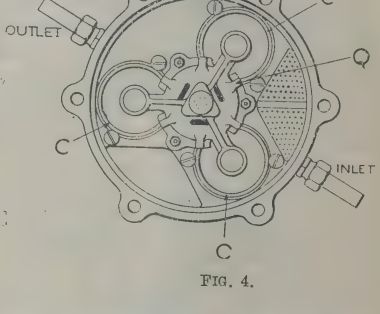

Fig. 4.

It will be seen that the valve cap V moves with a lens-grinding action. This ensures that it and the seating will remain polished and unscratched even when gritty water is being measured.

The valve cap and the pistons are made of hard gun-metal, the valve seat and bushes of vulcanite, and the cylinders of either vulcanite or gun-metal; vulcanite being used for water of exceptional hardness.

The Deacon Water Meter.

In the Deacon Water Meter (fig. 5) a weighted disc moves vertically in a conical shield. Its motion is transmitted to the diagram by means of thin wire passing through a gland. Guide plates are provided to steady the flow at the entrance to the conical shield.

The Kent Venturi Water Meter.

This meter (fig. 6) consists of (*a*) a Venturi tube VT through which the water passes; (*b*) a large mercury U-tube provided with floats FU and FT (which are displaced by the differential pressure which exists when water is passing between the upstream and throat pressure holes of the Venturi tube); and (*c*) diagram counter and recording mechanisms, which are actuated by the movements of the floats.

The motion of the floats is transmitted to the outside of the U-tube by means of gland spindles GU and GT, which actuate toothed wheels that engage with the racks RU and RT.

The law of flow through a Venturi tube is given by the equation :—

$$Q = \frac{\Omega\, a_1}{7{\cdot}88}\left[\frac{h\,W}{n^2-1}\right]^{1/2},$$

where Q = flow in lbs. per sec,; Ω = coefficient of discharge for the tube (usually about 0·99); a_1 = area of tube at upstream pressure holes in sq. ins.; na_1 = area of tube at throat pressure holes in sq. ins.; h = difference of pressure between upstream and throat pressure holes in ins. of water; W = weight in lbs. of 1 cub. ft. of the fluid passing.

The counter recording mechanism operates as follows :—A cylindrical cam LC, which has a slightly raised portion, is rotated once every ten minutes by clockwork. A pivoted arm A, which carries the roller L, which is kept in contact with the surface of the cam by a spring (not shown), is lowered by the rack to which it is attached when the flow increases. The greater the distance the arm is lowered, the larger is the fraction of each revolution of the cam during which the roller is on the unraised portion of the cam. By means of mechanism (not shown) it is arranged that a toothed wheel which drives the counter is put into gear with the clock train during the period that the roller L is on the unraised portion of the cam. The boundary line between the raised and the unraised portions of the cam is so shaped that when the pivoted arm A carrying the roller L moves down a distance H from its zero position an amount proportional to $\sqrt{H}$ is added on to the counter reading. In this way, with suitable gear wheels in the counter train, a counter record of the amount of fluid that has passed is obtained.

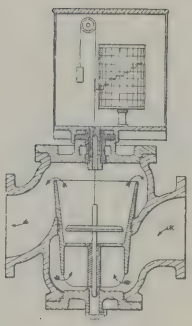

FIG. 5.

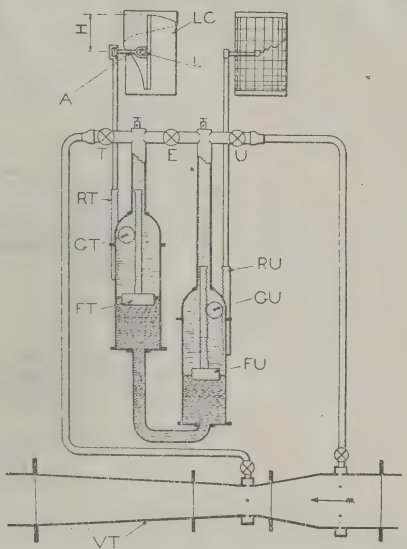

FIG. 6.

Valves U and T are provided so that the upstream and throat pressures may be shut off, and the meter checked by opening the equalising valve E.

Any air that accumulates in the pressure pipes may be blown off through the air vents provided.

To reduce the chance of air getting into the pressure pipes, these should be taken off horizontally, and not at the top, as shown for clearness in the diagram.

These meters will measure accurately down to one-fourteenth of the maximum flow (and special meters of this type down to one-thirtieth of the maximum flow).

The functions of the downstream cone of the Venturi tube is to recover the kinetic energy which exists at the throat, thus enabling the major portion of the pressure difference which has been created between the upstream and throat pressure holes to be recovered.

The friction loss due to the insertion of the water Venturi tube is about 2 lbs. per sq. in. at the maximum flow.

Venturi meters have been used to measure water in all sizes of pipes from about $\frac{1}{2}$ in. to 20 ft. in diameter. They provide the most convenient and accurate method known of measuring the flow of water in large mains. There is a minimum of obstruction to the flow, and there are no moving parts in contact with the flowing water.

Weir Recorders.

The Lea 'V' Notch Weir Recorder.

The discharge for a 90° V notch with sharp edges bevelled at 45° on the downstream side is given by the equation,

$$Q = 2{\cdot}48H^{2{\cdot}48}$$

where Q = discharge in cub. ft. per sec.; H = head, in ft. above the bottom of the notch.

In the Lea Recorder (fig. 7) the movement of the float F in the weir chamber which is proportional to H is transmitted to a cylindrical cam C. By means of this cam, a movement of the pen arm P which is proportional to Q is obtained.

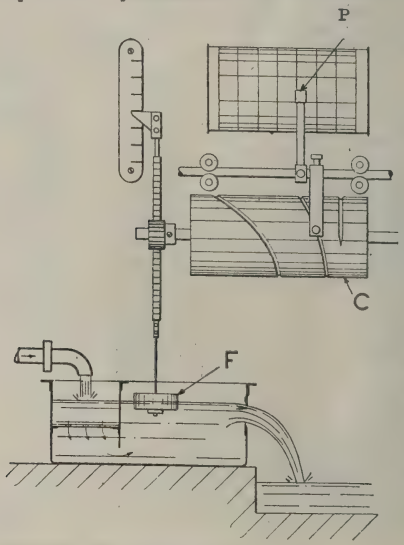

Fig. 7.

In the Kent Weir Recorder a flat cam is used, and the straight line movements are replaced by movements about fixed pivots.

In the Wright Weir Recorder the weir notch is made of such a shape that the motion of the float is proportional to the quantity passing. In this recorder there is, therefore, no cam between the float and the recorder pen. The approximate shape of the weir notch in shown in fig. 8.

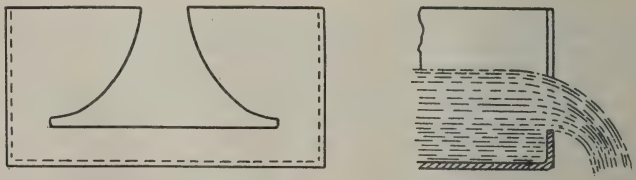

Fig. 8.

Gas Meters.

The 'Drum' Type Station Gas Meter.

In this meter (fig. 9) gas enters through the hollow axis in the four compartments of the drum in a pipe which is put just above the water level, and fills each compartment successively, and by its pressure causes the drum to revolve in the direction of the arrow and to register the volume passed on a set of dials.

Meters of this type are used to measure gas in mains of all sizes, from ¾ in. upwards.

Owing to their costliness, the larger meters of this description are now being superseded by new patterns of meter, such as the Thomas and the Kent-Hodgson Meters.

The main sources of error of this meter are deformation or corrosion of the drum, deposition of naphthalene in the drum, and variations in the water level. There are various ingenious devices for preventing the meters from being over-filled, and for maintaining the correct water level. If the meter is overloaded, the water level is depressed, and the meter reads slow.

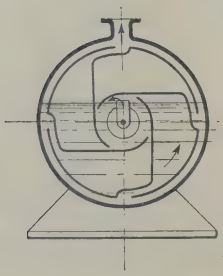

Fig. 9.

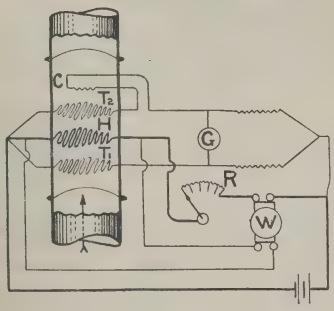

Fig. 10.

The Thomas Gas Meter.

In this meter (fig. 10) the gas is passed through a short length of pipe which contains two electrical resistance thermometers T_1 and T_2, which form part of a Wheatstone Bridge. An electrical heater H is placed between the two thermometers. Any increase in the flow of gas causes a lowering of the temperature of the downstream thermometer and a deflection of the needle of the galvanometer G. This is made automatically, by means of a suitable mechanism, to reduce the resistance in the heater circuit, so that the temperature of the gas is always raised the same amount (about 2° F.) by the heater.

The readings on a Wattmeter W, placed in the heater circuit, give the number of cubic feet of gas reduced to standard temperature and pressure.

The Kent-Hodgson Venturi Gas Meter.

In this meter (fig. 11) the 'Venturi Head' $(p_1 - p_2)$ is measured by means of the bell B and an amount proportional to $(p_1 - p_2)$ is added on to the counter reading by means of the cam, feeler, ratchet, and pawl device C.F.R. every time the cam G, which is driven by the wet gas meter W, makes one revolution.

The speed of rotation of this meter is determined by the amount of gas that escapes to atmosphere through a small orifice at O across which the pressure difference is maintained constant by means of the regulating valve R.V.

In this way the counter is made to register the volume of gas passing through the Venturi tube, irrespective of variations in the specific gravity of the gas; the registration of the meter being identical with that of the ordinary Drum type Station Gas Meter.

A diagram, D, is provided which shows the rate of flow of gas at any instant. The readings of this diagram are, however, not corrected for variations in the specific gravity of the gas.

If tar, naphthaline, or other depositable matter settles in the Venturi throat, the meter tends

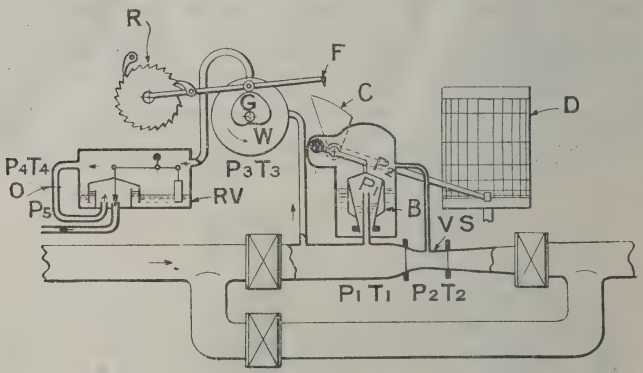

FIG. 11.

to read fast. It is found that when measuring coal gas, such deposits can be entirely prevented by keeping the walls of the throat at a few degrees higher temperature than that of the gas passing through.

The Venturi tube is installed on a bye-pass, and the throat section VS is made so that it can easily be swung out of the pipe line for inspection and cleaning.

The loss of pressure at the maximum flow due to the insertion of the gas Venturi tube is arranged not to exceed 1 in. of water gauge.

The range of accurate registration is down to one-tenth or one-fifteenth of the maximum flow.

If it is desired to reduce the meter readings to standard cubic feet of dry gas, corrections must be made for variations in the barometric pressure, atmospheric temperature, and the tension of aqueous vapour by means of tabular numbers, as is the case with the Drum type Station Meter.

The Venturi Gas Meter is also made in a cheaper form in which the integrating mechanism is driven by clockwork, and any variation in the specific gravity, temperature, and moisture content of the gas is corrected for by means of tabular numbers, *i.e.* the meter readings are multiplied by

$$\frac{(p_1 - p'_1)}{p_1} \sqrt{\frac{W_D}{W_S} \cdot \frac{p_1}{T_1} \cdot \frac{T_S}{P_S}},$$

where W_D = weight of a cub. ft. of dry gas at p_1 and T_1 ; W_S = weight of a cub. ft. of gas containing water vapour at p_1 and T_1 ; p'_1 = pressure of water vapour at temperature T_1, P_S and T_S the standard temperature and pressure.

See Hodgson, *Proc. Inst. C.E.*, vol cciv., p. 164–165.

THE THORP ROTARY GAS METERS.

In the Thorp Rotary Gas Meter (fig. 12), the counter C is actuated by an anemometer fan F, which rotates about a vertical axis.

The gas, after being carefully guided by a series of nozzles N into a vertical direction, impinges on the underside of the blades, thus helping to take the weight of the fan off the bottom pivot. The rate of revolution of the fan is proportional to the actual volume of gas passing,

except at low flows, when the friction of the mechanism is appreciable. At these flows a weighted valve V (which lifts at the higher flows) causes the whole of the gas to pass through a few jets J, and so to impinge on the fan at an increased velocity. In this way the friction of the mechanism is compensated for, and accurate readings obtained down to one-tenth of the maximum flow.

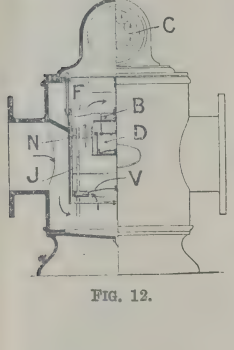

FIG. 12.

The dashpot D is provided to steady the motion of the weighted valve. A brake B is attached to this valve, which stops the fan immediately the flow is turned off, as the valve then falls.

This meter registers the actual volume of gas passed, and is subject to the same corrections for variations in the temperature, pressure, and moisture content of the gas as is the ordinary Drum type Station Meter, or the Kent-Hodgson Venturi Gas Meter.

Clogging of the nozzles through which the gas discharges on to the fan causes the meter to read fast. A special form of meter in which the nozzles can be cleaned from the outside, and in which any deposit thrown off from the fan does not accumulate round it, has been devised for measuring dirty gas.

HOT WIRE ANEMOMETER.

In this instrument a bare wire with a large temperature coefficient is heated electrically and exposed to the gas flow whose velocity it is required to measure. The velocity V of the gas can then be obtained from the relation

$$I^2 = A\theta + B\theta \left[V.W.K_p \right]^{\frac{1}{2}}$$

where θ = temperature elevation of the wire,
I = current in amps.,
V = velocity of the gas,
W = specific weight of the gas,
K_p = specific heat of the gas at standard pressure,
A & B = constants.

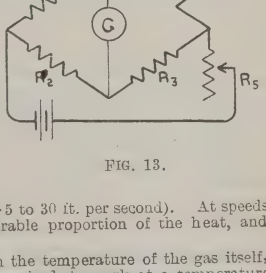

FIG. 13.

Referring to the diagram (fig. 13), R_1, R_2, and R_3 are resistances with no temperature coefficient, R_4 is the anemometer wire which is maintained at constant temperature when the gas velocity varies by adjusting the resistance R_5 so that the needle of the galvanometer G remains at zero. The current through R_4 is thus proportional to the reading of the high resistance voltmeter V.

The formula given above holds for ordinary gas speeds (9·5 to 30 ft. per second). At speeds below these, free convection currents carry away a considerable proportion of the heat, and the formula requires modification.

The accuracy of the instrument is affected by changes in the temperature of the gas itself, and for this reason it is desirable, when high accuracy is required, to work at a temperature elevation of about 1,000° C. In this case the anemometer wire should be of platinum. For ordinary work a temperature elevation of 200° C. or 300° C. is sufficient, and the anemometer wire may be made of electrolytic nickel.

It will be noticed that the velocity of the gas is approximately proportional to the fourth power of the current. This makes the accurate range of the instrument small, and it also makes it unsuitable for obtaining the mean velocity of fluctuating flows.

In Professor MacGregor Morris's Hot-Wire Anemometer, as made by The Cambridge & Paul Instrument Co., the four arms of the Wheatstone bridge are made of electrolytic nickel.

The wires which compose the two opposite arms of the bridge are shielded from the air current, and the two remaining wires are exposed to it. The instrument is thus automatically compensated for changes in the air temperature, so that it is not necessary for the temperature of the wires to be more than 100° F. above that of the air current to be measured. A constant potential difference is maintained across the bridge, and the air velocity is measured in terms of the out-of-balance current of the galvanometer.

The instrument is calibrated against known velocities in a wind tunnel.

Steam Meters.

The Kent-Hodgson Steam Flow Meter.

This meter (fig. 14) consists of an orifice O placed in the steam main, two cooling chambers CU and CD (whose function it is to condense any steam that passes into them and to serve as reservoirs of water), and pressure pipes PU and PD which transmit the difference of pressure between the upstream and downstream sides of the orifice, due to the steam flow, to the two sides of the differential pressure diaphragms D and to the inside of the pressure diaphragms P.

Any increase of the flow causes an increase of the difference of pressure between the upstream and downstream sides of the orifice, and consequently causes the diaphragms D to contract and the pointer B to move about its pivot C (the motion of the diaphragms D is transmitted to the outside of the diaphragm case through a stuffing box G); while any increase in the pressure of the steam causes the diaphragms P to expand and the arm H to descend.

Air vents V and an equalising valve E are fitted.

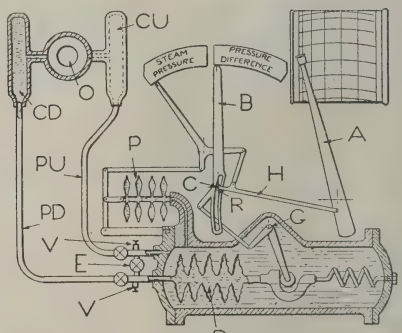

Fig. 14.

The product of the angular movement of the arm B (which is proportional to the differential pressure $(p_1 - p_2)$ and the travel of the roller R in its slot (which is proportional to the absolute pressure of the steam p_1) is transmitted to the pen arm A, which is thus given a motion proportional to $(p_1 - p_2)\, p_1$.

Since the rate of discharge of steam through an orifice is represented approximately by the equation,

$$Q = K \sqrt{(p_1 - p_2)p_1},$$

where p_1 = the absolute pressure of the steam on the upstream side of the orifice; p_2 = the absolute pressure of the steam on the downsteam side of the orifice; Q = lbs. of steam per hour; K is a constant depending upon the size and proportions of the orifice used—

the diagram can be divided to show the rate of steam flow at any instant, automatically corrected for variations in the pressure. (The corrections for variations in the superheat or wetness of the steam* are made by means of tabular numbers).

The meters can be arranged to record by counter also if desired.

With any given orifice plate the meter is accurate down to one-fifth of the maximum flow for which the plate is designed to deal. If it is desired to measure over a greater range of flow than this, a new orifice plate must be inserted. Each meter is designed to work in connection with any orifice plate. Each orifice plate is calibrated with actual fluid before leaving the works, and the accuracy obtained in practice with this meter is within plus or minus 1 per cent.

With slight modifications, the meters can be used for the measurement of compressed air.

---

* About 1 per cent. for every 2 lbs. change in the pressure, or 20° F. change in the superheat, or 2 per cent. change in the wetness.

(Author of 'Dock Engineering,' 'Harbour Engineering,' etc.)

HARBOURS.

Harbours are sheltered areas of water affording safe anchorage for ships, generally also provided with quays and facilities for landing passengers and cargo. There are many harbours where the requisite shelter is forthcoming naturally from the physical configuration of the coast line (Queenstown, Rio de Janeiro, etc.). Where protection cannot be obtained in this way it has to be provided by means of breakwaters, as at Portland, Dover, and elsewhere.

Breakwaters are of two types: (*a*) the mound of rubble stone, and (*b*) the upright wall of masonry or concrete. Frequently the types are combined. Sometimes the mound predominates

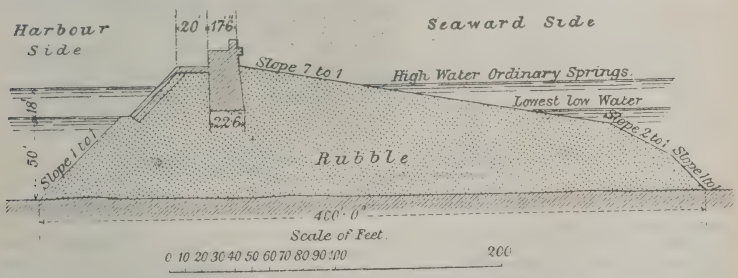

FIG. 1.—Holyhead Breakwater.

and is simply capped by a slight superstructure of regular masonry, as at Algiers and Oran; in other cases it is reduced to a minimum, becoming a mere foundation layer for a wall of massive proportions, as at Ymuiden and Zeebrugge.

The relative advantages of the mound and the wall are as follows:—

1. As regards *efficiency*, the mound is not so serviceable as the wall. The undulations of the sea are transmitted through the interstices of a mass of rubble, and the harbourage area is kept more or less in a state of agitation.

2. As regards *initial cost*, the mound can be formed by unskilled labour, and where that is plentiful and stone abundant, this type of breakwater will commend itself on account of the facility with which it can be constructed. In the absence of these essential conditions, and provided the depth of water be moderate and the foundation sufficiently firm, the wall, involving a much less quantity of material, will be found preferable. Especially will this be the case where skilled labour is readily procurable at reasonable rates. Even the difficulty of a defective foundation may be overcome by one or other of several expedients without perceptibly altering the relative positions. But where the sea bottom lies at a considerable depth (40 feet or more) the superior economy of the pure wall cannot be maintained.

CONSTRUCTIONAL COST OF BREAKWATERS.*

Harbour.	Type.	Mean Depth of Water.	Cost per lin. ft.	Remarks.
		Ft.	£	
Alderney .	Composite	90	259	Mound terminates 12 ft. to 15 ft. below L.W.
Algiers. .	Mound	50	122	Large random concrete blocks surrounding rubble.
Dover . .	Wall	40	415	Concrete blocks weighing 26 to 40 tons.
Holyhead .	Composite	54	162	Mound very predominant.
Marseilles .	Mound	35	87	
Bizerta. .	Composite	58	60	Wall built on caisson system.
Portland .	Mound	44	127	
Naples . .	Composite	93	186	

3. As regards the cost of *maintenance*, this is generally greater in the case of mounds than in the case of walls. A wall, provided it be properly constructed in the first instance, calls for no further attention, save for such rare and occasional damage as results from some storm of exceptional severity. The rubble mound, on the other hand, is peculiarly susceptible to wave

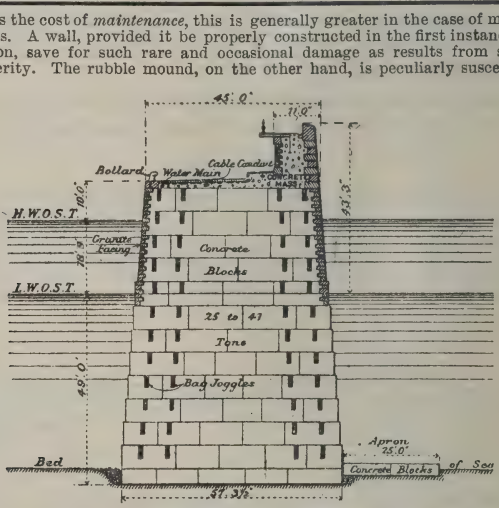

FIG. 2.—Dover Admiralty Pier Extension, Dover.

action, and needs constant replenishment. The cost of this varies very considerably according to situation and exposure. At Holyhead it was for many years as low as 1*s.* 3*d.* per lin. ft. per annum, but latterly there has been some extensive replenishment at considerable outlay ; at Genoa, the cost is stated to be 7*s.* ; at Naples, 13*s.* ; while at Alderney, during a certain period, it rose as high as 45*s.* This last, however, is quite an abnormal figure, and under ordinary conditions the pre-war annual expenditure on mounds of suitable design hardly exceeded a pound a foot.

Wave Action.

Wave Action.—Wave action on breakwaters is most keenly marked between the levels of high and low water, but it extends to a depth of 30 ft., and there are instances on record of serious disturbances at even greater depths. Thus, at Peterhead, blocks weighing upwards of 41 tons have been displaced at 36½ ft. below L.W.O.S.T. But cases of this kind are exceptional. Generally speaking, at a depth of 5 fathoms the sea is fairly quiescent and a rubble mound may be counted upon to stand therein with side slopes of from 45° to 50°.

Above this level much flatter slopes become necessary : 2, 3, 4, 5, and even 7 to 1. Unfortunately, while the equilibrium of the mound demands such gradual inclinations, they serve also

* The impossibility of accurately adjusting costs and prices, where they are quoted, to the altered and variable conditions arising out of the war has rendered it advisable to retain them on their old pre-war basis, leaving the necessary adjustments to be made as occasion may require.

to foster the disruptive action of waves, which, passing up a long seaward incline, have their oscillatory character changed into one of translation. At the summit the impact delivered is so powerful as to produce a pressure which Stevenson records as being six times as great as that against a steep wall. This inimical effect can only be counteracted by the use of huge blocks and monoliths, covering the exposed surface of the mound. The blocks, which in practice rarely weigh less than 25 or 30 tons apiece, and often considerably more, may be deposited either in courses or at random. In the former case they are generally stepped so as to conform to the general inclination. In either arrangement they should be laid as headers, pointing seaward, so as to expose the least extent of surface to wave-action and at the same time gain the utmost

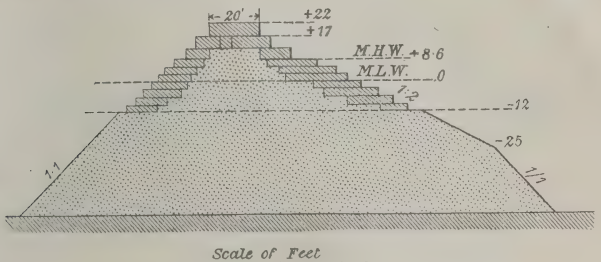

FIG. 3.—Sandy Bay (U.S.A.) Breakwater.

advantage from the moment of resistance to overturning. Hence prisms or parallelopipeds are decidedly preferable to cubes.

The *maximum pressure* exerted by waves does not appear to exceed 3½ tons per sq. ft. At Skerryvore, on the Atlantic, a pressure of from 2½ to 2⅞ tons per sq. ft. has been observed; at Bell Rock, in the German Ocean, 1½ ton; at Dunbar (East Lothian) 3½ tons, and at Buckie (Banffshire) 3 tons.

Composite breakwaters, in which the wall plays any important part at all, should be so designed that the *back draught* or *after-tow* of the waves cannot undermine the superstructure. To be really effective, this means that the wall should be carried down to a depth of at least 30 ft. below low water, and though in the past many such walls have been founded at low water level, or very slightly below it, yet the experience gained has proved that this depth is quite inadequate (the low water zone is particularly dangerous), so that of late years there has been a continual tendency towards increasing the depth of the foundation level. At Bilbao the wall commences at 16½ ft. below low water; at Madras 27½ ft.; at Naples 33 ft.; and at Peterhead 43 ft.

Methods of Construction.

Methods of Construction.—Breakwaters are constructed in several ways, according to situation and type.

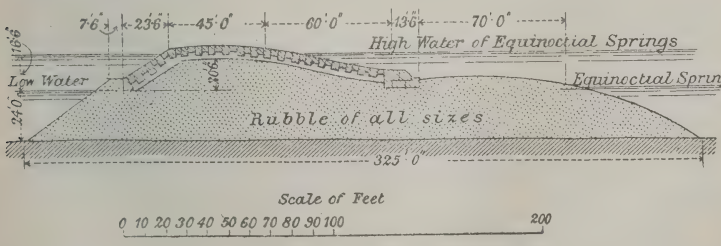

FIG. 4.—Plymouth Breakwater.

For **mound breakwaters,** rubble may be deposited—(*a*) from barges or scows; (*b*) by means of cranes running on temporary staging; and (*c*) from wagons passing over roads laid at or about the level of the top of the mound and extended as the work proceeds.

The first method is best adapted to sheltered situations, and affords an opportunity of depositing rubble uniformly and simultaneously over the whole site, but it is not practicable to carry on operations in this way at or about surface water level nor above it. Moreover, the progress of the work is very dependent on weather conditions, and there may be long periods of enforced inaction. It is to be noted in passing that irregular deposits of rubble lead to current action and scour. The second method (staging) admits of operations being carried on uniformly over the site, though not with quite the same degree of freedom as in the case of barges. But the advantages of a stable working base with infrequent interruptions and higher degree of safety and protection for workers, are very pronounced. The damage sustained by timber staging in storms

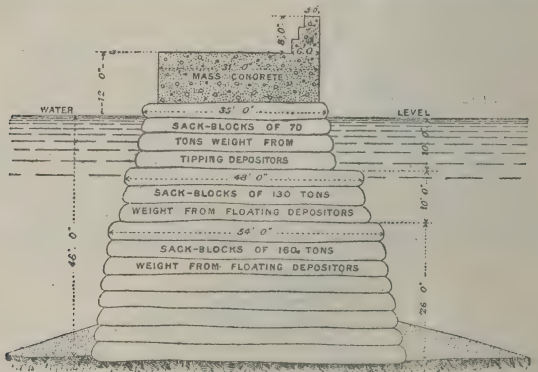

FIG. 5.—La Guayra Breakwater.

and from the attacks of marine borers are drawbacks which detract from the merits of the system, though, generally speaking, the former is proportionately not a serious matter, and any evil results of the latter can be to some extent guarded against by careful inspection. The third, or low-level system of construction, by means of tipping from wagons running on tracks laid on the breakwater itself, assists in the consolidation of the work as it proceeds, and saves the cost of staging, but the area of operation is limited and there is liability to interruption during the prevalence of heavy seas. It is a method more adapted to small embankments, where time also is perhaps not a matter of prime importance.

Wall-Breakwaters.

Walls are constructed either by means of staging, or on the low-level, end-on system: the former being generally more suitable when concrete is deposited in mass, and the latter for blockwork. The blocks, or monoliths, are deposited in place by huge revolving cranes, known as Titans, and overhead travellers known as Goliaths (p. 786). A modern Titan is a powerful cantilever crane capable of dealing with blocks of from 30 to 50 tons weight, at a working radius of as much as 100 ft. A 41-ton steam Titan used on the breakwater at South Shields had a radius of 75 ft., and was carried on 16 central-flanged wheels running on rails set to a 22 ft. gauge. The speeds of the various motions were as follows: Lifting full load, 6 ft. per min.; lifting loads up to 10 tons, 25 ft. per min.; racking full load, 20 ft. per min.; racking loads up to 10 tons, 50 ft. per min.; slewing, one revolution in 4 min. Goliaths are constructed to the same lifting capacity as Titans, and some command a lateral range of travel of 100 ft. or more, but the span is generally limited to about 50 or 60 ft. At Dover, a 42-ton steam Goliath had a range of 130 ft., a clear headway of 25 ft., and a total lift of 120 ft. The speeds of movements were: Lifting, 10 ft. per min.: crab travel, 50 ft. per min.; and main travel, 60 ft. per min.

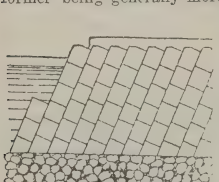

FIG. 6.—Sloping Bond.

Special Methods of Construction.

Special methods of breakwater construction include the use of bags, or sacks, of concrete, weighing from 50 to 200 tons, for deposition under water by divers, as at La Guayra; large caissons, or tanks, of reinforced concrete, with volumes of 60,000 to 70,000 cu. ft., floated out into position, sunk and filled in solid, as at Bizerta; and blocks set on end, slightly tilted (15° to 20°) out of the vertical, so as to form what is called *sloping bond*, the object being to allow for unequal

settlement in the foundation. Small breakwaters in shallow waters are sometimes constructed of cribwork—box-shaped frames of timber in openwork with cross partitioning and ties, weighted when in position with rubble—but the system is not very durable and only suitable for comparatively sheltered situations.

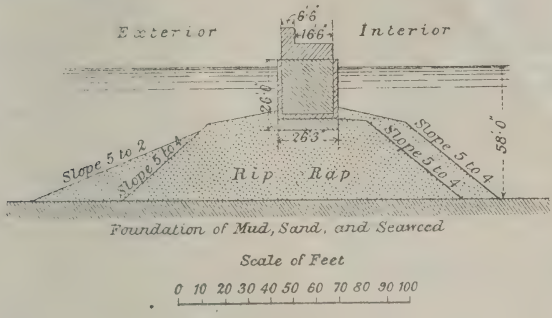

FIG. 7.—Bizerta Breakwater.

DOCKS.

Docks are enclosed repositories for shipping. Where the enclosure is not complete and there is free communication with the sea, the term *Basin*, though not universally employed, is more appropriate. Docks proper are fitted with gates or caissons, either in order to impound the water at a fairly constant level, in which case they are distinguished as wet docks, or to exclude the water, in which case they are known as dry or graving docks. *Floating Docks* are movable structures capable of lifting vessels out of the water and supporting them by their own displacement.

CONSTRUCTIONAL COST OF WET DOCKS.*

(Note: The variety and range of design and equipment render any very effective comparison out of the question.)

	Per acre of Water Surface.		Per acre of Water Surface.
Alexandra Dock, Hull . .	£28,900	Barry Docks	£12,950
Alexandra Dock, Liverpool .	23,300	Prince of Wales Dock, Swansea	18,600
Avonmouth Dock, Bristol .	22,600	Queen's Dock, Glasgow . .	24,450

KING GEORGE V. DOCK.

A notable event of the year 1921 was the opening of the King George V. Dock at London, which adds 64 acres to the enclosed water area of the port. The new dock has a depth of 38 ft., and the quayage aggregates approximately 10,000 ft. A section of the north, west, and east quay walls is given in fig. 11. An unusual feature on the south side of the dock, shown in fig. 12, is the provision of seven reinforced concrete jetties, each 520 ft. long and 22 ft. wide, which have been constructed at a distance of 32 ft. from the face of the main quay wall, the only shore connection being a timber foot-bridge. The arrangement is due to the fact that a preponderating portion of the goods arriving at the port is transferred to barges for conveyance to their ultimate destination up river. Ships are berthed on the outside of the jetties, and the jetty cranes will discharge goods therefrom either on to the quay for delivery to carts or railway trucks, or for sorting or temporary storage at the sheds behind, or, alternatively, into barges lying in the space between the jetties and the wall.

The entrance lock from the river Thames is 800 ft. long by 100 ft. wide, with a depth of water on the sill of 45 ft. below Trinity high water. The chamber is divided into two compartments, of 550 ft. and 250 ft. respectively, by 36-inch steel lock gates, each leaf of which weighs 309 tons. By the use of a floating caisson, for which provision has been made at the inner end of the lock, the available length can be increased to 910 ft.

* See footnote page 1324.

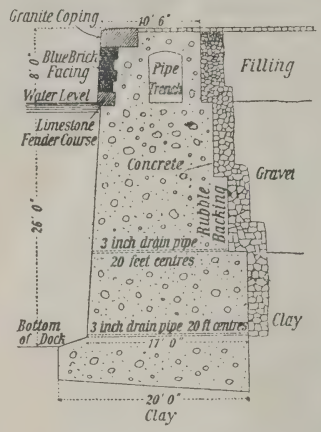

FIG. 8.—Manchester Dock Wall.

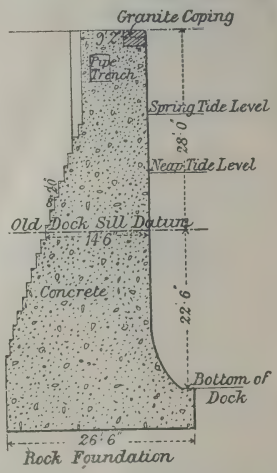

FIG. 10.—Liverpool Dock Wall.

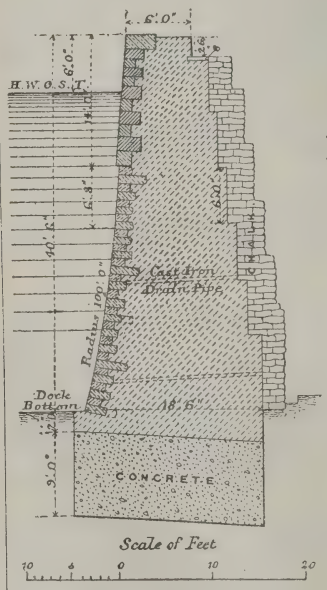

FIG. 9.—Hull Dock Wall.

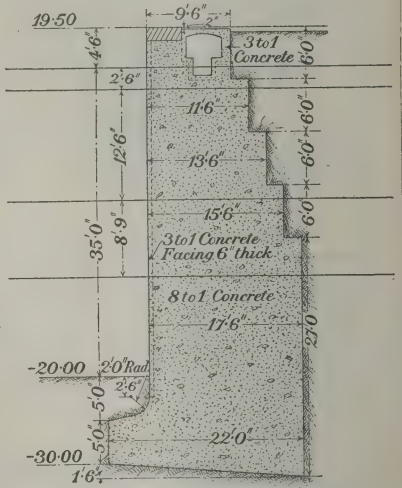

FIG. 11.—King George V. Dock, London: Section of N., E., and W. Quay Walls.

KING GEORGE V. DOCK, LONDON.

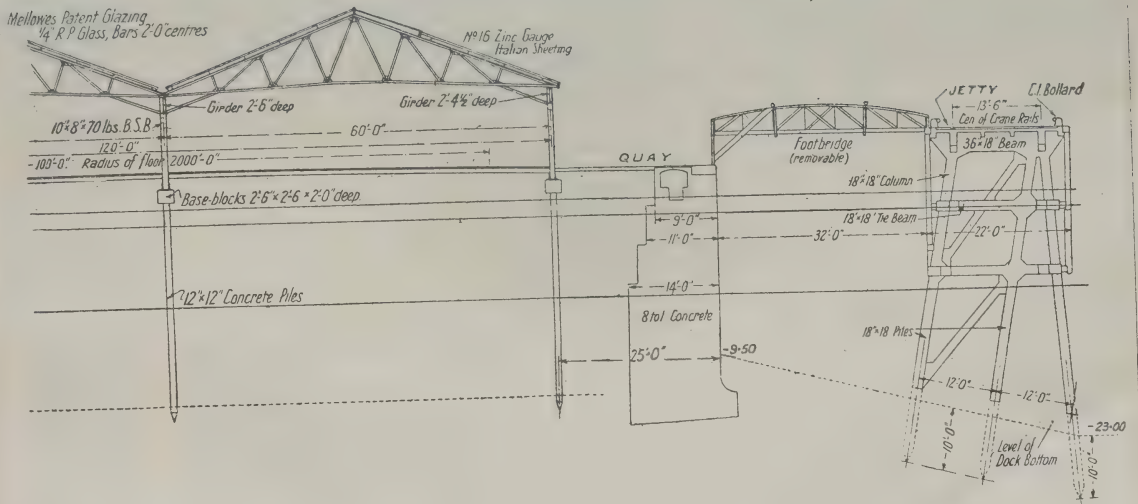

FIG. 12.—Cross Section of South Quay.

Dock Walls.

Dock Walls.—Under present-day conditions it is necessary for quay walls to possess a perpendicular, or almost perpendicular, face. Ships are now built to a square, box-like section amidships, with vertical sides inclining inwards towards the top. Unless, therefore, there is an absence of batter in the walls, vessels will be unable to lie as closely in contact with the quay coping as is desirable, and quay cranes for loading and discharging them will have to be provided with a greater outreach than is absolutely necessary, at an enhanced cost.

Dock walls are constructed of masonry, brickwork and concrete—nowadays generally the latter, deposited in mass with sometimes a brick or stone facing. There is nearly always a coping course of granite. A toe in front of the wall adds to its stability and prevents any undermining of the foundation. The material forming the backing should be carefully selected so as to admit of proper drainage, and weep or vent holes should be provided in the wall at intervals of 50 feet or so, to admit of water escaping through to the front when the level of the dock is lowered in any way.

The composition of *Concrete* for the hearting of dock walls may safely be put at 8 parts of aggregate by volume to 1 part of sound Portland cement. Of the aggregate the sand while not exceeding 3 times the cement will at least suffice to fill the interstices in the gravel. Stone rubble plums can be used to advantage, provided they are completely bedded in concrete and do not come within 6 inches of each other or the face. The facing of the wall, if of concrete, will be composed of equal parts of gravel, sand and cement.

The *essential features of a quay wall* are weight and resistance to slip. The first is secured by using heavy material and providing ample sectional area; the second by giving a suitable bevel to the surface of the foundation so that it slopes downward from the front of the wall to the back, at the same time taking care that the maximum intensity of pressure does not exceed a certain limit, which, in the case of stiff clay, is 3 tons per sq. ft.; in the case of unconfined sand and gravel, is 2 tons; and in the case of soft, uncertain ground, is 10 cwts. per sq. ft.

Stresses in Dock Walls.

Stresses in Dock Walls.—The calculation of the stresses in a dock wall is a very complex problem, involving a considerable number of elements, the exact determination of which is impracticable, so that they have largely to be based on conjecture. Briefly stated, the conditions are as follows: The wall is subjected to the overturning influence of a wedge-shaped mass of earth which represents the excess of material behind the wall lying above the plane of natural slope of the material. The pressure, of course, is intensified by any surcharge upon the surface area of the wedge. The restraining force is the weight of the wall itself, acting vertically downward, assisted to some extent by the earth backing which may rest upon offsets, if any, at the back of the wall.

In fig. 13, let A B D K G be the outline section of a dock wall.

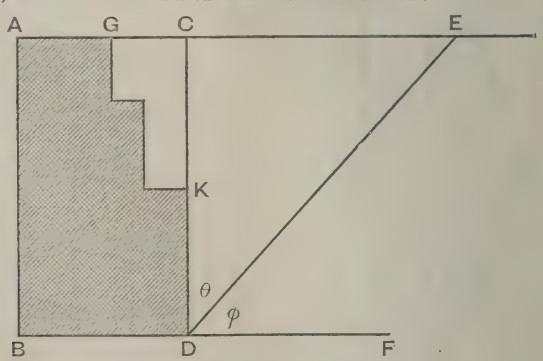

FIG. 13.

Let E D be the plane of natural slope of the ground behind the wall, i.e., the slope which the material would assume if left unsupported. The angle E D F will be designated ϕ and is known as the Angle of Repose.

Let the height of the wall A B be h, and w be the weight per unit volume: and let v be the weight per unit volume of the earth behind the wall.

Then the weight of the wedge of earth behind the wall, tending to overturn it, is

$$\frac{vh^2}{2} \cdot \tan \theta.$$

In order to cover cases where the back of the wall is not vertical and where the surface of the ground is not horizontal, this expression may be written in general terms :

$$\frac{vh^2}{2} \times \text{constant},$$

and the value of the constant, as determined by Professor Rankine in accordance with a theory which neglects any cohesion between the earth particles, is

$$\frac{1-\sin\phi}{1+\sin\phi}.$$

The line of action of the overturning force,

$$\frac{vh^2}{2} \cdot \frac{1-\sin\phi}{1+\sin\phi},$$

is taken as parallel to the surface of the ground and the point of application at one-third the height of the wall measured from the base.

For simple practical calculations for dock walls where the quay surface is almost invariably

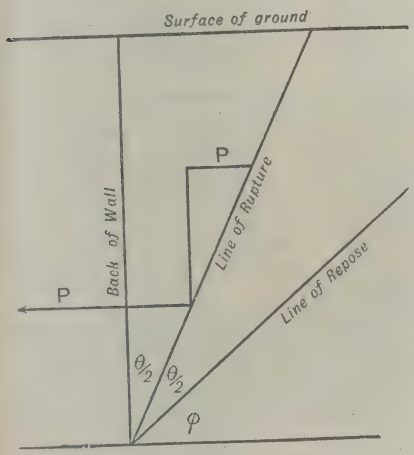

FIG. 14.

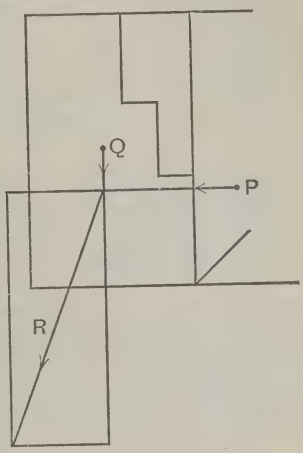

FIG. 15.

horizontal, the angle θ ($=90°-\phi$) is bisected and the value $\frac{\theta}{2}$, fig. 14, taken as representing the angle of the wedge producing maximum pressure, the other moiety being ineffective as regards overturning owing to the support it receives from the earth beneath it. The weight of the triangle $\frac{h^2}{2}\tan\frac{\theta}{2}$ is computed, and the horizontal component, P, taken of the force acting down the plane of rupture, of which $v\frac{h^2}{2}\tan\frac{\theta}{2}$ is the vertical component. This constitutes the overturning force, which may accordingly be written :

$$P=\frac{vh^2}{2}\tan^2\frac{\theta}{2}$$

The point of application of P is again at one-third of the height of the wall.

The restraining force Q is measured by the sectional area of the wall A B D G, fig. 13, multiplied by w, together with the sectional area of the earth G K C resting on the wall, multiplied by v, the two acting vertically downwards through their common centre of gravity.

Calling the overturning force P, and the restraining force Q, fig. 15, and completing the parallelogram of forces, the resultant R will be obtained, representing in magnitude and direction the force acting at the base of the wall.

So long as the line of action of R falls within the base of the wall, there is theoretical stability, but, for practical constructional purposes, it is essential :

(1) That the line of action of R should not fall outside the middle third of the base line, and

(2) That the magnitude of R should not be sufficient to crush the base ; in which connection it is to be noted that the intensity of pressure increases with the eccentricity of the resultant (i.e. its distance from the centre) and that when R passes through the limiting point of the middle third of the base, the intensity of pressure on the outer edge is just twice the mean intensity. As a rough practical rule in designing dock walls, the mean width or thickness may be made about one-third of the height. It should never be less than one-fourth. The base width may be about one-half the height, but need never be more than two-thirds.

EXAMPLES OF PROPORTIONS ADOPTED FOR DOCK WALLS.

Entrance Locks.

Entrance Locks.—During periods when the water in a dock is impounded at a higher level than that of the external water, the dock can only be entered through the medium of a lock. The size of lock chambers is governed by the dimensions of the ships making use of them, and these vary at different ports. The largest vessels in existence at the present time are 900 ft. to 950 ft. long by 95 ft. to 100 ft. broad, and they draw from 35 ft. to 38 ft. of water when loaded to their full capacity. No port can claim to be of the first rank which does not receive vessels from 500 to 600 ft. long, with 60 to 70 ft. beam and drawing 30 ft. of water.

Dock Gates.

Dock Gates.—Where the rise and fall of the tide does not exceed about 12 ft. the inducement to provide completely enclosed areas for shipping is not great, but above that limit the necessity for impounding the dock water becomes evident on account of the inconvenience arising from rapid changes of level, frequent alteration in moorings, and chafing against the quayside.

Dock gates are either of steel or wood—in the latter case of greenheart, jarrah, or other hard, heavy, durable timber. Greenheart gates cost more than steel gates—in some cases nearly 50 per cent. more—but their natural durability is very great and the cost of maintenance practically nil. Unfortunately, they are subject to the attacks of sea vermin, and in certain ports considerable trouble has been experienced from this cause. Salt water, especially if contaminated in any way with sewage, is extremely deleterious to ironwork, and the life of a steel gate, under these circumstances, can scarcely be expected to exceed 30 years. Greenheart gates have been found in excellent condition at the end of 50 years.

Stresses in Dock Gates.

Stresses in Dock Gates.—Dock (double-leaf) gates are maintained in equilibrium under the action of four external forces :—(1) the resultant pressure of the water against the back of the gate $= \frac{wh^2}{2}$ per lineal foot of gate, where w (62½ lbs. for fresh, 64 lbs. for salt water) is the weight of a cubic foot of water, and h its height behind the gate. This force acts horizontally at one-third of the height. When there is water on both faces $p = \frac{w}{2}(h^2 - h_1^2)$, and the line of action is

* See footnote page 1324.

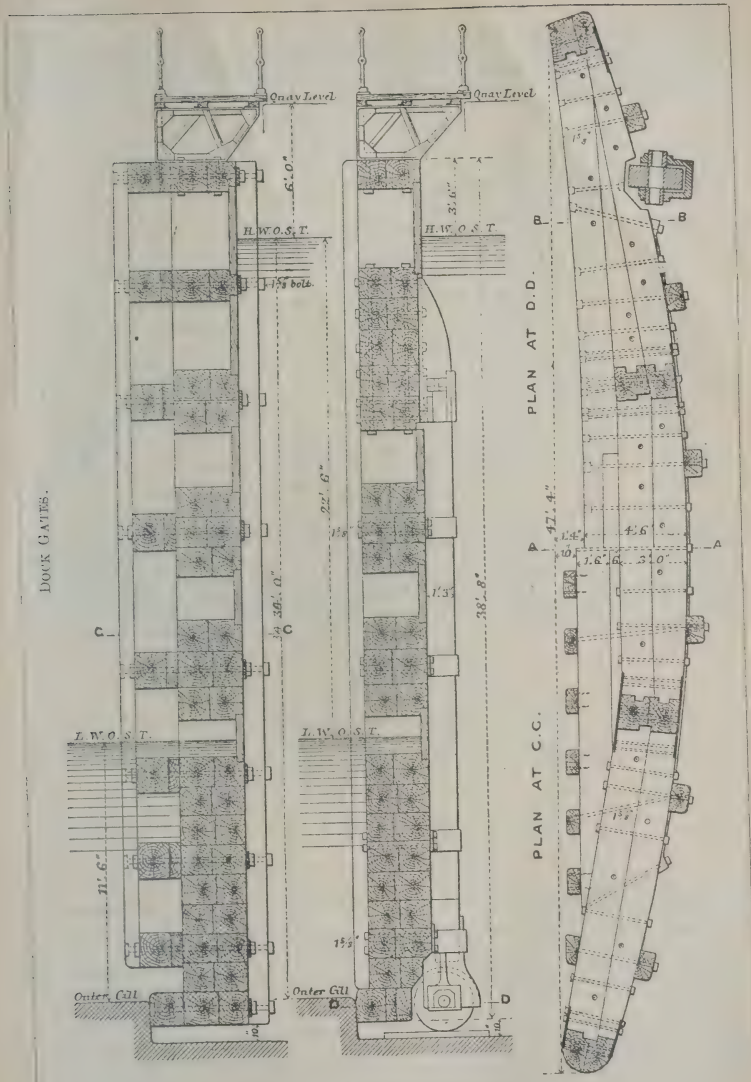

FIG. 16.—Dock Gates. (Timber.)

determined by the centre of gravity of a quadrilateral representing the difference in pressure. (2) The reaction of the mitre or meeting posts of the gates acting perpendicularly to the meeting faces, and therefore also perpendicular to the centre line of the waterway. (3) The reaction of the hollow quoins passing through the heel-post of the gate and also through the point of intersection of the other two forces. (4) The reaction of the sill, which is generally neglected.

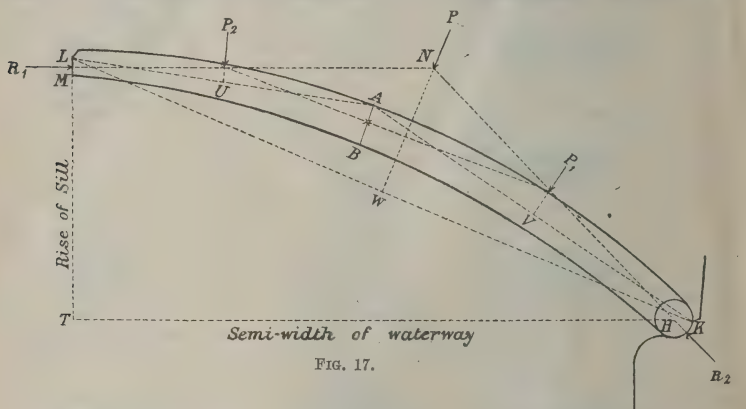

FIG. 17.

Fig. 17 represents the plan of one leaf of a pair of gates. P is the total water pressure upon the back of the leaf, assumed concentrated at its centre. R_1 is the mitre-post reaction of the adjoining leaf, taken as passing through the centre line of the abutting surfaces. R_2 is the reaction of the hollow quoin, assumed to act through the axis of the heelpost. These three forces being in equilibrium, the triangle of forces *ors* (fig. 18) can be drawn, having its sides parallel to

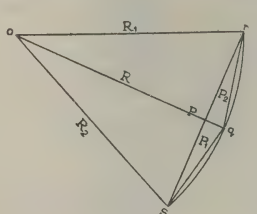

FIG. 18.

the forces P, R_1, and R_2 respectively, and since the magnitude of P is known, the magnitudes of the other two are determined.

If now it be required to find the position and amount of the resultant stress across any section AB (fig. 17) of the gate, the procedure is as follows:—Join the point A to each of the extremities K, L of the water-bearing surface of the leaf; bisect these lines at U and V respectively, and draw perpendiculars to represent the total water pressure on each section. Each section is in equilibrium under the action of these forces: in one case, the water pressure, the heelpost reaction, and the stress across AB; in the second case, the water pressure, the mitre-post reaction, and also the stress acting across AB in the opposite direction. Join the points of intersection of the known forces to obtain the line of action of the resultant pressure at the section AB. Its magnitude may be determined by drawing a parallel line, *qo*, in the force diagram from the point *o* (fig. 18). By taking a series of sections in this way, it will be found that the locus of *q* is sensibly the arc of a circle, and therefore that, except in the case of very flat gates, the resultant pressure is so nearly constant as to be justifiably considered so without serious error.

Rise of Sill.—The 'rise of sill,' MT (fig. 17), varies in different cases from $\frac{1}{2}$ to $\frac{1}{8}$ of the 'span of the gates' or width of waterway. The vicinity of the latter limit is the more common, especially for large cylindrical gates, where a large rise would entail a correspondingly long and deep recess in the side walls.

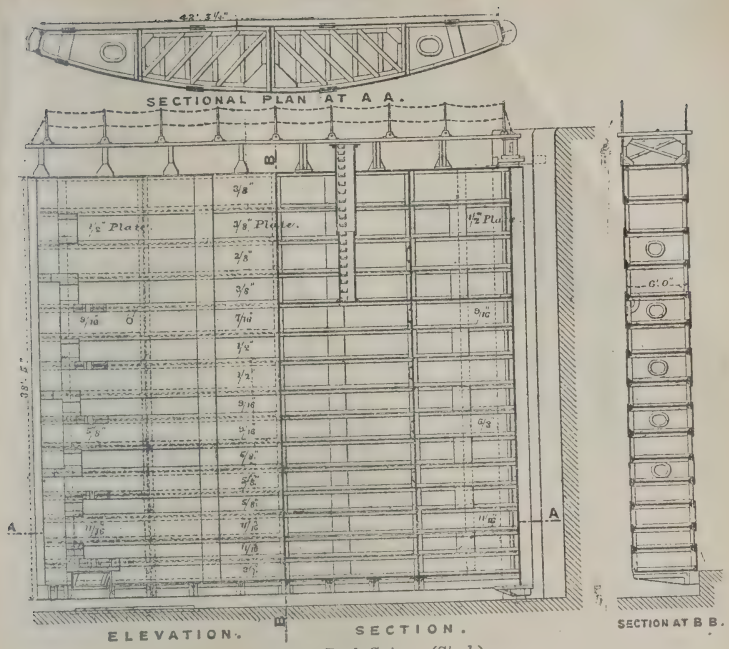

FIG. 19.—Dock Gates. (Steel.)

CAISSONS.

Caissons are sometimes preferred to gates on the ground that they do not absorb the length of side walls which is required to house gates when a passage is open. Furthermore, although the first cost of a caisson is undoubtedly in most cases greater than that of a pair of gates, yet if the cost of a swing bridge for vehicular traffic, which is a necessary adjunct in the case of gates, be also taken into consideration, the advantage will be found to lie with the caisson.

Caissons are mainly of two types: traversing and floating. Traversing caissons are rectangular boxes with a rectilinear motion either sliding or rolling. When withdrawn from the passage way, they are housed in a special chamber constructed in the side wall. Floating

* See footnote page 1324.

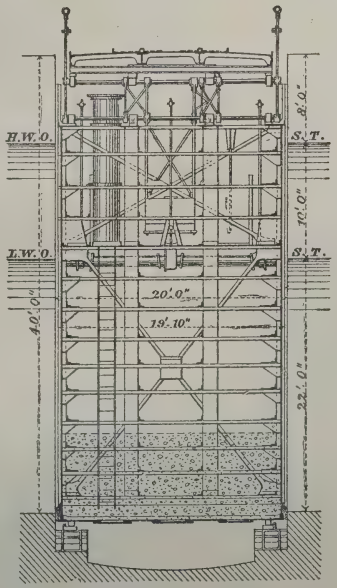

FIG. 20.—Section of Traversing Caisson.

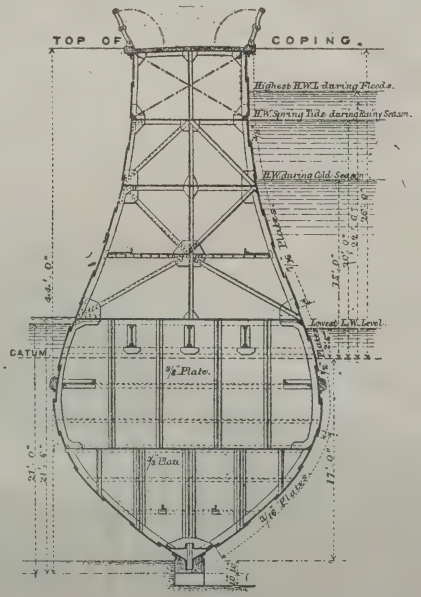

FIG. 21.—Section of Ship Caisson.

caissons are usually ship-shaped, having more or less the form of a navigable vessel, though the curvature of the sides varies very much with the depth of water in which they have to float. Floating caissons are not easy to manage in boisterous weather and strong currents.

QUAYSIDE APPLIANCES.

Quay Cranes.

For general work, quay cranes range in lifting capacity from 1 to 3 tons. The usual capacity is 30 to 40 cwts. It very often happens that the parcels from a ship's hold do not exceed 12 to 15 cwts., and, under these circumstances, a hydraulic crane of single and much higher power than this cannot be worked to advantage, as the consumption of pressure water is the same whether the load be infinitesimal or the maximum. Electric cranes are better adapted to variable loads, since the current consumed is directly proportional to the work done. On the other hand, the initial cost of electric cranes is some 30 to 40 per cent. more than that of hydraulic cranes, and the capital charges (interest and depreciation) are factors of considerable importance in estimating the relative economy.

Crane Types.—Quay cranes are generally movable and include several types.

(*a*) The ordinary crane, with a wheel gauge of 10 to 15 ft. running at quay level.

(*b*) The portal crane, with an arched base spanning one or more lines of railway sidings and admitting of the passage of rolling stock beneath the crane.

(*c*) The semi-portal crane, like an inverted L, with one leg or support running on a rail at quay level, and the back support carried by a rail at a higher level on an adjacent shed structure, the object being the same as in the case of the portal crane.

(*d*) The roof crane, carried entirely on the roof of the shed or warehouse.

Types (*a*) and (*d*) are adapted to cases where there are no sidings and type (*d*) where the shed is situated close to the edge of the quay.

The *cycle of operations* of a quay crane consists of lifting from a hold, slewing, depositing, and returning unloaded, and should, in ordinary cases, where the range of lift does not exceed 50 or 60 ft., be performed in about one minute. A good average under favourable conditions would be 50 cycles per hour; but spread over any lengthy period, this rate could hardly be maintained, for reasons entirely unconnected with the crane.

Speeds of Quay Cranes.—The ordinary speeds of 30 to 35 cwts. quay crane machinery are as follows:—

Lifting, full load	250 ft. to 300 ft. per min.
Lifting, light	350 ft. to 400 ft. per min.
Lowering, full load	400 ft. per min.
Lowering, light	150 ft. per min.
Slewing	one revolution in 25 or 30 seconds.

Luffing Cranes.—It is an important consideration in modern quayside work that cranes should have considerable outreach. Not only is it necessary for them to plumb the hatchways of vessels moored alongside, but in many cases it is desirable to command a barge or lighter beyond. This involves an outreach of 50 to 60 ft. from the face of the quay for even vessels of moderate beam, and entails a luffing or derricking movement of the jib. In view of the obstruction to radial movement caused by ships' yards and stays, the luffing of the crane jib has of recent years become an important feature of crane design. Formerly, the load was unavoidably raised during the inward travel of the jib with a correspondingly unnecessary expenditure of energy and time. This has now been obviated by the introduction of compensating luffing gear by means of which the load is carried at a uniform level throughout its range of travel.

Fixed Quay Cranes.—Fixed quay cranes are provided for dealing with special loads of considerable calibre. The powers provided are generally 5, 7, 10, 12, 15 and 25 tons, with appliances at first-class ports ranging up to 100 or 150 tons. The rates of lifting are correspondingly slower; about 150 ft. per min. for 5-ton cranes, 30 ft. per min. for 25-ton cranes, and 20 ft. per min. for 50-ton cranes.

(See also 'Wharf Cranes,' page 790.)

* See footnote page 1324.

Floating Cranes.

Floating Cranes.—For the heavier lifts, floating cranes are often preferred. It is a convenience to bring the crane to the ship rather than *vice versâ*. Against this must be set the greater initial and working cost of a floating crane. Floating cranes are provided at most first-class ports of lifting power ranging from 25 to 100 or 150 tons. A floating crane recently built for a Japanese port has a working load of 200 tons at 105 ft. radius, 100 tons at 150 ft. radius, and 30 tons at 160 ft. radius. The heaviest lifts are performed at the rate of 5 ft. per minute. A revolution takes 6 to 8 minutes.

(See also CRANE Section, page 783.)

A floating crane of 200 tons capacity has recently been acquired by the Mersey Docks and Harbour Board. It is an electrically-driven, derricking, and revolving crane, 154 ft. in length, 88 ft. in breadth, and 16 ft. in depth. The hoisting speeds vary from 6 ft. per min. for loads of 200 tons, to 20 ft. per min. for loads of 60 tons. The highest point of the jib at its highest position is 246 ft. above the water-line, with a maximum radius for loads of 60 tons amounting to 183 ft., and for loads of 200 tons, to 110 ft. The vessel is named the *Mammoth*; in conjunction with its outreach it is claimed to possess the largest lifting capacity of any existing floating crane.

Transporters.

Transporters.—Where loads are uniform, can be readily handled, and have to be transmitted some distance, a transporter offers considerable facilities for dealing with them at high speeds, ranging up to 1,200 or 1,500 ft. per minute. Quayside transporters have generally to be furnished with hinged cantilever ends capable of being raised when out of action. The travelling motion is not necessarily rectilinear, curved tracks being employed where necessary.

Coaling Appliances.

Coaling Appliances.—Coal is shipped in a variety of ways, principally by means of the hoist and tip, and also largely by crane. The hoist raises the wagon to the requisite height and tips it at an angle of 45° or 50°, so that the contents pass into a shoot. The crane lifts the wagon bodily, slings it over the ship's hatchway and there empties it. At Cardiff, the wagon, instead of being lifted, discharges its contents into a hopper placed in a pit on the quay, and the hopper is lifted by the crane and lowered into the hold, where, being fitted with cone valves, it can be emptied within a few inches of the floor. This system is adopted on account of the great liability of the South Wales coal to breakage and comminution. The protection of coal from breakage is of such importance that in nearly all cases where coal is tipped from a considerable height an anti-breakage crane is provided to lower the first few loads to the bottom of the hold.

The belt conveyor is now very generally in use for the purpose of loading coal.

Coal wagons are commonly built to contain 10, 12, 15 or 20 tons of coal, and the gross weight ranges from 15 to 30 tons. To this must be added from 6 to 9 tons for the cradle or platform. Consequently the lifting capacity of a coaling appliance will range between 20 and 40 tons according to the class of wagon dealt with. In certain special cases, as at Goole Docks, provision is made to lift a gross load of 50 or 60 tons, of which 40 tons is coal. The coal is brought along the Aire and Calder Canal in tanks which are floated under the hoists.

The rate of coaling by an ordinary crane or hoist is from 300 to 450 tons and may even reach 600 tons per hour, but it is largely governed by the rate of trimming operations in the hold. The lifting and lowering of the wagons is done at speeds of between 100 and 180 ft. per minute and slewing at about one revolution per minute.

Grain Elevators.

Grain Elevators.—Grain is handled either by the bucket elevator and conveyor, or by the pneumatic elevator or suction apparatus. The latter has the advantage that the pipes, being flexible, can easily be taken to the furthermost parts of a ship's interior, and that no restrictions are imposed by variations in freeboard and depth of hold. The bucket elevator, though cheaper to construct and requiring less power, is hampered in working by the necessity of ploughing and trimming a preponderant portion of the grain—often as much as 80 per cent.—to the elevator leg. A special gang of competent men is required for the purpose, and this, of course, increases the cost of handling.

It is impracticable to do trimming with a ship's winch at a higher average rate than about 80 tons per hour. Beyond this limit the pneumatic machine becomes more effective, and pneumatic elevators can be constructed so as to give outputs of between two and three hundred tons per hour. On the other hand, conditions at ports are often such that so high a rate of discharge cannot be maintained, operations being governed by the rate of delivery. In practice, something like 100 tons per hour is found to be the maximum consistent with effective working.

It has recently been realised that quite small pneumatic plants can be installed in warehouses, mills, etc., with extremely satisfactory and economical results in working. They vary in capacity from 15 to 50 tons per hour, and are generally driven either by the mill shafting or by electric current where available. Convenience in handling, absence of dust and avoidance of trimming are strong points in their favour.

An objection urged against the suction apparatus is that the surface friction of the pipes tends to injure some of the more delicate classes of grain, such as malting barley, but this drawback, for all practical purposes, has been eliminated of late years by the easing of bends and the removal of all internal projections in the pipes. In any case it should not be overlooked that the

cutting and driving action of the buckets of a bucket elevator cannot be without some similar attritional effect.

Bucket elevators are either housed at the quayside or are mounted on barges, in both cases being fitted with derrick supports and suspension gear to enable them to be projected forward and set into the ship's hatchway. Elevator speeds generally range between 200 and 400 ft. per minute, but may be as high as 600 ft. per minute. Band or belt conveyors (page 829) run at 300 to 600 ft. per minute, but for light grain, such as oats, the speed should not exceed 500 ft. per minute.

Timber Appliances.

Timber is not successfully handled by conveyors, and is best dealt with by steam cranes of moderate capacity (30 cwts. to 2 tons) which, arranged to run at right angles to the quay front, convey their loads to an adjacent storage ground at speeds up to 600 ft. per minute. The lifting speed is about 160 ft. per minute, and the slewing speed about 1½ to 2 revolutions per minute.

GRAVING AND FLOATING DOCKS.

A modern graving dock is an excavated chamber, two sides, one end and the floor of which are lined, either naturally or artificially, with watertight material, generally concrete with brick or granite facings and dressings. The remaining end is the entrance and is provided with a pair of gates or a caisson. After the entry of a ship, the entrance is closed and the water is pumped from within the dock, though, in certain cases, where graving docks are entered direct from a river or open waterway where tidal conditions prevail, the operation may be assisted, and sometimes be altogether effected, by the fall of the tide.

The floating dock is an open-ended hollow structure of steel or iron, which, in order to receive a vessel, is sunk to the requisite depth, by allowing its air chambers to fill with water. When the vessel has been berthed, this water is pumped out, the dock rises bodily and so lifts the vessel above the water line.

It is not altogether easy to make an effective comparison of the respective merits of graving and floating docks, on account of the wide divergence in the conditions to which each structure is specially applicable, and, although there are strong and convinced advocates for the general superiority of one or other of the two systems, a brief summary of the most salient considerations will show that it is scarcely justifiable to decide conclusively in favour of either. Floating docks are almost exclusively adopted at Hamburg, Rotterdam and other Continental ports; in the United Kingdom there are, at the present time, about 18 graving docks to every floating dock.

A graving dock requires a good foundation at a reasonable depth, and a disposition of site which frequently involves the appropriation of a considerable area of valuable land.

A floating dock requires a sheltered position with an adequate depth of water, which, if not obtainable naturally, will have to be gained by dredging. The depth of water to be provided for a floating dock must be sufficient to cover the draught of the ship, the depth of the pontoons and the requisite clearances of a foot or two between keel and blocks and between pontoon and bed. Where there is tidal variation, the amount of this must also be added if the dock is to be continuously accessible. In this country the tidal range may be anything up to 35 ft., and between 15 and 20 ft. is very general. For a modern ship of average size drawing 28 to 30 ft. of water, the pontoons would have to be at least 20 ft. deep. This means that the total depth of the floating dock berth below high water level would be about 70 feet, and there are circumstances under which dredging to so great a depth would be not merely difficult, but almost impracticable.

In sites where the foundation is defective, the depth of excavation required for the floor of a graving dock may easily equal the depth of the floating dock pontoons, and the difficulties and expense in these cases are just as pronounced.

The utility of a graving dock is measured by the linear dimensions of the largest vessel which it can accommodate. The weight of the vessel is relatively a matter of little or no importance.

On the other hand, the utility of a floating dock is gauged by its maximum lifting capacity and is independent of the exact size of the vessel. Floating docks can, and often do, take vessels many feet in excess of their own length and, in the case of one-sided docks, in excess of their own width.

The size of the entrance of a graving dock is influenced by the cost of the gates, or caisson, to be used for closing it, and by the greatest width that can safely withstand the pressure of water. In floating docks these considerations do not enter into account.

Relative Costs of Graving and Floating Docks.*

Initial Cost.—The initial cost of graving docks, including pumping and general equipment, measured in terms of their serviceable dimensions (i.e. internal length by breadth of entrance by depth of water over blocks or sill), has varied from 1*s.* 3*d.* to 3*s.* 6*d.* per cubic foot, and, in a rough-and-ready way may fairly be taken for a modern concrete and granite dock of ordinary size, constructed in this country under normal conditions, on a pre-war basis, at 2*s.* per cubic foot.

The initial cost of floating docks measured in terms of their lifting power had generally a range of from 8*l.* to 12*l.* per ton, and may similarly be taken in the United Kingdom as averaging a pre-war price of 10*l.* per ton.

For a vessel 500 ft. long by 55 ft. beam with 28 ft. draught, a graving dock 520 ft. by 60 ft.

* See footnote page 1324.

by 30 ft. would cost under normal conditions from about 95,000*l.* to 100,000*l.* The vessel would have a displacement of, say, 13,000 tons, and, assuming it to be lightened to 10,000 tons, the cost of a floating dock to lift that weight would be about the same. To this would, of course, have to be added the cost of shore connections and dredging where required.

As regards time of construction, a graving dock of any importance could hardly be completed within less than eighteen months or even a couple of years, whereas a floating dock could be ready in half the time. The floating dock could, moreover, be constructed in any convenient locality and transported to its destination at some additional expense for towage and insurance. Many floating docks for the colonies are constructed in home shipyards.

Durability and Upkeep.—A stone or concrete graving dock is practically indestructible, and the only charge brought against it, in this respect, is that of outlasting its utility and becoming obsolete. This is, no doubt, true in regard to the class of vessel for which it is constructed; but, on the other hand, when the growth of shipping has left the graving dock too small for the larger vessels, it is still utilisable for those of smaller size. With the exception of the expenditure on the gates or caisson, which close the entrance, there is practically no maintenance outlay. It is all probably covered by an allowance of $\frac{1}{2}$ per cent. per annum.

The life of a floating dock, considered as an iron or steel structure constantly afloat, will vary with its situation, some waters being more destructive than others. It may be fairly reckoned at from 30 to 40 years, although there is no reason why, with reasonable care and attention, the longer period should not be exceeded. The annual cost of maintenance estimated from several existing examples lies between 1 and $1\frac{1}{2}$ per cent. of the capital outlay. Any cost of dredging required to keep the berth clear of mud deposits must be added to this allowance.

Working Cost.—The amount of pumping to be done in the case of a graving dock generally greatly exceeds that in the case of a floating dock—it may be as much as 3 or 4 times. In a floating dock only so much work is required to be done as is necessary to raise the vessel and the deck of the pontoon above water level. The graving dock chamber, on the other hand, has always to be completely dewatered, no matter what may be the size of the vessel occupying it, and the smaller the vessel the greater the quantity of water to be pumped.

Small graving docks on the banks of a tidal river, in cases where time is unimportant, may be emptied of water by natural means. These cases are exceptional.

But even in the larger docks the cost of pumping is small in comparison with the capital charges. For one hundred dockings a year they probably do not amount to more than 10 or 12 per cent. of the whole annual expenditure.

Again, the pumps being only intermittently employed, one pumping station may be made to serve two graving docks, whereas each floating dock requires its own installation. Possibly an extra hand or two is also needed to attend to the valves of the floating dock in order to maintain an even keel during pumping operations, but generally all the valves are worked from a central position.

As regards general adaptability, floating docks have the advantage, already pointed out, of mobility, and they may be transferred from one port to another, whenever the circumstances require, and even, in case of urgent necessity, one of them could be sent to meet a sinking ship. This step, however, could only be taken as an extreme measure; the docking of a vessel in the open sea would be attended by grave risks.

A floating dock can be trimmed to take a vessel having a list which conceivably might interfere with its passage through a graving dock entrance with vertical sides. This operation was frequently performed during the war.

The mobility of a floating dock is in fact not free from certain drawbacks. The dock may capsize, founder, or be wrecked.

All these varying considerations point to the conclusion that there is scope for both graving and floating docks, and that each may be employed to better advantage than the other under some particular set of local conditions.

Notes on Floating Docks.

(Contributed by Swan, Hunter, & Wigham Richardson, Ltd.)

Floating docks may be conveniently divided into two classes : (*a*) those which are not self-docking, or ' box docks,' and (*b*) those which can be self-docked.

(*a*) The *box dock* is double sided and of ⌊ ⌋ section. It has two side walls, and is the only form of modern floating dock which cannot be divided into more than one part for the purpose of self-docking. The two side walls and the bottom pontoon are one permanent structure. Box docks of great size have been built ; for instance, the British Admiralty floating dock of 33,000 tons lifting capacity built at the Wallsend Shipyard and stationed at the River Medway.

(*b*) By a ' self-docking ' type is meant a dock divided into sections any one of which can be lifted on the remainder of the dock for painting or repairs. The following are the various types of self-docking docks, the *Bolted-Sectional*, the *Sectional Pontoon* or *Rennie*, the *Off-Shore*, the *Havana*, the *Sectional Box*, the *Multi-Sectional*, and the *Depositing*.

The *Bolted Sectional Dock* is the latest improvement, and combines the advantages of the great longitudinal strength of the '*Box*' type with facility for self-docking. It is probably the best

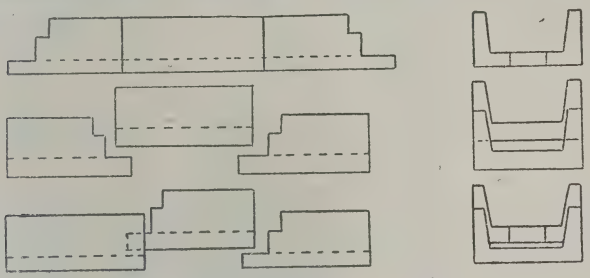

FIG. 22.—Bolted Sectional Floating Dock.

type of dock for large sizes. This type is usually built in three sections of approximately equal lengths, the two end sections being stepped to form landings when carrying out a self-docking operation.

Fig. 22 shows, firstly, the whole dock assembled ; secondly, the centre section lifted by the two end ones ; and thirdly, one of the end sections lifted by the centre and other end section. Examples of the former type of dock may be seen at Port of Spain (Island of Trinidad), Rotterdam, at Callao in Peru, and at Sténia in the Bosphorus. (See fig. 27, page 1343.)

The Sectional Pontoon Dock (also called ' the Rennie Dock,' after its inventor), consists of a number of separate pontoons lying transversely to the length of the dock. Upon these pontoons and bolted to them rest two continuous side walls. The length of each pontoon, i.e. on the keel line, is such that when detached from the rest of the dock it can be passed end-wise between

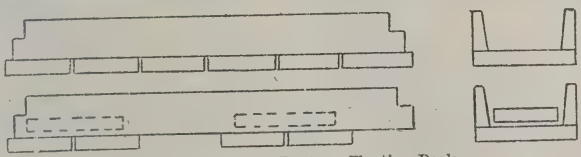

FIG. 23.—Sectional Pontoon Floating Dock.

the walls of the latter and so lifted in the same manner as a ship. Each pontoon can be successively dealt with in the same manner. Fig. 23 shows first the whole dock assembled and then two of the pontoons lifted by the remainder of the dock. This *Sectional Pontoon* type is very suitable for vessels of moderate dimensions, and owing to its form can easily be constructed in places where docks of other types could not be completed. The separate pontoons not being very large in size can be easily erected and launched, after which the walls can be built upon them. Examples of this type of dock were built at Wallsend-on-Tyne for the Government of Southern Nigeria, and for service at Saratov on the River Volga.

The Off-Shore Dock is an ingenious design patented by Messrs. Clark & Standfield in 1884; a well-known example of it was built at Wallsend-on-Tyne for a ship-repairing establishment at Sunderland, and there is another good example of it also constructed by Messrs. Swan, Hunter, & Wigham Richardson, Ltd., at Penarth, near Cardiff. The off-shore dock (fig. 24) of

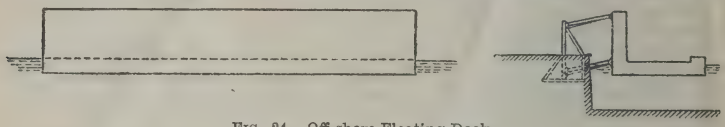

FIG. 24.—Off-shore Floating Dock.

which the end elevation is 'L' shaped, is very easily handled. The side wall is connected to the shore by booms or girders hinged at each end. When the dock is sunk to receive a vessel the latter can enter the dock from either end or may be warped in sideways. It is then rapidly centred by telescopic side shores and supported underneath by mechanical bilge-shores. This type of dock is divided into two sections, and as it has only one wall one-half of the dock can be lifted, so to speak, in the lap of the other.

The Havana type consisted of two continuous side walls between which were three separate pontoons attached to the walls by bolts passing through projecting lugs (fig. 25). This type of dock has been superseded by later types.

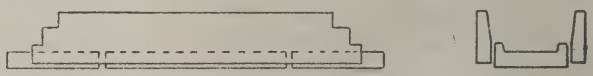

FIG. 25.—Havana Floating Dock.

The *Sectional Box Dock* combines the advantage of ease and simplicity in self-docking possessed by the Sectional Pontoon dock, with the strength of the solid or *Box* dock. The dock is divided, like the ordinary sectional dock, into sections of such a length that any one section can be turned round 90 degrees and docked on the rest of the dock. In the Sectional Box dock, however, the sections are all joined together by a strong, rigid joint of a similar type to that used in the bolted sectional docks running round the whole profile of the dock.

The *Multi-Sectional Dock* is a modification of the Sectional Dock type. In small docks it is not necessary to connect the bottom plating right across the width of the pontoon. The joints at the sections only occur, therefore, round the profile of the side wall, the spaces between the pontoons being decked over to form a continuous platform.

The *Depositing Dock* was designed as early as 1877, by Messrs. Clark & Standfield. In section it is 'L' shaped. The single side wall is continuous, but the bottom pontoon is made up of a series of 'fingers' with spaces between them (fig. 26). The necessary stability is given to the dock

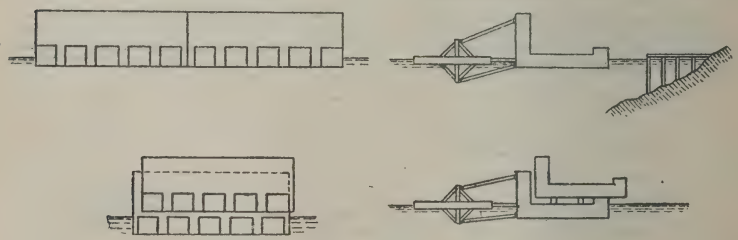

FIG. 26.—Depositing Floating Dock.

by means of parallel booms hinged at each end and connected to a floating outrigger. This type of dock can not only dock vessels, but owing to the peculiar construction of the bottom pontoon is enabled to deposit them on a gridiron formed by groups of piles. There are spaces between each set of piles of such a width as to admit the 'fingers' of the dock. The dock carrying a ship is pushed forward so that the 'fingers' are engaged between the piles and then on sinking the

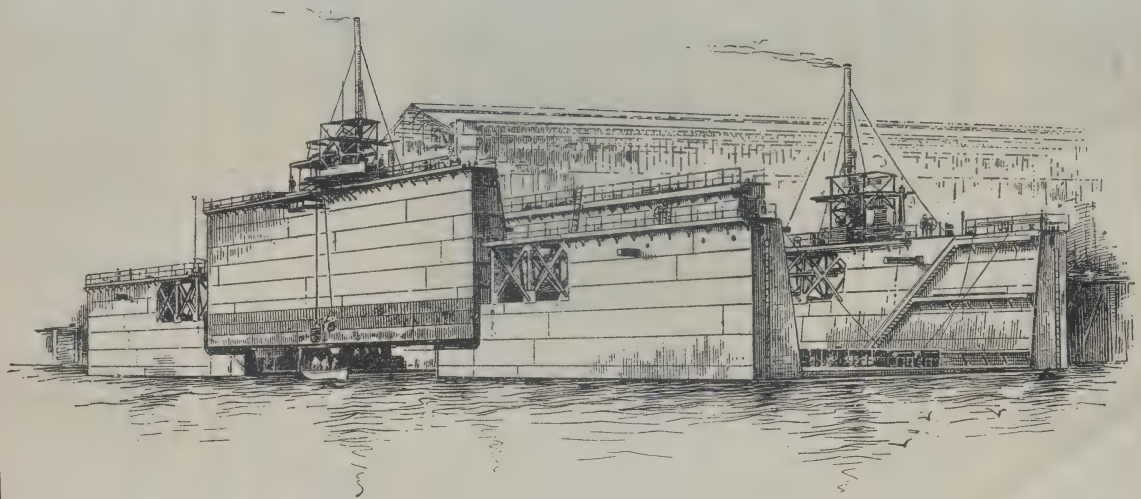

Fig. 27.—Bolted-Sectional Dock.

(Built by *Swan, Hunter, & Wigham Richardson, Ltd.*, Wallsend-on-Tyne, England.)

Self-docking operation; centre section lifted by the two end-sections.

dock the ship is left upon the gridiron. The wall of the dock is divided into two equal lengths either of which can be docked by the other as in the case of the off-shore type.

Depositing docks at Kobe and Barcelona have been used for the purpose of lifting large hollow ferro-concrete blocks for harbour construction. These were built upon the depositing grids, lifted off by the dock, and finally floated off so that they could be towed to their final position and sunk there. In the case of the Kobe dock, some of these monoliths were 120 ft. long by 41 ft. high, and weighed as much as 2,200 tons. In this way the difficulty of launching such large masses was avoided and much expense saved.

DREDGING.

Modern dredging appliances may be summarised under two classes, each with several subdivisions.

Class I.—Digging dredgers, comprising (*a*) the ladder, or elevator, dredger, with a continuous band of buckets; (*b*) the dipper dredger, with a single bucket at the extremity of a long arm, or lever; and (*c*) the grab or grapple dredger, with a drop bucket suspended at the end of a chain.

Class II.—Suction or hydraulic dredgers, comprising (*a*) the sand pump; and (*b*) the suction cutter dredger.

Rock cutters are not dredgers, but constitute an auxiliary class which will be treated separately.

Ladder Dredgers.

Ladder Dredgers, or Elevator Dredgers (sometimes in Europe called bucket dredgers), are characterised by high power and great serviceability under nearly any conditions. They are adaptable to the removal of every variety of material except the harder kinds of rock. The principle upon which they are constructed is that of an endless chain of buckets travelling in an elliptical path about two pivots, or tumblers, set one at each extremity of an inclined plane. The buckets excavate material at the lower tumbler and discharge it into a shoot while passing over the upper tumbler.

Single Ladder v. *Double Ladder Dredgers.*—Dredgers of the ladder type have either one or two ladders. In single ladder dredgers, the ladder is situated along the centre line of the vessel; in the other case, the ladders are placed at each side.

Single ladder dredgers are most in favour for ordinary operations. In machines of the same power, they have the advantage of few working parts and of less working friction. As seagoing craft, they possess a more convenient outline, and their lesser width enables them to pass through narrower waterways and lock chambers. But they cannot work so closely to a quay wall as side ladder dredgers, and, if any breakdown occurs in the chain of buckets, the whole dredger is thrown out of action, whereas, with the double ladder dredger, this is not necessarily the case.

Capacity of Ladder Dredgers.—The capacity of the buckets of ladder dredgers ranges from 5 to 54 cubic ft., but, generally speaking, about 35 cubic ft. is looked upon as the maximum size consistent with convenient utility. A moderately sized dredger, with buckets of 20 to 25 cubic ft. capacity, travelling at speeds from 15 to 20 ft. per minute, and working in water of depths up to 50 ft., may be expected to raise from 400 to 500 tons of stiff clay per hour; in suitable material, such as ballast and gravel, the rate obtained may be as high as 1,000 tons per hour. The most powerful dredgers can double this performance.

Examples of Ladder Dredgers.—The following particulars relate to the 'Corozal,' built in 1911 for the U.S. Government, for work on the Panama Canal:—

Dimensions.	Ft.
Length on load water line	239
„ between perpendiculars	259
„ over all	268¾
Breadth moulded	45
Depth moulded	19½
Draught fully loaded	15½

Propelling speed: 10 knots.

Dredging capacity: 1,200 cubic yds. of mud and sand per hour.

Buckets: Two sets; one of 54 cubic ft. capacity for soft material and one of 35 cubic ft. for stiff clay.

Maximum dredging depth: 50 ft.

The vessel is a hopper dredger, i.e. she discharges into herself instead of into an independent hopper ranged alongside.

Another ladder dredger, the Walter Glynn, of the Mersey Docks and Harbour Board, capable of dredging over 400 tons of stiff clay per hour, has the following dimensions:—

Length, 196 ft.; breadth, 35½ ft.; depth, 13 ft. The speed is 10 knots. The propelling engines are two sets of triple expansion, surface condensing engines with cylinders 14 ins., 22½ ins., and 36 ins. diameter, by 24 ins. stroke, driving twin screws; the indicated horse-power is 1,200. The ladder shaft is driven by a separate engine of 300 i.h.p., triple expansion, with cylinders 12 ins., 18¼ ins., and 30 ins. diameter, by 24 ins. stroke.

Utility of Ladder Dredgers.—Although the serviceability of ladder dredgers does not extend to the removal of hard rock, yet they are capable of scraping away the surface of the softer varieties of sandstone and chalk, and, for this purpose, the bucket edges are sometimes fitted with spikes or tines. A ladder dredger works admirably in marl and stiff clay, and no difficulty even is found

F. 1345

in dealing with heavy boulders which are frequently encountered in clays of glacial formation. The buckets of a first class dredger will readily lift stones weighing from 30 cwts. to 2 or even 3 tons apiece, bringing them up to the surface and within the range of a deck crane. As illustrative of the character of the material dealt with in many cases, the following particulars may be cited, relating to twelve months' work on the river Tees. A quantity of 417,963 cubic yds. was dredged at a cost of 22,432*l.*, equivalent to about 1*s.* 6¾*d.* per cubic yd. About two-thirds of this was hard, boulder clay and there were removed therefrom 1,651 stones, varying in weight from 5 cwts. to 4 tons apiece, of which 1,523 were raised by the dredgers unaided by divers; and, in addition, there were 19 tree trunks, ranging in length from 10 ft. to 20 ft., 16 tree roots and stumps, and 107 miscellaneous obstructions.

Dipper Dredgers.

Dipper Dredgers.—The dipper dredger is almost purely an American type, and is not yet found in European waters. It is mainly employed on the great lakes of the Northern Continent of America, and on river beds and channels when the working depth does not generally exceed 20 ft. or so, and where space for manœuvring is somewhat restricted. This is accountable for by the fact that the dredger is not manipulated by chain moorings, as in the case of the ladder dredger, but is maintained in position by vertical spuds, or posts, which pass down through the vessel to the bottom of the channel, and are raised and lowered as occasion may require. The dipper arm itself assists in manœuvring, being allowed to remain on the bottom while the position of the spuds is changed.

Capacity of Dipper Dredgers.—The single bucket, or scoop, at the end of the lever arm has a capacity ranging from 1 to 12 or 15 cubic yds. The bucket is operated in a curved upward sweep by suitable gearing, on the same principle as a steam navvy or land excavator. The speed of a good dipper dredger in sheltered inland waters is from 30 to 40 seconds per dipper load, and on the sea coast from 40 to 50 seconds. For hard material, the bucket, as in the case of the ladder dredger, is fitted with teeth.

Examples of Dipper Dredgers.—The following particulars relate to a very large dredger, the 'Onondaga,' which worked in New York Harbour:—

Length of hull	140 ft.
Breadth ,,	50 ft.
Depth ,,	15 ft.
Capacity of dipper bucket	12 cubic yds.
Dredging depth	50 ft.

Size of dipper arm: 80 ft. long by 36 ins. square.
Spuds: Four timbers, 80 ft. long by 5 ft. square.
The dipper arm and spuds are both of Oregon fir.
Engines: Double cylinder, condensing.
Cylinders: 20·5 ins. diameter by 24 ins. stroke.

Another instance of a dipper dredger at Montreal Harbour:—

Length of hull	90 ft.
Width ,,	36 ft.
Depth ,,	10 ft.
Capacity of dipper bucket	7 cubic yds.
Dredging depth	40 ft.
Diameter of hoisting rope	2½ ins.
Maximum pull on dipper	120,000 lbs.

Forward spuds: Single timbers (Douglas fir) 60 ft. by 42 ins. square.
Engines: Double cylinder (16 ins. by 18 ins. stroke) non-condensing.

Two dipper dredgers, the 'Gamboa' and the 'Paraiso,' each with buckets of 15 cub. yds. capacity, were built by the Bucyrus Co. in 1914 for work on the Panama Canal.

These dredgers have a displacement of about 1,500 tons, and the hulls, which are of steel, have an over-all length of 136 ft., a width of 44 ft., and a depth at bow of 15½ ft. and at stern of 13½ ft. Each dredger has two dipper buckets, the larger, of 15 cub. yds. capacity, for soft material, and the smaller, of 10 cub. yds. capacity, for harder material. The buckets, of ¾ in. plate, have lips of manganese steel, 2 ins. thick, which are 50 ins. deep at the centre, reduced to 9½ ins. at the back edges. They have no teeth. The handles are of Oregon fir, 72 ft. long.

The rate of working is said to average 6,000 cub. yds. per day each, in two 8-hour shifts.

A dipper dredger at work in Bombay Harbour has a bucket capacity of 6 cub. yds. dredges to a depth of 40 ft., and is capable of lifting boulders of over 12 tons weight.

Comparison of Dipper Dredger with Ladder Dredger.—Compared with the ladder dredger the dipper dredger is not quite so serviceable a machine for all-round purposes, and, for the more intractable kinds of material, it has been demonstrated that the former is more efficient than the latter. Thus, in excavating a channel in indurated clay in the St. Lawrence River, dipper dredgers of the most powerful design failed and were replaced by a ladder dredger which completed the work in a satisfactory manner.

The Grab or Grapple Dredger.

The Grab or Grapple Dredger has a bucket which consists of two or more curved plates, or jaws capable of opening and closing under the action of suitable gear. The grab is suspended from the jib head of a crane which does the requisite raising and lowering. The working is

actually done very largely under the influence of gravity, the bucket being allowed to fall with open jaws under its own weight and to bury itself in the ground, where the jaws are closed and the bucket with its contents is then withdrawn. The principle of the grab is simple, but there are many complex adaptations in practice. Thus, the appliance may be worked by one or by two chains, each of which arrangements admits of several variations, so that there are quite a number of different machines on the market, each possessing special characteristics and advantages.

Comparison of Single and Double Chain Grabs.—The drawback of a double-chain grab is that it cannot be fitted to an ordinary crane; but, on the other hand, it has less intricate and less delicate mechanism, and, consequently, does not run the same risk of getting out of order. With two chains, moreover, there is less likelihood of the bucket being lost through fracture of the hauling gear. There is the further consideration that in many, if not most, single-chain grabs, the full height of lift has to be made before the grab can be opened in order to discharge its contents. Double-chain grabs can discharge at any stage of the lift. This advantage is shared by a few of the single-chain systems. Its importance lies in the fact that the grab might close upon some immovable object below water, and therefore necessitate the sending down of a diver, unless the jaws can be opened mechanically in that position.

Utility of Grab Dredgers.—The grab is not a suitable appliance for extensive operations. It is best adapted to dealing with material in confined and awkward situations inaccessible to other types of dredger. It is thus excellently suited for the removal of mud and silt in the vicinity of dock entrances and passages. Silt is generally of so impalpable a character that any disturbance of the water in which it lies causes it to rise in suspension, and renders it difficult of removal. The grab proves a most effective appliance for dealing with this soft material, entrapping it with the least admixture of water and the least alteration in consistency. Moreover, the grab is an extremely convenient implement for picking up miscellaneous articles which find their way to the bottom of docks; logs of hard wood, rails, coal, bales of hay and wool, barrels of nails and cement, hoop iron, etc.

Capacity of Grab Dredgers.—Grabs are constructed of a capacity up to 10 cubic yards, but for general purposes the most useful size lies between 70 and 120 cubic ft. They work very successfully in water up to 50 or 60 ft. in depth, at a speed of about one dip per minute, raising in this way from 150 to 250 cubic yds. per hour.

Examples of Grab Dredgers.—Several excellent examples of this class of dredger are constantly at work in the Liverpool docks. The grabs are mounted on barges of 1,100 to 1,400 tons hopper capacity. There are four 5-ton or 7-ton cranes of 16 ft. and 19 ft. radius respectively on each barge, each actuating a grab of 70 or 115 cubic ft. capacity. The principal dimensions of the vessels are:—

1,100 ton barges . . . . 200 ft. long by 35 ft. beam by 15½ ft. deep.
1,400 ton barges . . . . 225 ft. long by 38½ ft. beam by 16 ft. deep.

The speed of the barges is about 11 knots.

Bag and Spoon Dredging.—This notice of dredging appliances would be incomplete without some reference to a very rudimentary form of apparatus still practised in restricted areas and where operations are on a small scale. This apparatus consists of a strong leather bag of a capacity of from one-half to one cubic yard attached to a steel rim at the end of a stout spar, or pole, from 20 ft. to 35 ft. long. The bag is kept at the bottom by means of the pole, while it is drawn along the surface by a line attached to the rim. The operation is performed by manual labour, and about half a dozen men are required to man a barge for the purpose. The quantity raised and loaded into the barge will range from 60 to 100 cubic yds. per day. The appliance is really only suitable for dealing with mud in timber ponds and in canals.

Suction or Hydraulic Dredgers.

Suction or Hydraulic Dredgers.—Turning now to the second class of dredging plant, the suction or hydraulic type may be described as consisting essentially of a continuous pipe, or tube, through which material is drawn up by suction from the bottom and discharged either into a hopper or through a long pipe line to a depositing site some distance away. The first application of the principle was to the removal of sand—hence the name Sand Pump—but it has since had a much wider application. As regards sand, the method proved extremely effective from the first, the light granular nature of the substance lending itself admirably to easy incorporation with the body of water flowing into the pump intake. Such difficulty as has been experienced has been merely in regard to securing the deposition of the sand within the hopper, the tendency being for a large proportion to flow out over the sides with the escaping water. Considerable reduction in this unremunerative pumping has been made by giving the effluent stream as long a distance to travel as possible and providing the channel with adjustable coamings.

Sand Pump Dredgers.

Sand Pump Dredgers.—For the purposes of suction dredgers, centrifugal pumps are universally employed, and of these, those with a single inlet have an advantage over pumps with a double inlet, in that there is less concussion and interference with the flow. A double inlet pump, on the other hand, disposes of any question of balancing, which has to be met in a single inlet pump by thrust bearings. The most efficient peripheral speed is stated by the Mississippi River Commission to be about 50 ft. per second. The form of the nozzle of the intake pipe materially influences the percentage of sand raised, which may be anything up to 50.

Examples of Sand Pump Dredgers.—The largest sand pump dredger in existence at the present day is the 'Leviathan' of the Mersey Docks and Harbour Board. Her dimensions are 465 ft. 9 ins. long between perpendiculars, by 69 ft. wide by 30 ft. 7 ins. deep moulded. She is fitted with four suction pumps, each of 42 ins. diameter, and is capable of filling herself with 10,000 tons of clean sand in 50 minutes from a maximum depth of 70 ft. The speed of the vessel is 10 knots. On arrival at the depositing ground, she discharges herself in 10 minutes through large cylinders extending from valve openings, 5 ft. 6 ins. diameter, in the bottom of each hopper to deck level. These valves have a lift of 4 ft. and are operated by hydraulic rams. At work on the bar and entrance channel of the Mersey, the Leviathan pumps up over 12 million tons of sand per annum.

The following particulars relate to the 'Coronation,' a vessel in the same service :—

Length between perpendiculars	332 ft.
Breadth moulded	52·7 ft.
Mean draught, loaded	17·2 ft.
Maximum dredging depth	65 ft.
Speed	10 knots.
Loaded capacity	3,500 tons.
Pumping capacity	4,500 tons per hour.
Suction pipes (two)	36 ins. diameter, 81 ft. long.
Propelling engines	2,000 i.h.p.
Pumping engines	800 i.h.p.
Cylinders of propelling engines	19 ins., 30 ins., and 49 ins. diameter by 30 ins. stroke.
Cylinders of pumping engines	12 ins., 20 ins., and 32 ins. diameter by 18 ins. stroke.

Suction Cutter Dredgers.

Suction Cutter Dredgers.—The success attending the introduction of the sand pump led to an investigation of the possibility of dealing with less tractable material by the same means. Water jets for loosening and disintegrating hard and compact strata were added, and some satisfactory results being obtained, the further step of introducing rotary cutters was taken. There was found to be little difficulty in treating in this way earth of a marly or brittle nature, easily resolvable into disconnected particles. Trouble, however, was experienced in dealing with clay and tenacious material, which clogged the cutters and choked the intake. Eventually this was overcome by the evolution of cutter blades of a suitable form and pitch.

Capacity of Suction Cutter Dredgers.—Suction cutter dredgers are now constructed capable of removing over 1,000 cubic yds. of stiff clay per hour. The 'Jinga,' one of two similar dredgers at work in the port of Bombay, has removed 2,700 cubic yds. of blue clay per hour during 80 actual working hours. In this operation a considerable quantity of heavy quarried stone was encountered, many of the pieces weighing over 400 lbs. each, and these were discharged without any trouble whatever, together with the mud and clay, through a tube or pipe line 4,500 ft. long, 2,000 ft. of which was afloat. This dredger worked to a depth of 30 ft. and is self propelling, with a speed of 8 knots.

Use of the Pipe Line.—The use of the pipe line for discharging purposes is becoming very general, especially in cases where it is practicable to use the dredged material for filling and embankment purposes. These lines are often of great length. A dredger working at Oakland, California, U.S.A., has successfully delivered material through 6,170 lineal ft. of 20-in. diameter pipe. Diameters reach as high as 42 ins. when altogether afloat, and 30 ins. to 36 ins. when partly ashore. In calm water thin sheet tubing will suffice, but in exposed situations long lengths of solidly built sections must be provided. The carrying capacity of a 36-in. pipe with 80 per cent. of solid matter conveyed at a rate of 10 ft. per second would be 7,400 cubic yds. per hour. Sand causes considerable wear and abrasion of the piping and requires a high percentage of water with greater velocity to keep it in suspension. Clay, from its unctuous nature, exercises far less frictional resistance and is sometimes rendered sufficiently fluid by 10 per cent. of water. A velocity of 7 ft. per second for clay and mud, and 10 ft. per second for sand, has been found to give good results.

Compound Dredgers.

Compound Dredgers.—A compound type of dredger has recently been introduced fitted with both the suction, or suction cutter, apparatus and a bucket ladder. This enables the dredger to be applied to a wide variety of material in the most effective manner. The bucket ladder is generally placed in the centre well and the suction apparatus at the sides of the vessel, but in some cases the suction pipe is also centrally situated.

Example of Compound Dredgers.—The dredger 'La Loire,' built for service on the river of that name, is a twin screw combined bucket and suction dredger with cutter gear and pipe line shore delivery. Her dimensions are 173 ft. 10 ins. in length by 32 ft. beam by 14 ft. deep. She is fitted with two centrifugal suction and force pumps, capable of raising material from a depth of 25 ft., and of driving it ashore through floating delivery pipes about 30 ft. long and 24 ins. diameter. The suction pipe is 26 ins. diameter and works, together with the bucket ladder, in a centre well.

The cutter has a diameter of 6 ft. 10 ins. and is driven at 12 revolutions per minute, the engine running at 140 revolutions.

The bucket ladder enables the dredger to work to a depth of 52 ft. 6 ins. The buckets have a capacity of 27½ cubic ft. They are driven at a speed of 16 buckets per minute with the engine running at 170 revolutions.

Both suction and bucket apparatus enable the dredger to excavate her own flotation in advance.

The machinery consists of two complete sets of direct acting, triple expansion, surface condensing, reversible propelling engines, each arranged to drive a centrifugal pump as well as the bucket dredging gear. Each set of engines indicates about 450 h.p. when running at 170 revolutions per minute. The cylinders are 13 ins., 21 ins., and 33½ ins. by 18 ins. stroke.

The cutter gear is driven by means of belting from a separate engine of 200 h.p., which also serves for a centrifugal pump delivering spoil from the buckets into the upper part of the shoot.

For the purpose of working the bucket dredging apparatus the suction pipes and cutter gear are dismounted, but in deepening the bed of the river Loire the latter proved so effective that over 13 million cubic yds. of alluvial material have been removed without recourse to the bucket apparatus.

Hopper Service.

When dredged material has to be removed some distance to a depositing ground it is excavated by the dredger into its own hopper, or into hopper barges ranged alongside.

A combined hopper dredger costs less in initial expenditure and subsequent upkeep than a separate dredger and hopper with corresponding or even greater capacity, and it occupies less valuable space in a crowded waterway.

On the other hand, it involves the discontinuity of dredging operations and the frequent getting out and taking in of moorings. This latter consideration is of importance more to dredgers of the bucket ladder type.

On the whole, it is found expedient on undertakings of considerable magnitude to maintain a fleet of hopper barges in attendance on bucket ladder dredgers. Suction dredgers, when they do not discharge through a pipe line, more commonly are compound vessels with self-contained hoppers.

Capacity of Hopper Barges.—Barges are constructed capable of receiving from 500 to 1,000 cubic yds. of dredged material (say 650 to 1,350 tons) and of making journeys to sea and back at speeds of 10 to 11 knots.

Example of Hopper Barge.—A typical barge of 800 tons capacity has a length of about 190 ft., breadth 30 ft. and depth 14 ft. The engines are triple expansion, surface condensing, with cylinders 16½ ins., 26 ins. and 43 ins. diameter by 27 ins. stroke, which at 110 revolutions per minute develop 820 i.h.p. and give a speed of 10 knots, steam being supplied at 180 lbs. per sq. in. from marine multitubular boilers.

Cost of Dredging Plant.*

The following figures may be useful as approximate indications of the cost of dredging plant which must, of course, vary from time to time with fluctuations in the price of material and the engagements of the shipbuilding yards.

Ladder Dredgers.—A 5 cubic ft. bucket, single ladder dredger, capable of raising 150 tons of soft material per hour from a depth of 40 ft., has cost in round figures 7,000*l.*

A 15 cubic ft. bucket, single ladder dredger, capable of raising 400 cubic yds. of sand, gravel and clay per hour from a depth of 45 ft., has cost about 27,000*l.* and was constructed in six months.

A one cubic yd. bucket, single ladder dredger, capable of raising 750 cubic yds. of ballast per hour from a depth of 55 ft., has cost about 43,000*l.*, and was built in nine months.

Dipper Dredgers.—A one to two yard dipper dredger costs from $8,000 to $12,000; say 1,600*l.* to 2,400*l.* The hull is of timber, about 60 ft. long by 25 ft. wide, with a draught of 3 ft.

A 3½ to 4 cubic yd. machine dredging to a depth of 30 to 35 ft., would cost about $80,000 to $90,000, say 16,000*l.* to 18,000*l.*

A 10 cubic yd. machine dredging to a depth of 35 ft. would cost about $130,000 to $140,000, say 26,000*l.* to 28,000*l.*

Grab Dredgers.—A twin-screw hopper dredger, with a hopper capacity of 1,200 tons, and fitted with 5 hydraulic grab cranes each of 5 tons bucket capacity, working to a depth of 47 ft., has cost about 35,000*l.*

Suction Dredgers.—A suction hopper dredger with a hopper capacity of 70,000 cubic ft., capable of raising 3,500 to 4,000 tons of sand per hour from a depth of 70 ft., has cost about 75,000*l.* A 2,000 ton suction hopper dredger would cost about 50,000*l.*

Compound Dredgers.—A sea-going hopper dredger, fitted with both ladder buckets (18 cubic ft.) and suction pumps, and capable of dredging by the former means 400 cubic yds. per hour, and by the latter means 650 cubic yds. per hour, from a depth of 50 ft., has cost about 53,000*l.*

Hopper Barges.—A steam hopper barge of 800 cubic yds. capacity, with a speed of 11 knots, costs from 18,000*l.* to 20,000*l.*

Cost of Dredging Operations.*

Conditions and circumstances vary with each locality, so that it is difficult to give reliable figures for general guidance. Sand pump dredging can be done for as little as 1*d.* per cubic yd.

* See footnote page 1324.

or even less, and grab dredging from 2*d.* to 6*d.*, but a very great deal depends on the distance the spoil has to be carried. In bucket dredging, either by ladder or dipper, the range of cost is considerable, depending in addition, as it does, on the kind of material dealt with. The following are a few collected records from various sources :—

Port Natal.—The following particulars (extracted from a paper by Mr. William Brown on 'Recent Progress in Dredging Machinery'; *vide* Min. Proc. Inst. C.E., vol. cciii.) relate to the performances of the four principal dredgers at Port Natal, Durban, within a period of several years ended December 31, 1914. The costs include all charges for working, maintenance, insurance, depreciation and interest on capital. The price of coal consumed by the dredgers was low, and seldom exceeded 8*s.* per ton. The three large vessels (Labrus, Cetus, and Nautilus) each employed fourteen Europeans, eighteen Kaffirs, and eleven Indians, or a total complement of forty-three hands, at an annual cost of about 3,850*l.* per vessel. 'With the possible exception of Liverpool, no port hampered by sandbars has made such progress in comparatively recent years as Durban.'

PARTICULARS AND WORKING COST OF SEA-GOING PUMP DREDGING PLANT AT PORT NATAL.

Name of Dredger.	Year Built.	Tonnage.		Hoppr. Capacity (Tons of Sand).	Pumping Speed (Tons of Sand per hour).		Average Spoil handled per ann. (Tons).	Average number of days worked per ann.	Cost per ton handled. (*d.*)	Remarks.
		Net.	Gross.		Contract.	Record.				
Labrus .	1911	1,215	2,097	2,000	2,000	2,000	719,500	244	6·806	Worked exclusively in stiff clay, being fitted with patent clay cutter. All spoil dredged repumped ashore from ship's hoppers for land reclamation.
Cetus .	1905	1,327	2,414	3,000	3,000	7,430	2,151,000	232	2·227	Largely employed for bar work. Spoil mostly coarse loose sand and fine stone, all dumped at sea, two miles from harbour entrance.
Nautilus	1903	1,050	2,034	2,500	3,000	7,894	1,466,000	247	3·109	Employed chiefly on maintenance and deepening of harbour bed and channels. Material mostly fine sand, with occasional admixture of loose clay and mud, all deposited at sea two miles from harbour entrance.
Snipe .	1903	180	265	200	300	340	358,000	256	3·201	Used for clearing up wharf and quay berthage, cutting and maintaining boat channels, occasional reclamation, etc. Spoil deposited within harbour.

Panama Canal.—During 1910 the sea-going suction dredgers 'Culebra' and 'Caribbean' removed 6,083,902 cubic yds. at a cost of 3·7*d.* per cubic yd. The ladder dredger 'Marmot' removed 1,372,665 cubic yds. at 7·82*d.*, and dredger No. 5 removed 560,622 cubic yds. at 13·65*d.* per cubic yd. The small 5 cubic yd. dipper dredgers 'Cardenas' and 'Mindi' removed 1,013,485 cubic yds. at 27·89*d.* per cubic yd. and the 20-in. pipe-line suction dredgers, Nos. 82 and 85,

dealt with 2,472,822 cubic yds. at a cost of 14*d.* per cubic yd. During a period of twelve months ended May, 1916, the dipper dredgers 'Gamboa' and 'Paraiso' each removed over 2,900,000 cubic yds., at costs varying from 2·25*d.* to 5·45*d.* per cubic yd., including operation and maintenance.

Mississippi River.—In 1907 three pipe-line suction-cutter dredgers dredged 1,279,000 cubic yds. at 4·12*d.* per cubic yd. including the cost of idle time. In 1908 the same dredgers accounted for 989,000 cubic yds. at 5½*d.* per cubic yd.

New York Harbour.—In 1909, the sea-going suction dredgers 'Manhattan,' 'Atlantic,' 'Raritan' and 'Navesink,' removed 10,786,638 cubic yds. at a total cost of $424,734 (say 85,000*l.*) or at the rate of 1·97*d.* per cubic yd. made up as follows: Dredging, 1·785*d.*; surveys and examinations, ·125*d.*; contingencies and supervision, ·06*d.* The 'Delaware' removed 1,675,562 cubic yds. at a total cost of 2·39*d.* per cubic yd.

River Thames.—The contract cost of removing hard material (ballast and clay) by ladder dredger from the Thames below London Bridge has ranged at various times before the war from 1*s.* 4*d.* to 2*s.* 6*d.* per cubic yd. largely dependent on the distance the material had to be conveyed. Some work has been carried out departmentally, including all establishment and capital charges, at a figure as low as 7½d. per cubic yd. This was for a quantity of about one million cubic yards, and the distance conveyed was about 30 miles.

River Mersey.—At the bar and in the entrance channels of the Mersey nearly 15 million cubic yds. of sand were removed annually at a pre-war cost of ·6*d.* per cubic yd. exclusive of interest and depreciation on the plant.

SUBAQUEOUS ROCK REMOVAL.

The removal of hard rock under water is generally effected by one or other of two means: (*a*) by drilling and blasting; and (*b*) by the use of the chisel or rock breaker. In both cases a dredger is subsequently required for the purpose of clearing the débris from the site.

Drilling and Blasting.

Drilling and Blasting.—The first is the older method and remains still a most effective means of dealing with rock of adamantine hardness in huge solid masses, such, for instance, as reefs of granite and other igneous rock, and for the harder varieties of limestone.

The holes are drilled by suitable plant at distances apart dependent upon the nature of the rock and the quantity to be removed. In very extensive operations chambers may be formed for the reception of powerful charges.

Two classes of drill are generally available for boring purposes: (*a*) diamond drills and (*b*) jumper drills. The former are hollow rods, fitted with a head or crown of diamonds, costing from 50*l.* to 60*l.*, and driven at from 200 to 300 revolutions per minute. The latter are bars or shafts of steel, furnished with bits, preferably of circular form, which are worked by percussion at the rate of from 20 to 30 blows per minute.

The blasting material is usually dynamite, or any of the numerous compounds of nitro-glycerine to be found on the market.

The following are brief notes on the methods employed in several instances.

Blyth Harbour.—The rock at Blyth harbour is sandstone of the hardness of basalt in places, and the work was done by six drills lifted by steam power and guided by hand. The distance between the shot-holes was 5 ft. in one direction and 6 ft. 2 ins. in the other. The blasting material, bellite, was lowered in canisters through the drilling tubes and fired by fuses and detonators, the holes being tamped with small gravel. The cost of drilling and blasting came to 3*s.* per cubic yd. of rock *in situ*, adding to which 2*s.* 6*d.*, the cost of dredging, and 8·2*d.* for interest and depreciation on the dredger, the total amounts to 6*s.* 2·2*d.* per cubic yd. The average quantity of rock drilled and blasted per week by one barge was 488 cubic yards. The system was afterwards abandoned in favour of the rock-cutter.

Black Rock Harbour, Buffalo, U.S.A.—Here the rock formation is a very hard limestone containing veins of flint. The blasting material was dynamite and, for a quantity of 14,450 cubic yds., the holes were drilled to an average depth of 9 ft. 9 ins. The cost of drilling and blasting only, including an allowance for interest and depreciation of 2 per cent. per month on 8,000*l.* (the value of the plant), came to 2*s.* per cubic yd. On the other hand, a smaller quantity of 333 cubic yds. with holes drilled only to 3 ft. 6 ins. deep cost 23*s.* 2*d.* per cubic yd.

The drill boat employed on this work was a steel hull, 137 ft. by 33 ft., divided into 20 water-tight compartments. It was equipped with five drill frames located along one of the gunwales each with a travel of 25 ft. on longitudinal tracks. Each frame was fitted with an Ingersoll-Rand drill 2½ ins. in diameter, with 4-in. bits, having a vertical range of 21 ft. without changing the drill bars. Each frame was also provided with an engine for hoisting the drills, two davits for handling drill steels and charging pipes and a pipe which was driven, whenever required, through

loose material to the rock to prevent the drill holes from clogging. A 250 h.p. boiler supplied steam to the drills, spud engines and capstans.

Detroit River.—On three sections of the Detroit River, where the blasting material was dynamite and the holes ranged from 5 ft. to 8 ft. in average depth, the total cost is stated to have been 3*s.* 4*d.*, 4*s.* 4*d.*, and 4*s.* 1*d.* per cubic yd., respectively, of useful material, or about half the rates for the whole quantity removed. The holes were spaced 5 ft. apart, and the total number drilled was 94,631 at a cost of about 52,000*l.* It is not apparent that this figure includes any allowance for interest and depreciation.

Fremantle Harbour, Western Australia.—On account of the shallowness of the water, the work of drilling at Fremantle Harbour could be carried on from light wooden stages resting on four-footed trestles. In a couple of days it was possible to erect 20,000 square ft. of this staging, which carried 120 to 160 men drilling with regularity in 20 ft. or more of water. The holes were from 8 ft. to 12 ft. apart, and the charges consisted of 12 to 15 lbs. of dynamite or gelignite. One ton of explosive accounted for 5,600 cubic yds. of rock blasted. The cost of drilling and blasting 1,503,099 cubic yds. was 238,345*l.*, equivalent to 3*s.* 2*d.* per cubic yd.

Rock Breakers or Chisels.

Rock breakers, or chisels, are steel rams weighing from 15 to 20 tons, with pointed ends of hard chrome steel which are detachable for renewal. The appliance is suspended from a frame, or tripod, mounted on a barge, and is worked by a winch. A drop of from 6 ft. to 10 ft. is generally sufficient to produce disintegration. Blows can be repeated with advantage until a depth of 3 ft. is reached, with holes spaced about 3 ft. to 4 ft. apart (about eight blows will give the required penetration), when it becomes desirable to dredge the broken material before proceeding further. A net depth of 2½ ft. over the site will probably thereby be obtained. It is found that the average result in hard rock is 2 cubic ft. per blow and that about 150 blows can be given per hour. This is equivalent in uninterrupted working to about 10 cubic yds. per hour for a single-cutter machine; about 50 per cent. more will be achieved by a double cutter. In moderately hard rock the output will be greater, as about 250 to 300 blows can be given per minute About 200 cubic yds. may be reckoned a good day's work.

There are several types of cutter, but perhaps the Lobnitz rockbreaker is that which is best known. The following are some instances of its employment.

Suez Canal.—On the Suez Canal, where the rock consisted of limestone, calcareous agglomerates and tufa, gypsum and alabaster, 132 blows were delivered per hour of effective working, or 83 blows per hour of whole time, allowing for interruptions from passing ships and stoppages for repairs. The average thickness of rock shattered was 2 ft. 7½ ins., and each cubic yd. of rock required a mean of 5·4 blows. The cost, exclusive of dredging but covering everything else except general charges, varied from 2½*d.* to 7*s.* 6½*d.* per cubic yd.

Blyth Harbour.—At Blyth in hard sandstone of the coal measures, a ram of 15 tons weight, falling through a distance of 8 ft., penetrated the rock to a depth of 3 ft. on an average of 8 or 9 blows. The holes were spaced 4½ ft. apart. The plant comprised two Lobnitz rock-breakers, each consisting of a steel barge carrying sheer legs, from which the rams, 40 ft. to 50 ft. long and 17 ins. to 19 ins. diameter, were suspended. The cost of one rockbreaker was about 6,800*l.* The quantity broken per week by a single machine working night and day was 908 cubic yds., at a cost (including wages, coal, stores, repairs and insurance) of 46*l.* 11*s.* 3*d.*, equivalent to 12·3*d.* per cubic yd. Adding 6½ per cent. for interest and depreciation on plant, the total cost was 14·5*d.* per cubic yd. The cost of subsequently dredging the loose material (including capital charges) was 2*s.* 9·1*d.* per cubic yd., making 3*s.* 11·6*d.* per cubic yd. in all.

Black Rock Harbour, Buffalo, U.S.A.—The cost of working two Lobnitz machines at Black Rock Harbour in hard limestone rock was 2*s.* 9½*d.* per cubic yd. for a quantity of 52,500 cubic yds This does not cover the cost of dredging.

Panama Canal.—On the Panama Canal, a Lobnitz cutter worked mounted on a barge 100 ft. long by 28 ft. beam by 8 ft. deep. The extreme variation in the tides necessitated the use of 3 rams, weighing 15, 16 and 19½ tons respectively. The holes were spaced 4 ft. apart, and 3 ft. of penetration was made in each case. From records during 1910–11 the work done was an average of 16·2 cubic yds. per hour of actual working time, or 11 cubic yds. per hour of total time, at an average cost of 3*s.* 4*d.* per cubic yd.

Value of the method of Drilling and Blasting as Compared with the use of Rock Breaker.—While drilling and blasting is most commonly adopted for hard rock in large masses, it does not necessarily follow that the cutter always gives better results in soft rock. In some cases it is found that the cutter has a tendency to stick in the hole which it makes, and for that reason the extent of penetration should be carefully limited. On the other hand, the cutter offers less interruption to the passage of ships close to the area of operations, and it can be used in positions where blasting is inadmissible. Moreover, the rock is broken to a more uniform and more convenient size, which facilitates the action of dredging. The cost of the work done by the cutter is generally, though not invariably, less than the cost by the alternative method.

CHANNEL DEMARCATION.

Entrance channels to ports are outlined by buoys and important changes of direction are also indicated by beacons and lightships.

Uniform System of Buoyage.

The general Lighthouse Authorities of the United Kingdom have adopted the following uniform system of buoyage.

Conical Buoys (those with pointed tops) denote the starboard hand, or that side which would be on the right hand of a mariner, either going with the main stream of flood tide, or entering a harbour, river or estuary from seaward.

Can Buoys (those with flat tops) denote the port hand, being the left-hand side of the mariner under the circumstances described.

Spherical Buoys, with domed tops, mark the ends of middle grounds.

Pillar Buoys, having a tall central structure on a broad base, mark special positions.

Colour.—Starboard-hand buoys are always to be painted in one colour only; port-hand buoys are to be painted another characteristic colour, either single or particolour. Spherical buoys are to be distinguished by white horizontal stripes. Wreck buoys are to be coloured green with the word 'wreck' in white letters across.

Types of Buoys.

Buoy Construction.—Buoys are generally hollow structures of steel or iron plating about ¼ in thick. They should be constructed in two watertight sections to prevent sinking in case of penetration of one part.

The size and weight of buoys is as follows:—

	Diam. ft.	Weight. tons.
First class	12	4
Second class	10	2½
Third class	8	1¼
Fourth class	6	¾

Gas buoys should be made of welded iron or mild steel, not riveted. Under high pressures the riveted joints tend to leak and are not satisfactory.

Buoy Moorings.—Mooring chains for first-class buoys are about 1½ ins. diameter, and they are attached to sinkers weighing about 50 cwts. For second-class buoys the chains are usually 1¼ ins. diameter, and the sinkers weigh 40 cwts.

Bell Buoys (fig. 28, page 1353) are provided with a bell from 3 to 7 cwts. in weight struck under the action of the sea either by pendant clappers or by a set of balls rolling freely in horizontal grooves.

Whistling Buoys emit a sound by means of air imprisoned in a long central tube during the period of rising in a swell and expelled through a whistle during the period of falling. The tube descends into the water to a considerable depth—about 20 ft.

Luminous Buoys.

Luminous Buoys are lighted by means of oil or gas: the former, petroleum; the latter, either oil gas, Blau gas, or acetylene. On account of the high pressure required for compact storage, coal gas is unsuitable for use as a naked flame, the luminosity of the gas being rapidly reduced by pressure. The heating power, however, remains almost intact, and with a mantle satisfactory incandescence is produced, though the brilliancy and luminous intensity are lower than those of the other agencies. The ratio of calorific value is approximately as follows:—Coal gas, 5; oil gas, 10; Blau gas and acetylene, 14.

The difficulty connected with the use of oil burners is the necessary attention to the wicks. In France carbonised wicks are employed, but they call for extreme nicety of adjustment. In this country the *Wigham* burner has an automatic contrivance which ensures a constant change of surface. The consumption of oil amounts to from 2 to 4 pints per day of 24 hours, according to the size of the lamp. Including oil and attendance, but not repairs, the approximate pre-war running cost of a 31-day buoy lamp works out at about ·13*d.* per hour, of which ·065*d.* is for oil. The prime cost of buoys equipped with the *Wigham* lamp is from about 200*l.* upwards.

Oil gas, as manufactured on the *Pintsch* system, is produced at a cost of about 60*s.* per 1,000 cubic feet, about 75 cubic feet of gas being obtained from one gallon of oil. The average burner of a fixed light consumes about ·75 cubic feet per hour. The gas is stored under pressure, generally of about 90 to 105 lbs. per sq in., but reaching up to 150 lbs. A reservoir of 380 cubic feet in a buoy of 10 ft. diameter, charged to 90 lbs. pressure, would hold a sufficient supply of gas for about four months.

Lenses are usually of 200 to 300 millimetres (8 to 12 ins.) diameter. The candle power of lanterns fitted with incandescent burners and lenses of 200 mm. diameter is about 220, and with 300 mm. lenses about 330.

Blau gas is derived from the decomposition at a lower temperature of the raw or residuary products from which ordinary oil gas is extracted, and is richer than the latter in heavy carbides of hydrogen. It is liquefied for storage in bottles. Before use, the gas requires to be expanded

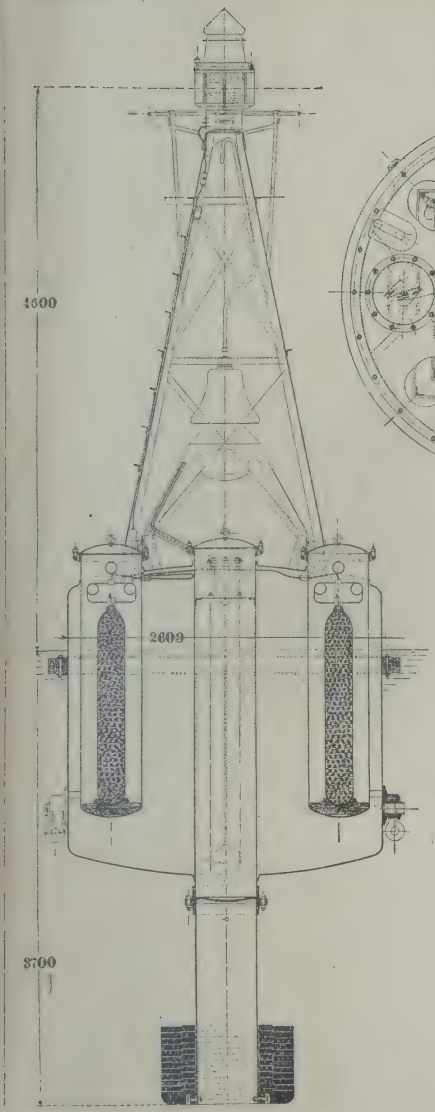

FIG. 28.—Gas and Bell Buoy, the light being obtained from cylinders of dissolved acetylene and the bell operated by carbonic acid mechanism.

[*Gas Accumulator Co. (United Kingdom) Ltd.*]

in an intermediate receiver. The cost of production of Blau gas is considerably higher than that of oil gas, but the cost of transport is much less, and the increased heat of the flame gives an increase of 30 per cent. over oil gas to the intrinsic brilliancy of the mantle and the intensity of the lens.

Acetylene, a gaseous compound of hydrogen and carbon, is produced by the access of water to calcium carbide. In the case of buoys, the water is generally admitted to the chamber containing the carbide through a hole in the bottom, the generation of gas being regulated by the pressure arising from its formation. The system is wasteful of carbide, and only suitable for positions where the buoys can be periodically cleaned and recharged. The better principle, wherever feasible, is the inverse arrangement of the application of carbide to water.

From 1 lb. of commercial calcium carbide can be produced about 4½ cubic feet of acetylene, at a pre-war cost of about 1½*d.* for material only.

Acetylene gas produced as above is not chemically pure, and gives rise to deposit on the burners, but this difficulty can be overcome by the addition of a suitable purifier between the gas-generating chamber and the burner. Unattended lights working on this system will run for six months, or even a year, without recharging.

Dissolved Acetylene.—The compression of acetylene for storage purposes is generally illegal, on account of the liability of the gas, so stored, to explode. On the other hand, compressed acetylene in what is known as the dissolved form is perfectly safe, and cylinders of dissolved acetylene, prepared in accordance with official regulations, are classed by the Home Office as non-explosive.

The solvent commonly employed is acetone, which is a liquid hydro-carbon, possessing the property of absorbing about 25 times its own volume of acetylene at atmospheric pressure, and multiples of this to correspond with the number of atmospheres to which compression is carried.

The steel cylinders for the reception of the dissolved acetylene are first completely filled with a substance having a porosity of 80 per cent., which is then caused to absorb as much acetone as would occupy 40 per cent. of the volume of the cylinder. The actual gas capacity of the cylinder is thus 40 per cent. of 25, or 10 volumes per atmosphere of pressure.

Dissolved acetylene cylinders should not be discharged below the atmosphere gauge pressure, because the rate at which the acetone is carried off by the gas greatly increases as the pressure approaches zero. Acetone vapour has no detrimental effect upon the consumption of the gas in the burner. It is generally found necessary to make up the quantity of acetone, after five to ten refillings of the cylinder with acetylene.

Economies in the consumption of dissolved acetylene have been effected by the introduction of mechanism for emitting flashing or occulting lights invented by Mr. Gustav Dalen and others whereby a wide range of intermittent light signals can be produced automatically.

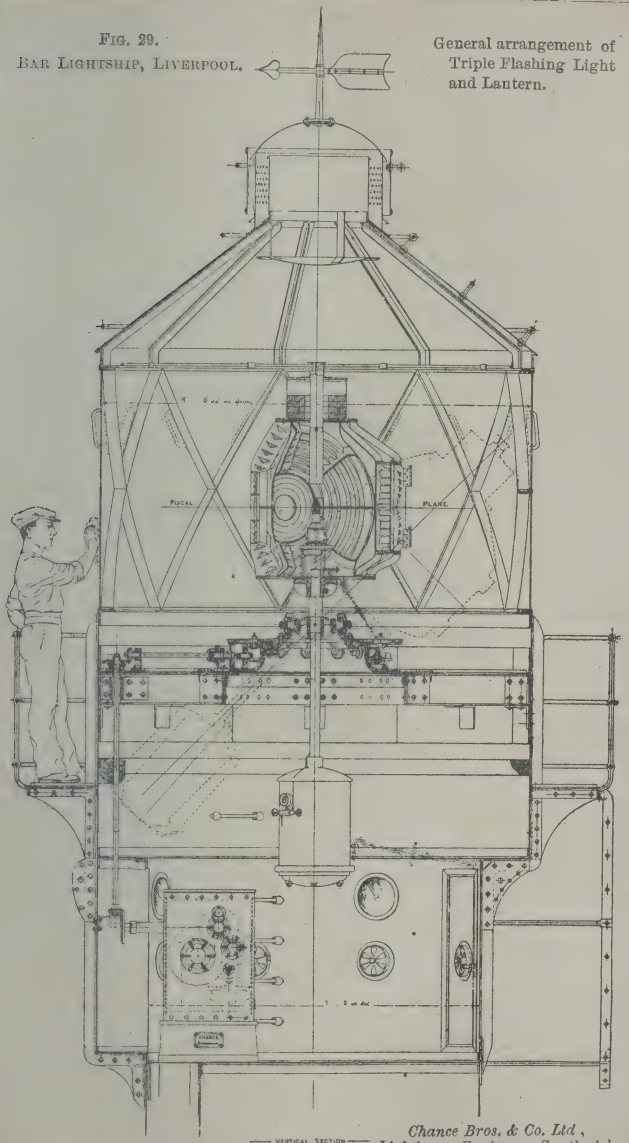
To the same scientist is attributable the *Sun-valve*, or, more correctly, the *Light-valve*, which is a mechanical device sensitive to light and actuated entirely by the alternation of daylight and darkness. It opens the gas supply at nightfall and closes it at daybreak with perfect regularity, resulting in a saving of some 25 to 40 per cent. of the gas, according to climate, as compared with a constantly burning light. The use of the instrument is generally restricted to shore lights, or lights of considerable magnitude.

Mr. Dalen has further produced complete automatic apparatus for mixing in correct and constant proportions the dissolved acetylene and air and for burning the compound in conjunction with incandescent mantles, either as a constant or intermittent light. This apparatus also by its nature, is most applicable to lights of considerable power, superior to those generally fitted to buoys.

As an instance of the cost of buoy illumination by dissolved acetylene may be mentioned nine light buoys in the entrance channel to the Port of Lido, Venice, which command a light range of 6 miles under conditions of average atmospheric clearness, and contain a supply of gas for a period of 110 days. The lenses are 300 mm. diameter, and the burner consumes 15 litres per hour. According to a statement of Sig. Carlo Duse in the 'Giornale del Genio Civile,' the annual pre-war cost per buoy, covering attendance and repairs and four charges of gas, each of 3 cylinders of 5 cubic metres, at 4*s.* per cubic metre, was 15*l.* 12*s.*

Further reference to the cost of acetylene lighting will be found below under the section on Lighthouses, page 1360.

Lightships.



Lightships afford a more powerful light than luminous buoys, and the focal plane is at a much higher level—generally about 35 ft. above the water surface. They are, of course, more costly both in first outlay and maintenance, and are usually manned by a crew, though this is not essential in all cases.

A notable example of an attended lightship is the Bar at the entrance to the River Mersey. The illuminant in this vessel is petroleum with an incandescent mantle, and the lens is of small third order (750 mm. diameter). The whole optical apparatus is swung on gymbals, so that the beam emitted is kept practically horizontal. It is revolved by clockwork, and gives three powerful flashes, so that the whole installation resembles a floating lighthouse (see fig. 29).

Small lightships, without constant attendance, are stationed at several places on the coast of this country and of France. A vessel of this type is about 40 ft. long, 12 ft. beam, and 8 ft.

FIG. 29.

Chance Bros. & Co. Ltd., Lighthouse Engineers, Smethwick, nr. Birmingham.)

deep, fitted with a storeholder containing 2,500 cubic ft. of gas, which is sufficient to maintain a light for 3 months.

Larger vessels, with crews, range from 60 to 150 ft. in length, from 20 to 30 ft. in breadth and from 10 to 20 ft. in depth, the draught being from 7 to 10 ft.

Lenses vary from 500 mm. to 750 mm. in diameter and the candle power from 800 to 5,000. The consumption of gas varies with the type of burner from ·75 to 3 cubic ft. per hour.

LIGHTHOUSES.

The Eddystone Lighthouse.

The most recent type of foundations and general construction of lighthouses is well exemplified by the new Eddystone Lighthouse. In this structure the tendency of the curvilinear outline of Smeaton's and of other similar sea-towers that have succeeded it, to elevate the centre of force of each wave-stroke on the structure, induced Sir James Douglas to adopt a cylindrical base, from which base, at a level of 2½ feet above high-water spring-tides, the curved shaft of the tower commences. The difference in the rise of heavy seas on the two structures during stormy weather is remarkable. The cylindrical base has the further advantage of affording a convenient landing platform, thus adding considerably to the opportunities of relieving the lighthouse.

The base is 44 feet in diameter by 22 feet in height. The tower is a concave elliptic frustum, the generating curve having a semi-transverse axis of 173 feet, and a semi-conjugate axis of 37 feet. With the exception of the space occupied by the fresh-water tanks, the tower is solid for 25 ft. 6 ins. above high-water spring-tide level. At the top of the solid portion the wall is 8 ft. 6 ins. in thickness, diminishing to 2 ft. 3 ins. in the thinnest part of the service-room. All the stones are dovetailed both horizontally and vertically. The system consists in having a raised dovetailed band 3 inches in height on the top bed and on end joint of each stone. A corresponding dovetailed recess is cut in the bottom bed and end joint of the adjoining stones, with just sufficient clearance for the raised band to enter it freely in setting. From experiments made with blocks put together in this manner with Portland cement, it is found that the work is so homogeneous as to be as nearly as possible as strong as the solid granite.

Each stone of the foundation-courses (figs. 30, 31) is sunk to a depth of not less, at any part, than 1 foot below the surface of the surrounding rock, and is further secured by two Muntz metal bolts, 1½ inch in diameter, passing through the stone, and 9 inches into the rock below, the top and bottom of each bolt being fox-wedged.

The masonry consists of 2,171 stones, containing 62,133 cubic feet of granite, or 4,688 tons.

70	11·067	200	18·708	1,000	41·833

Optical Apparatus.

The essential part of a lighthouse is the optical apparatus, which is formed of glass lens and reflecting prisms in order to concentrate the light from the burner in the required directio The optical apparatus of a fixed light concentrates the rays in the vertical plane only, and sen out a disc of light which illuminates the horizon over the whole 360° or any less angle which ma be required. That of a flashing light concentrates the rays in both the vertical and horizont planes, and thus throws out a series of beams, the number varying with the character whic the light is required to give. The whole apparatus is revolved, and by this means the bea sweep round the horizon and appear as flashes at definite intervals to the mariner.

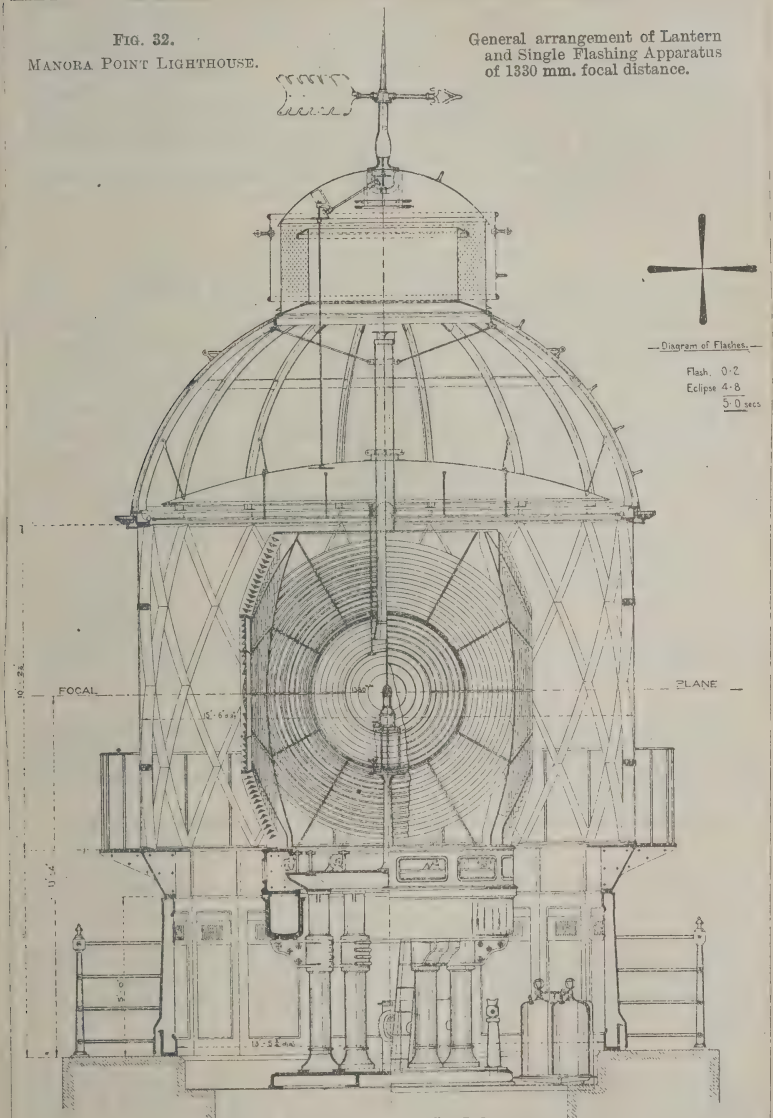
Large lights are supported on a mercury float whereby friction of movement is reduced t a minimum; ball bearings are satisfactory for lights of the fourth order and upwards. Th adoption of the mercury float and of the group flashing system, which was invented by Dr. J Hopkinson in 1874, and introduced by *Messrs. Chance Bros. & Co., Smethwick, Birmingha* has revolutionised lighthouse practice. The former enables the largest type of optica apparatu the weight of which runs up to 10 tons, such as that illustrated in fig. 32 (p. 1359), to be rotate by the little finger only, and the latter has so greatly increased the distinctive characters whic can be given to lights that there is now no danger of confusion between them.

It is usual to arrange the optical system so that the flashes have a minimum duration ·2 seconds; it has been found that a shorter duration is not sufficient for the mariner to dete the flash. Fig. 32 also illustrates the lantern which protects the optical apparatus.

Sources of Lighthouse Illumination.

For the ordinary necessities of lighthouse illumination mineral oil is the most suitable an economical illuminant. The use of paraffin in the place of colza oil increases the luminou intensity of a four-wick burner by 10 per cent., and of a one-wick burner by 100 per cent.

Oil and gas lights, when shown through similar lenses, are equally affected by atmospheri variations. The electric light is absorbed more largely by haze and fog, but in all weathers an at all distances its penetration has proved superior.



The luminary now in general use at lighthouses is the incandescent oil burner, to whic paraffin oil is supplied under pressure, and is vaporised in a retort beneath the burner or in vaporiser over the burner, being afterwards consumed in an incandescent mantle. The fo sizes of mantle usually employed are 35 mm., 50 mm., 85 mm., and 110 mm. in diameter, t intensities being 500, 1,250, 2,000, and 3,500 candles, respectively.

The Trinity House has adopted a burner having a 50 mm. mantle and consuming one pi of oil per hour, and a triple-mantle, consisting of a group of three single-mantle burners, wit a service intensity of 3,300 candles and a consumption of 3 pints per hour.

The substitution of incandescent oil burners for concentric wick burners has not only greatl augmented the intensity of the lights, but has resulted in a considerable economy in consump tion, in addition to obviating excessive labour and expense of landing large quantities of o at lighthouses, especially at rocks and isolated positions. The following may be cited as a

Audible Signals.

Fog Bells.

The clockwork of American fog bells is driven by weights of from 700 to 1,000 lbs. The bells themselves weigh about 1,200 lbs.

Sirens.

Sirens require an expenditure of energy to work them of from 7,000 to 29,000 lbs. per second of sound; the air pressure is usually about 40 lbs. per square inch.

When a siren is placed at the summit of a lighthouse the reservoir on which it is mounted cannot have a greater capacity than 500 litres.

Under favourable conditions a steam siren may be heard at a distance of 14 miles, but sometimes the range does not exceed 2 miles.

A compressed-air siren (·125 metre in diameter) has been heard at a distance of 13 miles, but the range is sometimes as low as 1·75 mile. A small-sized siren (·042 metre diameter) cannot be heard at a greater distance than 1·85 mile under favourable conditions.

About 12 horse-power is required for working a large siren.

Explosive Signals.

A 4-oz. charge of cotton powder can be heard under favourable conditions at a distance of 20 miles, and under unfavourable conditions at a distance of 2½ miles.

Submarine Sound Signals.

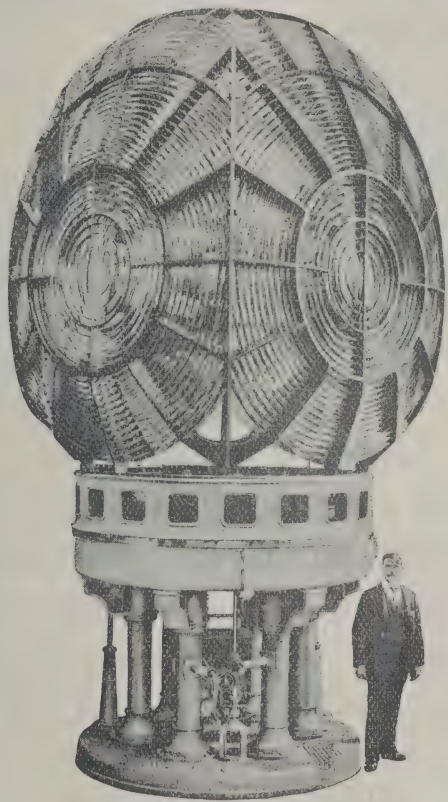
The Submarine Signal Company, of Boston, U.S.A., have successfully introduced a system of submarine signalling by means of a bell struck by a clapper at depths varying from 10 to 30 ft., but preferably about 25 ft. below the surface of the water. The distance traversed by the sound has reached 15 miles, but 1 to 3 miles is a serviceable test. The apparatus for receiving it consists of two metal tanks, about 22 ins. square, filled with seawater and located, one on each side of the ship, at a certain distance from the forefoot, against the inside skin and below the water line. A specially designed microphone is suspended, wholly immersed, in each tank, and wires connect this microphone with an indicator box on the bridge or elsewhere.

A series of experiments made to determine the most effective weight and shape of the sending apparatus has resulted in the adoption of a bell weighing 220 lbs. with a period of 1,215 vibrations in water.

DIVING.

Forms and Limitations.—Diving is practised in three forms—either naturally, without any extraneous supply of air during submersion, or artificially, under pneumatic pressure (*a*) with a diving dress or (*b*) with a diving bell. The first is the most primitive method and, though still in vogue among natives in Eastern seas, is bound to be intermittent, in spells of short duration, as it causes great physical strain, leading not merely to acute discomfort, but at times to bleeding at the nose, mouth and ears. When practised with the aid of pneumatic apparatus, the period of submersion may be greatly prolonged. The only practical limitation is in regard to depth. For every 33 ft. below water, the pressure on the lungs is increased by 1 atmosphere (14·7 lbs. per sq. in.) Thus, at 50 ft. below the surface the pressure is 22½ lbs. in excess of atmospheric pressure; at 100 ft. it is 44½ lbs., and so on. Such pressures, though considerable, may be sustained with impunity and even a depth of 150 ft. may be reached without ill effects. But greater depths necessitate considerable powers of resistance and are attended with risk. The maximum depth to which any diver has descended, as recorded by authentic testimony, is 210 ft., at which depth the pressure was rather more than 7 atmospheres absolute. Harbour work does not generally entail diving in water of more than 10 fathoms (60 ft.).

Caisson Disease.—After immersion under pressure the blood becomes more or less saturated with nitrogen in dissolved form, and when the pressure is relaxed the surplus gas is given off—if too rapidly, bubbles of gas form in the circulatory system resulting in pains ('pins and needles'), asphyxiation, paralysis and death, according to the intensity. To these symptoms is given the name of *Caisson Disease*, from its association with work carried on in caissons under pneumatic pressure. It is the most formidable antagonist of the diver, prostrating even the most powerful and robust. Fortunately the malady does not manifest itself at all under moderate pressures, viz., those less than 2 atmospheres absolute. For depths exceeding 35 or 40 ft., it is necessary to use circumspection during the process of decompression, i.e., the ascent to the surface should be made slowly, with stoppages at intervals. By this means the evil effects can be neutralised.



The following table indicates the ordinary time limits in deep water, stoppages in ascent and approximate air supply, in accordance with Prof. Haldane's recommendations and the latest British Admiralty practice.

Diving Bells.

Diving Bells.—As an alternative to the diving dress, the diving bell, a chamber constructed of mild steel plating, carefully riveted and securely caulked so as to be perfectly watertight, may be suspended over the place of operation and lowered or raised as required. The scope of movement by workers is naturally restricted to the area occupied by the bell, which may be 20 ft. by 10 ft. or thereabouts. Some submarine caissons are of much greater dimensions, but they are not diving bells in the true sense of the word. The interior is fitted with seats and footrests for the occupants, who may perhaps number a dozen. The bell is ballasted with cast-iron kentledge to enable it to sink without risk of overturning.

(Contributed and revised by Brysson Cunningham, D.Sc., B.E., F.R.S.E., M.Inst.C.E.)

NAVIGABLE WATERWAYS.

Classification.

Navigable Waterways are conveniently classified as

(1) Natural Channels, i.e., those rivers, or portions of rivers, including estuaries, the normal flow of which is not interfered with by artificial works;

(2) Canalised Rivers, frequently called 'Navigations,' the flow of which is more or less under artificial control, and

(3) Canals, proper, entirely artificial in conception and construction.

The distinction between the three classes is fundamental and important. In the case of the natural channel, improvement works are limited to a rectification of the bed, and no attempt is made to control or augment the natural flow of water, which being derived from the drainage

of the basin, is normally sufficient for purposes of navigation, within the limits of the channel capacity. The canalised portions of rivers consist of sections in which the natural flow is conserved and controlled, as in the manner of a canal, but generally without extraneous sources of water supply. Canals, being works of an entirely artificial character, have to be fed with supplies obtained by the interception of streams, or from other external sources, frequently necessitating pumping and reservoir storage.

Internal Waterways in the United Kingdom.

According to the Report of the Royal Canal Commission, issued in 1909, the total mileage of Canals and Navigations in use in the United Kingdom is about 4,670. Of this total, about 3,639 miles lie in England and Wales, 183 in Scotland, and 848 in Ireland. The length of canals in existence in England and Wales is given as 1,927½ miles, and of navigations, 1,312½ miles. There are 812½ miles of open river and estuary.

IMPEDIMENTS TO NAVIGATION OF RIVERS.

From the point of view of navigation, few rivers are without defect of some kind or other, and, in most cases, artificial treatment is required to produce and maintain a serviceable channel.

In the seaward section the most pronounced disability, where it exists, is the bar. For its removal a very efficient means, producing immediate amelioration, is dredging; but the effect in the majority of cases is merely temporary, and operations must be continuous if the improvement is to be maintained. Where bars are not in evidence, or not very pronounced, a river mouth is often encumbered by shoals, due either to detritus brought down by the river itself or to coastal erosion and drift. In this case also, dredging may be resorted to with immediate advantage. For permanent benefit it is requisite to supplement this temporary expedient by training works of a scope and magnitude dependent on circumstances. Such works comprise longitudinal training walls, or embankments, and groynes, dykes, or jetties, to be alluded to later.

In the upper sections of rivers the principal difficulties encountered are irregularities in flow, due to floods in rainy seasons and depletion of water in periods of drought, excessive current velocity, instability of channels and the formation of shoals. In low-lying lands, it is often necessary as a protection against inundation to raise the river banks with impervious material, well supported from behind. Insufficiency of water may be met by the introduction of weirs, or the formation of storage reservoirs. The remedy for excessive and irregular currents lies in training works of a suitable character.

Velocity of Flow in Rivers.

The velocity of river flow varies very considerably, as will be seen from the following table. As regards navigation, currents exceeding three to four miles an hour or four and a half to six feet per second make a serious deduction from the speed of propulsion of vessels proceeding upstream, and render control difficult in the case of small craft travelling downstream. See also note on Horse Traction, page 1385.

River	Seine at Meulan	2·45 ft. per second.

,,	Durance, below Sisteron	8·65 ,, ,, ,,
,,	Maranon, S. America	13·00 ,, ,, ,,

Velocity Observations are taken by means of (*a*) Floats, (*b*) Current Meters, and (*c*) Pressure Tubes.

Floats.—For surface velocities an orange is excellent, floating almost wholly immersed. In the winter season, fragments of ice give similarly good results. The topmost layers of water, however, are frequently affected by the wind. To obviate this the float should extend some distance below the surface. A corked bottle, weighted at the bottom, has proved satisfactory for the purpose. Tube floats are also employed, consisting of tin cylinders about 1 in. diameter, weighted so as to maintain perpendicularity, and leave two or three inches projecting above the surface. Double floats are sometimes used, consisting of a small surface float connected by means of a cord to a float of larger bulk below. In Mississippi experiments, the lower floats were kegs 9 ins. high and 6 ins. diameter, or 12 ins. high and 8 ins. diameter, according as depth

was less or greater than 5 ft. They were without top or bottom, and ballasted with lead. The connecting cords were $\frac{1}{10}$ in. to $\frac{1}{5}$ in. diameter. The upper float was of light pine, $5\frac{1}{2}$ ins. square by $\frac{1}{8}$ in. thick, or of hollow tin, $5\frac{1}{2}$ ins. by $1\frac{1}{2}$ in.

Current Meters.—These record velocity by means of the revolution of a screw, being calibrated by drawing through still water at various speeds. Price current meter, used by United States Geological Survey, consists of six cups attached to a vertical shaft, which revolves on a conical hardened steel point when immersed in moving water. Meter measurements can be made from a bridge, from a cable and car specially installed for the purpose, from boats or by wading. Current meters are affected by friction, and are not very suitable for low velocities; in fact, in feeble currents they cease to act.

Pressure Tubes.—Pitot tubes, which are ⌊ shaped with the lower horizontal limb pointing upstream, record the velocity by the height to which the water in the tube is forced above surface level by the pressure of the current. Darcy's adaptation consists of two tubes in communication, enabling the differential reading to be taken more accurately and eliminating the effect of ripples and oscillations. The apparatus gives good results in small channels with currents of fair velocity, but it is not suitable for large rivers or for very low rates of flow.

Position of Maximum Velocity may be taken generally at or about surface level, but is not infrequently below. The view is generally held that the velocity varies as the abscissæ of a parabola, whose axis is parallel to the surface. The equation for the parabola in the case of the Mississippi was found to be

$$v = -0{\cdot}79222\ d^2 + 3{\cdot}2611$$

where v = velocity in feet per second and d is distance from axis in fractional parts of whole depth considered as a unit.

Mean Velocity.—The position of mean velocity has been found by repeated experiments in U.S. Geological Survey to be located at about 0·6 of the total depth. The mean of velocities obtained at 0·2 and 0·8 of the depth gave the mean velocity of the stream very accurately.

In ordinary cases the least, mean and maximum velocities may be taken in the ratio 3 : 4 : 5. In very slow currents they are nearly as 2 : 3 : 4.

Prony's Formula:

$$\frac{\text{Mean velocity}}{\text{Maximum velocity}} = \frac{\text{Maximum velocity} + 7{\cdot}71 \text{ ft. per sec.}}{\text{Maximum velocity} + 10{\cdot}28 \text{ ft. per sec.}}$$

Computed Velocity.—A great number of formulæ have been published connecting the velocity with the hydraulic mean radius (R) $= \frac{\text{area of stream}}{\text{wetted perimeter}}$, and the sine of slope (S) $= \frac{\text{fall in level}}{\text{length of channel}}$. Most of these expressions can be reduced to the form

$$v = c\sqrt{\text{RS}},$$

where c is a coefficient varying with the class and nature of the channel, as well as with the personality of the observer. Some of the coefficients are very complicated, and the values are variable to a considerable degree. Mr. A. A. Barnes ('Hydraulic Flow Reviewed,' 1916) proposes to modify the powers of R and S so as to admit of a coefficient of constant value. His expression is

$$v = 58{\cdot}4\ \text{R}^{\cdot 694}\text{S}^{\cdot 496}$$

or, approximately,

$$v = 60\ \text{R}^{\cdot 7}\ \text{S}^{\cdot 5}$$

In nineteen observations with ranges in width of stream from ·26 ft. to 2,598 ft., in depth from ·19 ft. to 69 ft., in hydraulic mean radius from ·0786 ft. to 53·6 ft., and in slope from $1\frac{3}{4}$ to 241·2 ft. per mile, velocities of from 1 to $7\frac{1}{2}$ ft. per second were computed and found to agree, within 1 per cent., with actual observation.

In the course of investigations made during three years in connection with the regulation of the Whangpoo and Yangtse Rivers, Dr. Herbert Chatley found that in fairly straight and uniformly sectioned reaches when the flow is steady the above exponential form $v = c\text{R}^{\cdot 7}\text{S}^{\cdot 5}$ gave consistent results. But when the flow was unsteady he found it more satisfactory to take the expression

$$v = c\text{R}^{\cdot 7}\left(\text{S} - \frac{a}{g}\right)^{\cdot 5}$$

where a is the acceleration. In other words, the effective slope was equal to the algebraic difference between the actual slope and an 'acceleration' slope determined by the ratio of the actual mean acceleration of the water to the gravitational acceleration.

Critical Velocities.—The following is a statement founded on the researches of Dubuat and Beardmore of velocities at which various materials in a river bed commence to be eroded :

Soft clay	3 inches per second.
Fine sand	6 ,, ,, ,,
Coarse sand and pea gravel	9 ,, ,, ,,
Gravel as large as French beans	12 ,, ,, ,,
Rounded pebbles, 1 inch diameter	2 feet per second.
Rough gravel ,, ,,	2½ ,, ,, ,,
Pebbles 1½ inches ,,	3¼ ,, ,, ,,
Heavy shingle	4 ,, ,, ,,

TREATMENT FOR EROSION.

Protection of River Banks.—Water plants form a very efficient natural protection, and they assist in retarding the current—sometimes not an unmixed advantage.

Earthen banks of a soft and erodable character may be artificially protected, where stone is procurable, by rubble pitching, laid at a slope of 1½ or 2 to 1, from 8 to 12 ins. thick at the top, and increasing in thickness downwards at the rate of 3 ins. per yard. The foot of the slope should be adequately secured to some firm abutment, such as piling, otherwise the pitching may be undermined and, in that case, it will subside.

Where stone is not procurable, fascine aprons or mattresses, formed of brushwood, may be utilised. These are bundles of branches and twigs (usually willow) from 9 to 12 ins. in diameter, about 12 ft. long and bound with tarred rope at intervals of 4 ft. or so, laid side by side and tied together so as to produce a surface covering of the desired extent. The 'fascines,' as they are termed, should be secured by stakes or short piles to the bank upon which they are deposited.

A plantation of small willows above water level is useful in counteracting the more deleterious effects of floods.

Mississippi River Bank Protection.—The banks of the Lower Mississippi are protected where necessary from erosion below water surface level by means of brushwood mattresses loaded with stone. The portion of the bank above surface level is protected by a covering of stone only, 10 ins. thick, laid to a suitable slope.

The mattresses were deposited from a single barge, or from a couple of barges, placed end to end, so that the combined length of the barges exceeded the width of the mattress. The ordinary size for mattresses was 800 ft. by 250 ft., but some mattresses were 1,000 ft. long by 300 ft. wide. 'The mattresses are constructed on the mattress-barge by laying parallel to the shore, and, 8 or 10 ft. apart, a series of poles, whose aggregate width equals nearly that of the proposed mattress. These poles are small trees from 3 ins. to 6 ins. diameter at the butt, and 25 ft. to 30 ft. long. Smaller poles are then placed at right angles to the larger series, so as to pass alternately beneath and above the successive larger poles, as in basket-work. These smaller poles, when forced into close contact with each other and with the other series, form a tolerably compact web or mattress. When so many of the small poles have been added that they approach the ends of the larger series, whose poles are parallel to the shore, these larger poles are each continued by having another large pole spliced to it, and so on, for the length of the mattress. The brush in the mattress is fastened together frequently with iron wire and cross poles. The whole mattress is strengthened by wire cables about 20 ft. apart, and by ⅝ in. to ¾ in. wire ropes running longitudinally the whole length of the mattress. Transverse cables of wire, about 16 ft. apart, also strengthen the mattress ; and transverse wire ropes in addition are sometimes used.'

As each mattress was woven it was allowed to be floated down stream off the barge by the current, and when a sufficient length had been accomplished it was loaded with stone and sunk, the upper end being sunk first. The customary under-water slope did not exceed 1 in 3, and the depth of the outer edge often ranged from 60 ft. to 100 ft. (*From Report by General C. B. Comstock, on Mississippi River Improvement, to Chicago International Congress*, 1893.)

CHANNEL TRAINING WORKS.

The instability and eccentricity of channels is remedied by training works, comprising (*a*) projecting jetties and groynes, (*b*) longitudinal dykes and embankments, and (*c*) ground sills.

Groynes or Jetties project from the banks to the stream at right angles, or thereabouts (generally within 70° to 90°) to its course, and have the effect of reducing the channel and concentrating the scour of the current within certain bounds. The beneficial effect, however, is largely local, and, in the absence of restraint between the jetties, the stream tends to diffuse

itself over a wider area, so that while the bed may be deepened and improved opposite the ends of the groynes it often becomes actually shallower in the intermediate spaces. To be effective, groynes should be spaced apart not more than five times their own length, and this often renders them less economical than a system of longitudinal dyking, which, on the whole, will be found far more satisfactory and is often ultimately adopted. Groynes should, in fact, only be looked upon as of the nature of a temporary expedient. They may be formed of piling, fascine work, or rubble.

Groynes on the River Waal.—These are so arranged as to point upstream with the axis of the groyne on the concave bank forming an angle of 80° with the projected channel, and that on the convex bank an angle of 70°. This system has been found favourable to the deposit of alluvium between the groynes.

The groynes themselves are formed of a core of sand extending to 11 ft. 6 ins. below ordinary low water. The core is covered with mattresses of fascine work, having a lateral slope of 6 to 4, surmounted by a layer of broken brick and rubble stone. The slope towards the river is 1 in 4. The width of the crown of the groynes is 11 ft. 6 ins., and their height along the boundary of the normal river bed 1 ft. 6 ins. above ordinary low water level, corresponding to about 1 ft. 6 ins. below mean water level.

It is stated that sand forms a satisfactory core if banked in large quantities at a time, and that no harmful results ensue from the slipping away of a certain amount during submergence. A few years after formation the groynes receive a protective covering of basalt.

The River Waal has a velocity varying between 2¼ and 3½ ft. per second. The discharge is about 21,000 cubic ft. per second at lowest water level, and 220,000 cubic ft. during highest floods. (*From Report by M. Baucke to Philadelphia Navigation Congress*, 1912.)

Longitudinal Dykes are walls or embankments of timber, stone, concrete, fascines, or other material built up so that the channel is rigidly confined within definite limits throughout the length treated. At the outlet of the Fen Rivers in the Wash, banks of fascine faggots and clay were constructed 22 ft. wide at the base, 17 ft. high, and 13 ft. wide at the top, at a cost of about 1*s.* 8*d.* per cubic yard. On the River Weser, stone and gravel embankments have been found preferable to fascines on the ground that the surface slopes may be rendered less steep than 45°, which is stated to be the limit for fascine work.

Levees constitute a type of longitudinal dyke. They contract the river channel in its higher stages and protect the adjacent country from inundation. As used in American practice, they are generally banks of earth or spoil, well consolidated, with a central trench forming an impervious connection with the natural ground.

Channel Curves.—The natural tendency of river channels is to form a series of deep water pools on the concave sides of bends, with shoals at the intervening points where the current passes over from one side of the river to the other. A judicious system of training will maintain the natural sequence of these deep pools, at the same time suppressing any unduly sharp bends which might be awkward for navigation. Generally speaking, for vessels of 400 to 600 tons moving at a fair rate of speed a radius of 550 yards should be regarded as a minimum—at low speeds, 220 yards will suffice. The minimum for vessels of very small tonnage (say, 200 tons and under) may be as low as 66 to 88 yards.

Ground Sills are serviceable where there is excessive scour of the bed or undue restriction in width of channel. They have the effect of rendering the fall of the stream more uniform. In German practice they are set from 40 to 50 feet apart, and found to be better than continuous pitching or filling of the bed. They are laid across the river so that their highest levels at the bank are about 12 inches below the normal surface, and they slope downwards to the centre of the stream at an angle of about 1 in 40. On the Mississippi the ground sills consist of either rubble mounds or cribs filled with rubble, or, again, of brush mattresses and stone in alternate layers. Whatever form be adopted, the top should be finished off smoothly to prevent injury to passing vessels. Ground sills may be used where it is desired to raise the low water level or lengthen out a slope.

Storage Reservoirs.—For the augmentation of the flow in dry seasons storage reservoirs have been advocated, and in two instances—the Mississippi and the Volga—have been adopted. Circumstances, however, have to be favourable if they are to prove a satisfactory and economical arrangement. The Volga has its source in a lake and swamp region where land is cheap and unfit for agriculture. The dams required were only 17½ feet high, and a storage capacity of 35,000 million cubic feet was obtained. On the Upper Mississippi above St. Paul, five reservoirs were formed out of an extensive lake area of 480 square miles, with a storage capacity of 93,400

million cubic feet. It is stated that the increase in height obtained at St. Paul during the low water period—about 90 days—averages only 14 inches. The system is not regarded as sufficiently satisfactory to justify its extension elsewhere in the United States. Where there is no original headwater accumulation its adoption is out of the question.

RIVER DREDGING.

The improvement of river channels by means of mechanical dredging has received considerable impetus of late years by reason of the development in power and capacity of dredging plant. The various appliances are described in detail in connection with harbour dredging (*vide* p. 1344, *et seq.*). In some cases, as for instance the Volga, with its tributaries the Oka and the Kama, the application of dredging alone, without the assistance of artificial training works, has proved sufficient to ensure the maintenance of a serviceable channel, while in other cases, notably on the Mississippi and the Mersey, engineers employ both systems conjointly.

Dredging Plant on the Volga.—On the Volga, dredgers work from the shallowest depths up to 20 ft. and consist of both bucket dredgers and suction pumps.

One of the former has a hull 131 ft. by 26 ft. with a draught of 3 ft. 3 ins. It discharges about 300 cubic yards per hour by means of shoots, or 370 cubic yards per hour through a floating pipe-line. Two other dredgers have a length of 157 ft., a breadth of 31 ft. 2 ins., and a maximum draught of 4 ft. 11 ins. They are self-propelling with a speed of 4 knots. The pipe-line is 1,740 ft. in length. The buckets have a capacity of $\frac{1}{2}$ cubic yard, and they are reinforced by centrifugal pumps of 5 ft. diameter. The pipe-line has a diameter of 19 ins. A still more recent dredger is 131 ft. long by 28 ft. wide, with a draught of only 2 ft. 4 ins., a dredging depth of 17 ft., and a working capacity of 196 cubic yards per hour in sandy material.

Particulars of Dredging Plant used on Mississippi River.

All self-propelling, with two main pumping engines, each of horizontal tandem compound condensing type, and centrifugal pumps with water-jet sand agitators.

RIVER CANALISATION.

The canalisation of rivers is effected by dividing their beds into a series of reaches separated by dams, or weirs, which are provided with a communicating lock, or locks, arranged generally at one side. Dams are either fixed or movable, and they may also be permeable or impermeable. Fixed, impermeable structures are generally resorted to as being more economical in construction and more convenient in action. Movable dams may be said to be required only in cases of excessive flood flow, or where the conditions admit of free navigation during appreciable periods. Fixed weirs are usually constructed of solid stonework, rubble, piling or concrete provided with

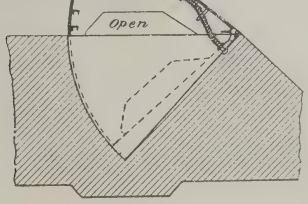

Fig. 1.—Section of Weir near Bremen.

the requisite sluices and overflows. Movable weirs are more often of timber or iron framework with mechanism for lowering and raising them, either wholly or in part by means of leaves or panels. They are of various types with distinguishing names, such as Needle, Chanoine, Boulé and Bear-trap.

Sector Weir near Bremen.—A notably large sector weir which constitutes a development of the bear-trap type, across the River Weser, near Bremen, is illustrated in cross sectional outline in fig. 1. The weir is in two lengths of 177 ft. each, and holds up the water on an average to a height of about 12 ft.; in winter, the height rises to 18 ft. The structure forms the hollow horizontal sector of a cylinder of 21½ ft. radius turning on a horizontal shaft, the angle of the sector being about 45 degrees. The weight of each sector is 129 tons. A description of the weir with the method of raising and lowering is contained in *Engineering* of July 7, 1916.

Lateral Canals.

As an alternative to river canalisation and where the channel exhibits features which do not conveniently lend themselves to treatment, an independent lateral canal may be constructed, generally following the lie of the river, but also making use of any facilities which may offer themselves for straightening and rectifying the course.

The River Rhone, in the chequered history of its amelioration, has been furnished with three lateral canals to overcome the difficulties of navigation at its natural mouth. Each in turn of the earlier two became inadequate for dealing with the traffic which accrued from its construction, and now there is a recently constructed artificial waterway to the port of Marseilles which is described in detail at p. 1376.

BRITISH CANALS.

The following summary of the conditions prevailing in Great Britain is extracted from the Report of the Royal Canal Commission (1909):

'On the whole, the waterways may be roughly divided into two classes, those having locks of more, and those having locks of less, than 14 ft. in width. Corresponding with these two classes of locks are two classes of vessels usually known respectively as barges and narrow boats, the latter being often called "monkey boats," and chiefly in use on the Southern and Midland canals of England. The barge usually measures from 60 to about 72 ft. in length by 14 ft. in width of beam; the narrow boat is about 70 to 72 ft. in length, but only 7 ft. in width. The narrow boat when loaded, and drawing about 3 ft. 3 ins. of water, will carry about 30 tons over many of the canals. The barge will carry about twice that weight, with the same draught. Both the narrow boat and the barge could carry a heavier cargo if the depth of water were increased sufficiently.

'The usual length of lock, both on the wider and the narrower waterways, in the South and the Midlands, is, accordingly, about 75 ft. But on the wider, or barge canals, the locks are usually between 14 and 15 ft. or more in width, and on the narrow canals between 7 ft. and 8 ft. In both classes of lock the depth of water on the sill varies, speaking very generally and with many exceptions, from 4 ft. to 5 ft.'

	Miles.	Chains
Canals with locks under 14 ft. (narrow)	1,165	5
" " " over 14 ft. (barge canals)	762	29*
Navigations under 14 ft.	478	57
" over 14 ft.	834	20

* Including the Manchester, Gloucester and Berkeley, and Exeter Ship Canals.

DEVELOPMENTS IN CANAL CAPACITY.

In France and South East Belgium the standard boat carries about 300 tons, while in Germany the newest canals are adapted to boats of 600 tons and upwards. In this country opinion as to future policy is divided between the adoption of the 300-ton type and the retention of the smaller class of boat in general use, not exceeding 100 tons. The following are the dimensions recommended for the two classes respectively by Sir J. Wolfe Barry and Partners, who were called in to advise the Royal Commission on the matter:

Dimensions.	100-ton Boat. Canal.	300-ton Boat. Canal.
Length of barge over all	80 ft.	115 ft.
Beam " "	14 "	21½ "
Draught	5 "	6½ "
Area of immersed midship section of barge	69 sq. ft.	138 sq. ft.
Cross sectional area of canal	350 " "	690 " "
Depth of canal	7 ft.	8½ ft.
Top width of waterway in open country	59½ "	92½ "
" " " " in towns	51¾ "	83 "
Width of waterway at bridges	32 "	48 "
Minimum headway of new bridges	10 "	13 "
" " " existing bridges	9 "	13 "
Ruling radius for bends of canal	12 chains	17 chains
Locks: Length, mitre to mitre of gates	253 ft.	266 ft.
" Width between side walls	15 "	22½ "
" Depth on sills	6½ "	8 "

1,200	295·2	32·8	5·9	77·7	8·4	6,888/R	3,509	311·6	39·4	8·2

A boat, 24 to 25 ft. wide by about 200 ft. long, with 6½ ft. draught, has been recommended by experts as a suitable type for a 600-ton barge on the Canal du Nord.

On the Rhone, barges of the same width and 220 ft. long have been put into service, carrying 650 tons on a draught of 6 ft.

The type of boat on the Rhine is the lighter of 246 ft. by 36 ft., which with the same draught carries about 900 tons, but when immersed to 6½ ft. is capable of taking 1,200 tons, with a displacement coefficient of 0·75.

(*'Annales des Ponts et Chaussées,' March–April* 1920.)

Capacity of German Inland Waterways.

Inland waterways have reached a very high pitch of development in Germany. Certain inland harbours surpass important seaports in the amount of traffic handled. The size of craft accommodated far exceeds anything attempted in this country. The following is a statement of the lengths of waterway available for successive grades of tonnage:—

	Tons.	Kilometres.
For vessels of	3,000 or more	615
,, ,, from	1,200–3,000	1,463
,, ,, ,,	600–1,200	2,064
,, ,, ,,	400– 600	2,607
,, ,, ,,	250– 400	1,705
,, ,, ,,	170– 250	1,565
Smaller vessels	—	4,515

An important project now in contemplation is the Rhine-Neckar-Danube Canal, which will complete the waterway connection right across Europe from the North Sea to the Black Sea. The length of the proposed canal will be about 165 miles, of which 125 miles come upon the Neckar section from Mannheim to Plochingen, and the remaining 40 miles on the section Plochingen-Ulm.

CONTINENTAL CANALS.

Canal du Nord, France, duplicating the St. Quentin Canal, which forms part of the navigable waterway connecting Paris with the Northern parts of France.—The ordinary cross

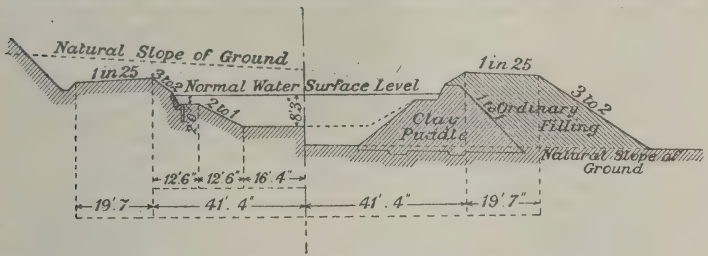

FIG. 7.—CANAL DU NORD.

Section in Excavation. Section in Filling on Impermeable Ground.

section has a minimum width of 33 ft. at the bottom and 39 ft. at a depth of 6½ ft., with a navigable depth of 8 ft. Towpaths, 13 ft. to 20 ft. wide on each bank, one for upstream and one for downstream traffic. Locks provided to accommodate two 300-ton barges in tandem; dimensions, 279 ft. long by 19½ ft. wide by 8 ft. deep. Lifts, 13 ft. to 22 ft., with minimum reach of 1,100 yards between locks. Tunnels of two types: those for single train of boats are 33 ft. wide at springing of arch, and those for double trains of boats abreast are 52½ ft. wide at springing. Each type has two side platforms, 6½ ft. wide carried on piles. Largest tunnel at Ruyaulcourt, which is 2¼ miles long. Canal designed for mean speed of two miles per hour, with barges mechanically hauled. Fig. 7 gives typical sections.

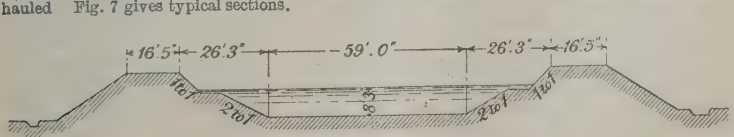

FIG. 8.—Brussels-Charleroi Canal.

The Rhone-Marseilles Canal.—The cross section in the straight lengths gives a width of 82 ft. at a depth of 6½ ft., while the normal depth is 8 ft. 2 ins., and that in the outer portion approaching Marseilles 10 ft. Sills and inverts throughout are laid to this lower level, in order to admit of future deepening. The width of the canal is narrowed to 59 ft. where it passes through the Nerthe Mountain (Rove Tunnel). The canal section on the straight portion has been fixed at five times the immersed section of the present Rhone barges, when loaded to their maximum capacity of 600 tons on a 5 ft. 9 in. draught. These barges have a beam of 26 ft. 3 ins. The dimensions of the locks are 525 ft. internal length, by 52½ ft. in width. The lock at Arles has a lift of 23 ft. at low water. The total cost of the canal is estimated to exceed 3,560,000*l.* The section of the Rove Tunnel shown in figs. 9 and 10 cost 52*l.* per ft. run, of which the masonry work accounted for 16*l.* per ft. run.

Modern German Canals.—Herr Germelmann, in a Report to the Philadelphia Navigation Congress 1912, remarks that in Germany high economic value is attached only to large efficient canals, suitable for vessels of 213 ft. in length by 26¼ ft. in breadth (600 ton barges), or, at least, for vessels of 180½ ft. in length and 26¼ ft. in breadth (400-ton barges) with draughts of 5 ft. 9 ins. The cross sectional area of canals recently constructed is as follows:—Spree-Oder Canal from 705 to 760 sq. ft.; Dortmund-Ems Canal, in cuttings, 640 sq. ft.; in embankment, 810 sq. ft.; Teltow Canal, 652 sq. ft.; Ems-Weser Hanover Canal, in cuttings, 662 sq. ft.; in embankment, 780 sq. ft.; Rhine-Ems Canal, 986 sq. ft.; Berlin-Stettin Canal, about 732 sq. ft.

Trollhätta Canal, Sweden.—This canal, first opened in 1607 and recently enlarged and extended at a cost of about 1,300,000*l.*, has a length of about fifty-two miles, and connects Lake Vänern with the Kattegat, between which there is, at ordinary water level, a vertical difference of 146 ft. The canal is built to accommodate vessels of 13 ft. 1½ in. draught, but with a view to future developments the locks are constructed to pass vessels of 16 ft. 5 ins. draught. The normal bottom width of the canal is 79 ft., but this, at passing places, is increased to 95 ft. and 115 ft. The maximum depth in rock cutting for vessels drawing 13 ft. 1½ in. is 14 ft. 5 ins., and in earth excavation, 18 ft. 3 ins. For the 16 ft. 5 in. vessel these dimensions are increased to 18 ft. and 19 ft. 7 ins. respectively. The lock chambers have a length of 295 ft. and a width of 45 ft., with 18 ft. of water over sills. The greatest change in level at any one lock is 26 ft.

New York State Barge Canal.—This canal, the inception of which dates back to the beginning of last century, has recently been enlarged so as to afford accommodation not only for the largest class of barges at present constructed, but also for those up to 3,000 tons which may be built in the future. A minimum depth of 12 ft. has been provided, with a minimum width of 94 ft. in rock cuttings and of 125 ft. in earth excavation. The locks, 57 in number, have chambers 328 ft. long and 45 ft. wide and are capable of passing vessels with maximum dimensions of 300 ft. by 44½ ft. The lock at Little Falls has a range of 40½ ft., exceeding any single lift on the Panama Canal. The syphon lock at Oswego is the first of its type in the United States, and with a range of 25 ft. is probably the largest of its kind in existence. A description of it is as follows (*vide* '*Engineering*,' August 2, 1918). The general design of the culverts is not unlike that of an ordinary lock, except that at the upper and lower ends the culverts are curved upwards so as to form necks. These rise a little above the highest water level and are shut off from all communication with the outer air, except through the operating pipes. The flow of water in the syphon is started by means of tanks, one of which is built in each wall near the upper end, and communicates through pipes with the upper and lower levels and with both syphons in the same wall; they are shut off from all other communication with the outer air. The cycle of operations is as follows: The tank is first filled with water, then the intake valve is closed and the outlet valve opened. In consequence there is a body of water suspended by its weight, but tending to escape into the lower pool, and thus producing the necessary vacuum. Therefore, on opening the air valve, the air in the syphon rushes towards the vacuum, and water begins to flow up and over the crest in the neck. When using both syphons, the lock chamber can be filled in from 4½ to 5 mins., and it can be emptied in from 5½ to 6 mins. It has been found that the draught of the vacuum is such that, soon after the flow has started, the direction of the air is reversed and the vacuum is restored in the flask. The operating power is accordingly self-renewing except for a small amount of air leakage.

Cost of Canal Construction and Improvement in Great Britain.

In 1905 Mr. J. A. Saner estimated the constructional cost of new canal, suitable for two lighters of not less than 250 tons carrying capacity, or 200 tons when self-propelled, with locks 230 ft. by 22 ft. having 6½ ft. draught of water over sills, the canal itself being 40 to 45 ft. wide at bottom, 80 to 85 ft. wide at top, and 8 ft. deep in centre, at 30,000*l.* per mile, and the cost of improving existing routes to reach the same standard at 15,000*l.* 'These figures are based on the actual cost of the Weaver Navigation and the Manchester Ship Canal; the former has cost about 42,000*l.* per mile, and the latter about 440,000*l.* per mile, inclusive of docks in each case. The Worcester and Birmingham Canal originally cost 20,000*l.* per mile and between 1879 and 1891, the French improved 2,500 miles of river, 2,250 miles of canal, and built 875 miles of new canal, for a total of 21,000,000*l.*, or an average of 3,734*l.* per mile; so that the foregoing figures should be ample.' (*Saner on Waterways in Great Britain, Min. Proc. Inst. C.E.*, vol. clxiii.)

RELATIVE ADVANTAGES OF LOCKS AND LIFTS ON CANALS.

Changes of level in canals and canalised rivers are effected by (1) locks, and (2) mechanical lifts, the latter being either (*a*) vertical or (*b*) on an inclined plane.

Locks are the simplest and most stable means of attaining the desired object. There is no question of their superiority for all differences of level up to 12 or 15 ft., and circumstances are generally favourable for their adoption for differences up to 25 or 30 ft., and even more. Among

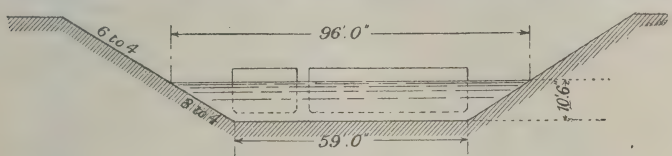

FIG. 15.—Bruges-Ghent Canal (General Section).

the older canals may be instanced a lock on the River Moldau, which has a lift of 29 ft., and another on the St. Denis Canal, which has a lift of 32½ ft. Such heights used to be considered as marking about the limit of the advantageous employment of locks over mechanical appliances. For

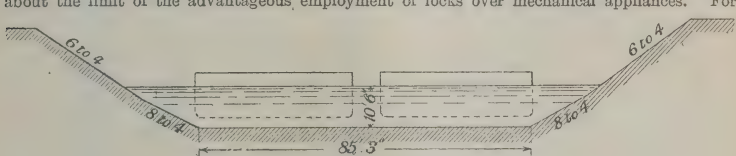

FIG. 16.—Bruges-Ghent Canal (Side Bay).

greater lifts, the strain on the lower gates became very considerable, and the consumption of water in the majority of cases was more than could be afforded.

It is true that by the aid of side ponds and syphons a large proportion of the water used in lockage could be saved—as much as 50 or 60 per cent. in many cases—but even allowing for this the loss was heavy and a mechanical lift was almost universally substituted.

In modern German practice, however, a very striking advance has been made owing to the development in size of vessels, which have now reached to a tonnage of 600 to 1,000 tons. A lock recently constructed at Henrichenburg has a lift of 46 ft. It is provided with five side ponds for the economisation of water, the saving amounting to about 76 per cent. The chamber (312 ft. long by 33 ft. wide with 9 ft. 10 ins. depth of water over sill) is built in concrete on a rock foundation, requiring an invert only 19½ ins. thick. Other locks are being constructed which attain lifts of over 60 ft. The former limit therefore can no longer be said to apply, except in so far that, if it be exceeded, due provision will have to be made for the increase in strength of the gates and side walls, and for the economisation of water.

An appropriate test to apply to the serviceability of locks is the gradient or slope of the canal route. Where this is fairly regular and does not exceed 1 in 100 the rise lends itself to convenient subdivision into reaches of a quarter of a mile each, or more, separated by single locks of about 13 ft. lift. Under ordinary circumstances this is found to be a suitable standard for barge traffic, with barges of moderate tonnage, such as are customary in this country.

Where, on the other hand, the level of the ground changes abruptly, locks of higher lift or a series of locks may be employed, but only if an adequate supply of water is forthcoming to make good the loss from lockage. Where water is scarce it will be necessary to fall back upon some system of mechanical transfer.

Mechanical Lifts are generally more expeditious and time saving in action than locks, but they are also as a rule more expensive, and from their nature they are less durable and more liable to derangement.

From a number of examples of direct acting vertical lifts may be mentioned those at Anderton (Cheshire), Les Fontinettes (France), and Peterborough (Canada).

Lift at Anderton.—In this case the difference in level is 50 ft. The lift consists of two wrought-iron troughs, each 75 ft. long by 15½ ft. wide, originally worked hydraulically and counterbalancing one another, so that it was only necessary to reduce the depth of water in the lower trough by 6 ins. in order to set the apparatus in action. Owing to excessive wear and tear which developed in the hydraulic rams and cylinders, these were replaced in 1907–8 by a system of suspension gear passing over pulleys on an overhead gantry with counter weights at

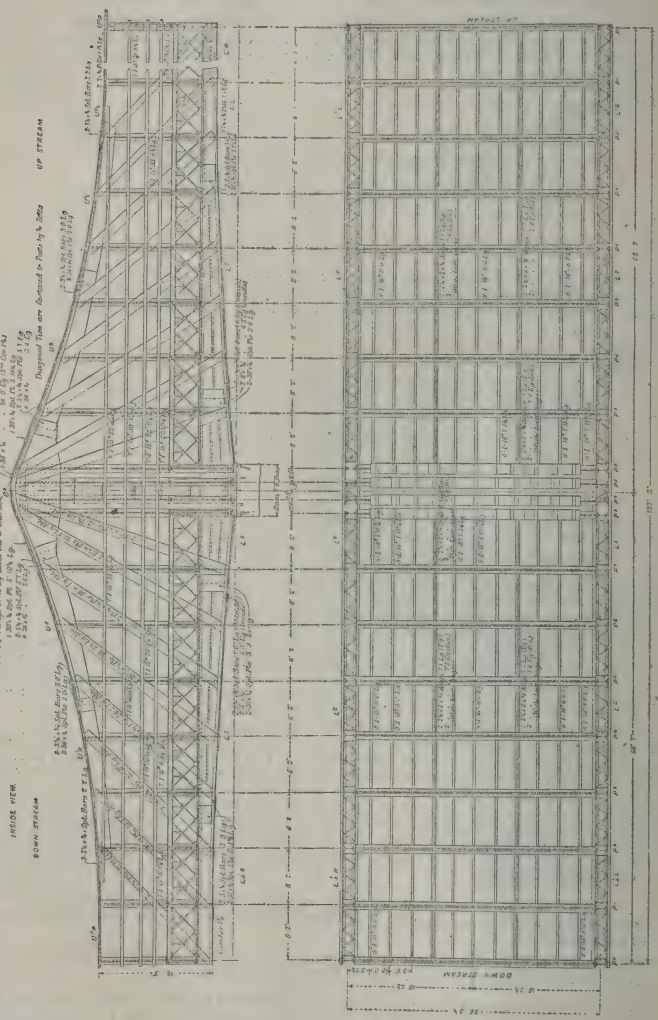

Fig. 17.—Internal View and Plan of Canal Lift Lock at Peterborough, Canada.

the free ends of the ropes. The total weight so suspended is 1,000 tons, each of the caissons weighing 250 tons, of which 80 tons is iron and the remainder water. The reconstructed lift is worked electrically. The main 30 B.H.P. motor runs at about 750 revs. per min., and the large 6 ft. pulleys make about 1 revolution in 2 minutes.

Lift at Les Fontinettes, near St. Omer, France.—The lift consists of two iron troughs containing water and each capable of taking a boat of 300 tons. Each trough is bolted at its centre to the head of a ram or piston, working in an hydraulic press. The two presses are in intercommunication by means of a pipe and constitute an hydraulic balance, vertical movement being obtained by admitting a surcharge of water to the upper tank. The surcharge is 12 ins. in depth, equal to about 64½ tons weight. The difference in level is 43 ft. The troughs are 129 ft. 7 ins. long by 18 ft. 4½ ins. wide, with a minimum depth of water of about 7 ft. The ends are closed by lifting gates. The rams or pistons are 57 ft. long, 6 ft. 6¾ ins. diameter, and 2 ft. 8 ins. thick. They are formed in sections 9 ft. 2 ins. long, flanged inside, bolted together

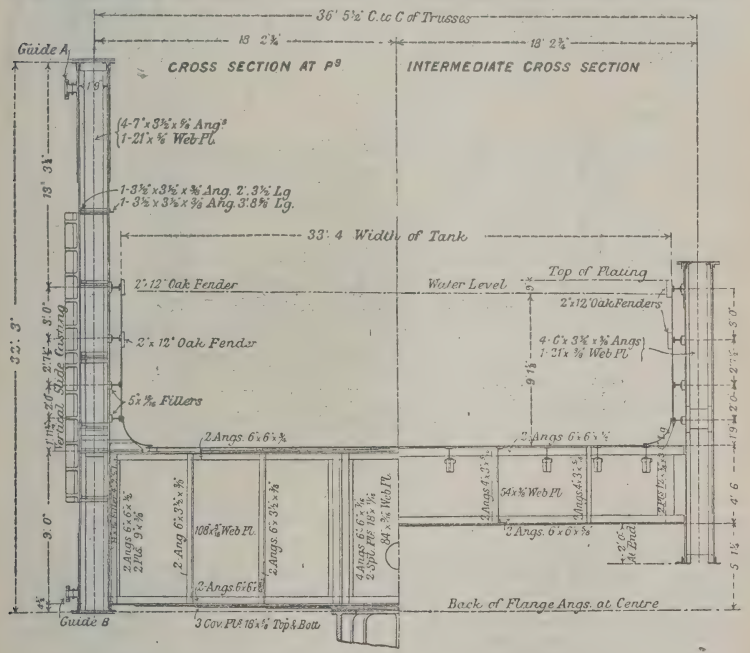

FIG. 18.—Cross Sections of Canal Lift Lock at Peterborough, Canada.

and made water-tight by a ring of sheet copper inserted between the flanges. The hydraulic presses are 71 ft. high and 6 ft. 10 ins. diameter, resting upon concrete foundations at the bottom of excavated pits.

When one trough is raised to summit level there is a margin of 1⅞ ins. between its upstream extremity and the downstream end of the canal aqueduct. At the moment of lifting the gates to allow of the passage of a boat in or out, the joint is made good by indiarubber hose running round the end of the aqueduct and protected by springs. This hose is inflated by air at a pressure of 1½ atmospheres. The same connection is made at the lower level.

The machinery consists of two turbines, one of 50 H.P. and the other of 15 H.P.

The actual time of descent and ascent of the troughs is five minutes. An entire operation, including entry and exit of barges, takes twenty minutes.

The total cost of the lift was about 74,800*l.*

Lifts on the Trent Canal, Canada.——There are two large lifts, one at Peterborough and the other at Kirkfield. The former consists of a pair of tanks, or chambers, 137 ft. long by

33 ft. 4 ins. wide, and with 9 ft. depth of water. Each tank is supported by a ram 7 ft. 6 ins. diameter worked hydraulically, so that the descent of one chamber automatically forces up the other. The range of lift is 65 ft. Under ordinary conditions the upper chamber is held in position at a level about 6 or 8 ins. below the limit of stroke, and this surcharge of water is sufficient, when the by-pass is open, to overcome friction and give the necessary movement. The tanks are supported by openwork lattice trusses, and the total load of water and steel is carried to the top of the ram by four plate girders 9 ft. deep. The following is a description of the gates, which are in pairs, one closing the chamber end and the other the canal reach. 'Each gate is made up of three main 15-in. channels, with a small plate and angle girder at the top, and is stiffened vertically by 10-in. I beams. In every space between these vertical I beams there are placed two galvanised iron air chambers about 11 ft. long. These have the effect of making the gates practically buoyant, and this decreases markedly the amount of work which has to be done in raising the gates from a horizontal to a vertical position. The water-tight plating is, in each case, on the outside of the gate, and the hinges are at the bottom. In the case of the lower reach gates and chamber gates, the hinge for the reach gate is 2 ft. 4 ins. below the hinge of the chamber gate, and 1 ft. 10 ins. separates them in a longitudinal direction. Consequently, the chamber gate is approximately 10 ft. deep, while the reach gate is about 12 ft. 6 ins. deep. As it is never necessary to operate any gate singly, the gates are arranged to work in pairs. At

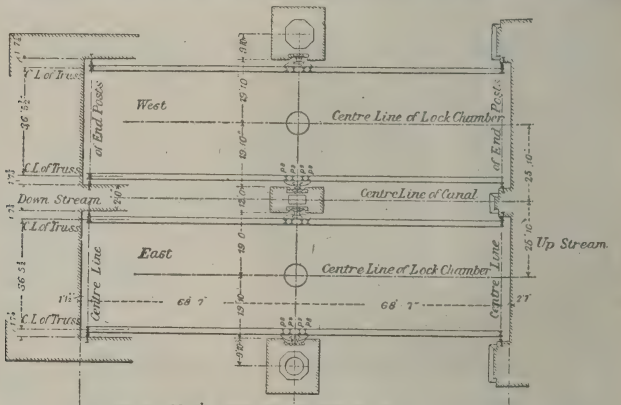

FIG. 19.—General Arrangement of Canal Lift Lock at Peterborough, Canada.

each end of the reach gate there is a pinion meshing into a circular rack set into the dock wall. The centre of the pitch circle of this rack is, of course, coincident with the centre of the hinge of the reach gate. The pinions above referred to are connected by a horizontal shaft running right across the gate, and power is applied to this shaft by means of a sprocket with chain, driven from another shaft, the centre of which is the same as that of the hinge. This shaft is actuated by one of the hydraulic gate engines provided.

'The seal between the reach-gate and the reach is accomplished by a small rubber strip, which lying over the adjacent surfaces is made water-tight by hydrostatic pressure. A similar arrangement is used for making the joints between chamber-gate and chamber water-tight. The seal between the end of the chamber and the end of the reach is accomplished by a collapsible rubber tube, which, when the chamber is away from the reach, lies almost flat against the end of the reach-gate frame. When, however, the chamber is in its proper position, the tube is inflated by compressed air at 90 lbs. per sq. in., and a water-tight joint is obtained.'

The hydraulic cylinders are plain steel castings, built up in flanged sections 5 ft. 3 ins. long. The inside diameter is 7 ft. 8½ ins., and the metal is 3½ ins. thick. The joint packing is of copper, ⅞ in. wide and $\frac{1}{10}$ in. thick, with $\frac{7}{16}$ in. diameter lead wire in press sections. The rams are of cast iron in flanged sections, also 5 ft. 3 ins. long, 90 ins. external diameter, thus giving a water space of 1¼ in. completely round the rams. The jointing is the same as that for the cylinders, except that the lead ring is omitted.

A very full description of this lock appeared in *Engineering* of June 9 and 16, 1916, from which the above particulars were extracted.

Inclined Planes represent a class of mechanical appliances suitable for intermediate conditions, viz., a route gradient too steep for single locks with intermediate reaches, and not suffi-

(*From Report by Col. H. F. Hodges, U.S. Army, to 12th Int. Nav. Cong., Philadelphia*, 1912.)

ciently abrupt at any one point for a vertical lift. Generally speaking, gradients of between 1 in 8 and 1 in 10 are most favourable, but they may run up to 1 in 75, or 1 in 80, and, on the other hand, inclined planes are sometimes adopted where the rise is much steeper, as, for instance, at Foxton on the Grand Junction Canal, where the gradient is 1 in 4. The Foxton incline is similar in character to the balanced vertical lift, consisting of two caissons travelling transversely, each maintaining a barge of 70 tons afloat. It is claimed for inclined planes that, in comparison with locks, they save water, and, in comparison with vertical lifts, they save time, since a boat is travelling forward simultaneously with its alteration in level. Moreover, they do not require such deep or expensive foundations as the lift proper. In spite of these advantages, inclined planes have not attained a very marked degree of acceptance among canal engineers.

Canal Curves.—The formula adopted in Belgium for the increased width at curves is

$$S=\frac{A^2+a^2}{R}.$$

Where S is the increase in bottom width to be added to the normal semi-width on the convex side of the curve, R is the radius of the curve, and A and a are the half lengths of the boats which have to pass one another. The units are all in metres, and the value of S must therefore be multiplied by 3·28 to bring it to feet. The increased width is splayed into the straight length at a distance of 2 $(A+a)$ from the commencement of the curve.

LOSS OF WATER ON CANALS.

Rankine summarises the sources of loss of water on canals as follows :

Waste of Water by leakage of the channel, repairs and evaporation *per day* = area of surface of canal × ¼ of a foot, nearly.

Current from the higher towards the lower reaches, produced by leakage at the lock gates *per day*, from 10,000 to 20,000 cubic ft. in ordinary cases.

Lockage.—Single locks are more favourable to economy of water than flights of locks. At a single lock, single boats ascending and descending, alternately, cause less expenditure of water than equal numbers of boats in trains. On the other hand, at a flight of locks, boats in trains cause less expenditure of water than equal numbers of boats ascending and descending alternately. For this reason where a long flight of locks is unavoidable, it is usual to make it double, using one flight exclusively for ascending boats and the other exclusively for descending boats.

Loss by Percolation from Erie Canal.
In Cubic Feet per Second per Mile of Canal.

Location.	Material in Bank.	Cub. ft. per Sec. per Mile of Canal.
Near Dunsbach Ferry	Gravel	1·68
Near East of Schenectady	Sandy loam	1·50
Near West of Schenectady	Gravel	2·24
East of Amsterdam	Gravel	3·03
West of Amsterdam	Coarse gravel	12·89
Canajoharie	Gravel	2·00
Fort Plain	Gravel	6·85
East of Utica	Sandy loam	4·45
East of Rome	Sand and gravel	8·48
West of Rome	Clay loam and gravel	1·75

Note.—The Erie Canal has bottom widths of 52½ ft. and 42 ft. and depths of 7 ft. and 9 ft. in various portions.

Canal Bank Protection in Italy.—The sandy banks along the Candiano Canal in the province of Ravenna are strengthened with a row of reinforced concrete piling. The king piles, 10 to 16 ft. long and 8 ins. square, are driven at intervals of 10 ft. They are secured together at the top by a longitudinal runner 8 ins. by 8 ins., behind which is driven a row of sheet piling from 5½ to 6½ ft. long and 2 ins. thick. The length of the piles depends upon the nature of the ground and the depth of water, and, where necessary, further security is obtained by anchorage tie rods and bars to short piles in the rear. At points where it was possible to remove the water from the canal, or where the bottom was occasionally exposed, it was considered desirable and economical to revet the banks with a surfacing of reinforced concrete 2½ ins. thick in which the reinforcement consisted of expanded metal ·4 to 1·6 in. mesh and ·2 to ·32 lbs. per sq. ft. Where the canal bottom is not subject to erosion during floods, this revetment is continued down as far as 18 ins. above the level of the bottom, and the toe is protected by rubble. In cases of erosive action there is a concrete foundation or sill, sometimes supported by piling : and where the water level cannot be lowered sufficiently for the formation of a sill, the toe of the revetment rests against sheet piling.

TRACTION AND HAULAGE.

Means of Traction.—On ordinary small barge canals horse traction has hitherto remained the principal means of traction, although locomotives have been tried from time to time, generally without success. On the larger canals, such as those on the Continent and abroad, tug haulage is frequently employed and some vessels are self-propelled. Ship canals are navigated by vessels under their own steam, but for passage through the locks of the Panama Canal electric locomotives are provided.

Horse Traction on a straight reach is most effective at speeds between 2½ and 3 miles per hour. Within these limits a steady pull of between 100 and 125 lbs. can be maintained, which is sufficient for loads up to 60 tons. There is the further consideration that at higher speeds the wash against the banks becomes excessive for unprotected surfaces. Where tugs or locomotives are employed some form of bank protection becomes essential.

As regards river navigation Rankine gives the following formula as a rough estimate of the effect of the current of a stream on the load which one horse is able to draw against at a walk.

Load drawn against current = load drawn in still water $\times \left(\frac{3{\cdot}6}{3{\cdot}6 + v}\right)^2$; v being the velocity of the current in feet per second.

Cable Towage.—Lévy system, as adopted on St. Maur Canal between Paris and Joinville.—Cable weighs 2·45 lbs. per lin. ft. Set with permanent tension of five tons. Breaking strength 50 tons. Deflection due to haulage does not exceed 4 ins. Vertical supporting pulleys are 2 ft. 7½ ins. diameter, and have depth of groove of 7½ ins. Circuit may cover distance of 10 to 11 miles, so that two driving machines may be set 20 to 22 miles apart. For a speed of 1½ miles per hour 2 H.P. is required to draw a barge loaded with 350 tons. For a speed of 2½ miles an hour 4½ H.P. is required. Tractive force = $\frac{Wv^2}{2gl}$, where W = weight of boat in lbs., v = velocity in ft. per sec., g = acceleration due to gravity = 32 ft. per sec., and l = length of towline in feet. For a boat of 300 tons a velocity of 3 ft. per sec. and length of line of 300 ft., the tractive force = 315 lbs. Estimated cost of plant, about 12*s.* 6*d.* per lin. yd. Cost of working ranges from ½*d.* to ¼*d.* per ton per mile.

(*Report of Dr Watson to Water Commerce Congress at Chicago*, 1893.)

Electric Traction on an elaborate scale has been installed on the Teltow Canal in Germany since 1905. The tractors run on rails on both banks. The current is continuous at 550 volts, from overhead mains, and each locomotive is driven by two 8 h.p. motors, which are sufficiently powerful to haul two 600-ton barges at a speed of 2½ miles per hour. A similar system is in use on the Douai section of the Canal d'Aire, where the tractors are of 10 h.p. In 1918, some petrol locomotives of 20–25 h.p. were introduced on the Rhine-Rhone Canal in place of horses, but though the experiment was successful the system did not come into general use on the Canal because it would have entailed considerable alteration in the permanent works.

The following advantages among others have been claimed for the use of electric tractors in place of steam tugs:—

1. Assuming that the electric lines are laid on each bank, there will be greater regularity and uniformity of speed in the service than where tugs are used, and there will be less delay in despatching cargoes at short notice and at regular intervals.

2. The banks and bottom of a canal are not so much injured by electric-towing as by tug-towing. In the latter case the peculiar disturbance to the bottom, with consequential injury to the side banks, caused by the motion of the screw, is added to the wave from the moving boats common to each mode of transport.

3. In the case of electric towing there is considerable economy of space and water in locks and lifts, because tugs and steam boats, which, by reason of their machinery, have a smaller cargo-carrying capacity than barges of like dimensions, need not be taken through.

4. Electric power, when once installed along a line of waterway, can be utilised not only for traction, but also for operating locks and other works, and lighting the waterway at night, and can even, perhaps, be utilised for factories establishing themselves along the waterway.

(*Report of Royal Commission on Waterways*, 1909.)

SHIP CANALS.

General Considerations.—It is desirable that the ratio of cross sectional area of the canal to the immersed section of ships, where the traffic is commercial, should not be less than 4 to 1, and it may with advantage be much higher. In the Suez Canal it is about 7 to 1. For vessels

of war, the ratio may be slightly less, as, for instance, in the Kaiser Wilhelm Canal where the ratio is about $3\frac{1}{2}$ to 1. The limiting value is, however, dependent on the speed at which vessels are permitted to travel. In the artificial portion of the Suez Canal the speed is limited to between 6 and 7 knots, and about 8 knots represents an approximate upper limit for narrow shallow waterways. In passing through such waters vessels sink to a lower level than in the open sea on account of the displacement. Thus pilots have a rough rule that when a ship is near the bottom her 'squat' or 'sinkage' in feet may be about one-fifth of her speed in statute miles per hour.

For curves, M. Quellenec, Consulting Engineer to the Suez Canal Commission, recommends widening the bottom so that the longest vessel may preserve in its own direction a free space equal to $1\frac{1}{2}$ times its own length from the slope of the concave side. The formula used on the canal was:

$$W = \sqrt{R^2+(2a)^2}-(R+b).$$

Where
W = amount of widening in feet.
R = radius of axis in feet.
a = length of ship in feet.
b = $\frac{1}{2}$ bottom width (on tangent) of canal in feet.

Kaiser Wilhelm Canal.—This canal, which connects the North Sea and the Baltic, was originally constructed between 1887 and 1895 at a cost of about 7,800,000*l.*, including land purchase. It has a length of $61\frac{1}{4}$ miles. The former dimensions have since been very considerably increased, viz., the bottom width from 72 ft. to $144\frac{1}{2}$ ft., the surface width from 226 ft. to $334\frac{1}{2}$ ft., the depth from about 30 ft. to 36 ft., and the cross sectional area from about 4,500 sq. ft. to 8,868 sq. ft.

At the entrances at each end of the canal there are new twin locks of 1,083 ft. available length, by $147\frac{1}{2}$ ft. clear width and 45 ft. 2 ins. sill depth at mean water level. These locks take the place of the earlier locks, which were 492 ft. long by 82 ft. wide with 32 ft. of water over sill. The new locks are constructed in concrete, and each has three pairs of caissons dividing the chambers into lengths of 725 ft. and 330 ft.

Manchester Ship Canal.—The Manchester Ship Canal was constructed between 1887 and 1893. It has a total length of 36 miles and includes four sets of locks, with an average lift of 15 ft. each, about 160 acres of docks with warehouses and railway sidings, six high level

MANCHESTER SHIP CANAL: TYPE SECTIONS.

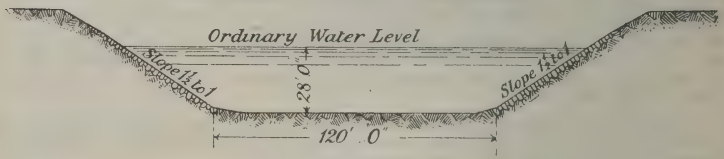

FIG. 20.—Ordinary Section.

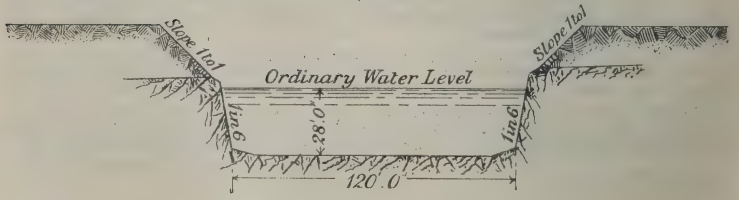

FIG. 21.—Section through Rock.

bridges, seven swing bridges, and a swing aqueduct. The cost was 13,500,000*l.*, including land purchase and promotion, the actual constructional cost being about 9,000,000*l.* The bottom width is 120 ft. The original depth was 26 ft., but this has now been increased to 28 ft. The average annual cost of maintenance is stated to be about 2,000*l.* per mile of canal.

Suez Canal.—The length of the Suez Canal is about 100 miles. It was opened in 1869, the cost of construction, apart from promotion, etc., having amounted to 10,680,000*l.* It has been progressively deepened so that the authorised maximum draught for ships in the canal has been as follows :—

From	1870 to 1890	7 m. 50 = 24 ft. 7 ins.
„	1890 to 1902	7 m. 80 = 25 ft. 7 ins.
„	1902 to 1906	8 m. 00 = 26 ft. 3 ins.
„	1906 to 1908	8 m. 23 = 27 ft. 0 ins.
„	1908 to 1914	8 m. 53 = 28 ft. 0 ins.
„	1914 to 1915	8 m. 84 = 29 ft. 0 ins.
„	1915 to 1919	9 m. 15 = 30 ft. 0 ins.

The canal is in process of being deepened throughout to 12 metres, or 39 ft. 4 ins.

Of the total length of 99·86 miles, 90·08 miles are in straight reaches ; 3·48 miles in curves of 3,280 to 3,500 yds. radius ; 4·97 miles in curves of 2,187 to 3,270 yds. radius ; 1·11 miles in curves of 1,105 to 1,930 yds. radius ; and ·22 mile with a curve of 321 yds. radius. These curves are in process of being modified so that the minimum radius shall be over 2,200 yds.

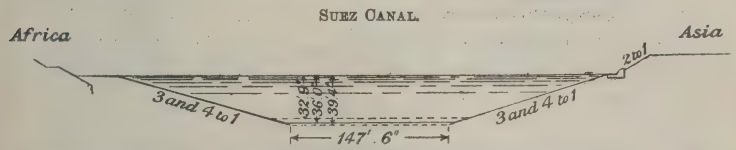

Fig. 22.—Section of Suez Canal, showing progressive deepening, as completed, in course of execution, and contemplated.

There are no locks, the canal being level throughout. At the Suez entrance there is a tidal range, amounting to about 6 ft. in the average at springs. The current flow does not exceed about 3½ ft. per second.

Panama Canal.—The total length of the Panama Canal, measured along its axis, is 50½ miles, but the portion actually within land area between coast lines is only 41½ miles. Of the total length, 14½ miles are at sea level, over 23½ miles in Gatun Lake, nearly 3 miles in locks or alongside approach walls, 1½ miles in Miraflores Lake, and 8 miles in the Gaillard Cut. The summit level is 85 ft. above sea level. The depth lies between 40 and 45 ft. The bottom width varies as follows : For 16 miles the canal is 1,000 ft. wide ; for 4 miles, 800 ft. ; for 22 miles, 500 ft. ; and for 8 miles, 300 ft. wide.

Diagrammatic Sections of Panama Canal. (Not to Scale.)

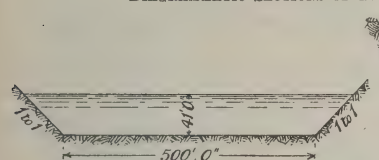

Fig. 23.—From Mindi River to Gatun Locks, and from Miraflores to Panama Bay.

Fig. 24.—Gaillard (formerly Culebra) Cut.

There are six pairs of locks with dimensions of 1,000 ft. in length and 110 ft. in width ; three of these are at Gatun, one at Pedro Miguel, and two at Miraflores. With the exception of the

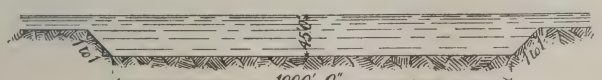

Fig. 25.—From Gatun Locks to Angle North of San Pablo.

lower lock in the Miraflores flight, the chambers are provided with intermediate gates, dividing them into two sections of 600 ft. and 400 ft. The range of lift of the Pedro Miguel Lock is 30⅓ ft.

At the Gatun flight the lift is 85 ft. divided among the three locks; the actual operating pressure between consecutive locks is therefore nearly 60 ft.

There are 46 pairs of lock gates, constructed of mild carbon steel with yokes and pintles of vanadium steel. The height of the gates varies from 46 ft. to 82 ft. The largest gate weighs about 700 tons.

The approximate cost of the canal, including purchase money, is 75,000,000*l.*

The following is a statement of the unit cost of excavating the Culebra (now Gaillard) Cut for the year 1912:

	Cost per cub. yd.
Transportation	$0·1331
Drilling and blasting	·1157
Tracks	·0885
Loading by steam shovels	·0681
General expenses and supervision	·0503
Dumps	·0479
Plant, arbitrary	·0395
Drainage, structures and clearing	·0045
Total unit cost	$0·5476

CLARKE, CHAPMAN & CO. Ltd.,

GATESHEAD.

Contractors to the British and Foreign Governments.

MANUFACTURERS OF

Direct-acting Slow Speed Feed Pumps.

('Woodeson's Patents.')

Constructed on the Simple, Tandem Compound or Twin Compound Systems of the Piston or Outside Packed Ram Types.

Suitable for all purposes and working pressures.

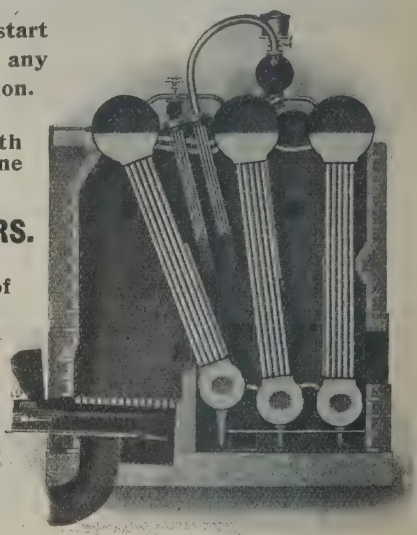
ECONOMICAL——SIMPLE.

Wear and tear reduced to a minimum.

Will start from any position.

Can also be fitted with controlling tank for Marine Purposes.

WATER-TUBE BOILERS.



('Woodeson's Patents.')

All Tubes straight and of equal length.
No joints exposed to action of fire.

Maximum Steam release. Minimum Deposits.

Can be fitted with patent Superheater.

Special design for utilising waste gases from Coke Ovens.

WOODESON PATENT WATER-TUBE BOILER FITTED WITH PATENT SUPERHEATER AND UNDERFEED TYPE OF STOKER.

ENQUIRIES SOLICITED.

(Revised and largely rewritten by T. B. Morley, D.Sc., M.I.Mech.E.)

STEAM

When water is converted into steam by the addition of heat no steam is produced until the temperature of evaporation, or boiling point, is reached. This temperature increases with, and is determined by, the pressure. Whilst evaporation is taking place the temperature remains unchanged, and for this reason the heat required during this process is called the 'latent' heat. After the water has all been converted into steam, the addition of further heat raises the temperature and is said to superheat the steam.

If steam contains liquid moisture mixed with it, it is said to be wet. The percentage of actual steam to total steam and moisture is the dryness fraction.

When the steam is not superheated, but yet contains no moisture, it is dry and saturated, or, for short, dry steam.

It has been established that under certain conditions of expansion, as in turbine nozzles, steam may for a time not be in stable thermal condition, continuing to behave like a vapour although for equilibrium at the prevailing pressure and temperature a portion of it must become condensed. In other words, condensation is temporarily delayed. Steam in this condition is said to be 'supersaturated,' or, since its temperature is lower than the saturation temperature corresponding to the pressure, to be 'supercooled.' This condition is important in connection with the study of steam turbines.

The above general remarks apply to the vapours of all liquids, but the temperatures of evaporation at equal pressures vary widely with different liquids.

Atmospheric pressure in this country is taken as 14·69 lbs. per square inch. At this pressure water boils at 212° Fahr., and has a latent heat of 970 British Thermal Units (B.Th.U.) per pound.

Gauge pressures are measured above atmospheric and are approximately 15 lbs. per square inch below the absolute pressures.

One inch of mercury column at 32° Fahr. is equal to 0·491 lb. per sq. in. Reduce one-hundredth per cent. for each extra degree Fahr. of mercury column temperature.

Heat and work are mutually equivalent. One British Thermal Unit is equal to 778 foot-pounds of work.

The following are useful data relating to heat and work.

1 British Thermal Unit	= 778 ft.-lbs.	2,545 British Thermal Units . . .	= 641 kg. cals.
"	= 0·252 kg. calorie.		= 746 watts.
"	= 107·7 kg. metres.	1·34 h.p. hours . . .	= 1 k.w. hour.
3·968 " " Units	= 1 kg. cal.		= 3,410 B.Th.U.
2,545 " " "	= 1 h.p. hour (British).		= 858 kg. cals.

Steam Tables.

Prof. Callendar has established equations correlating the principal properties of steam, dry and saturated, superheated and supersaturated. His equations are based on general thermodynamic principles, and the constants are chosen to accord with experimental data. He has thus produced valuable steam tables which agree well with the most reliable experimental observations and which are also thermodynamically consistent.

In the following Table I., the total heat, volume, and total entropy of steam are abstracted from Callendar's Tables, published by Edward Arnold, London. The remaining data in Table I. and the other following tables have been calculated by the writer on the basis of Callendar's figures.

TABLE I.—PROPERTIES OF SATURATED STEAM (BASED ON CALLENDAR'S VALUES)

NOTES.—Mercury column at 60° F. Referred to a 30-in. barometer. Pressure in lbs. per sq. in. absolute. Height of mercury gauge at a given pressure increases one-hundredth per cent. per deg. F. of mercury temperature above 60. At 60° F. 1 lb. per sq. in. pressure = 2·045 ins. mercury, and 1 In. mercury = 0·489 lbs. per sq. in.

Table IV. gives the extra heat, above the total heat of saturated steam given in Table I., contained in superheated steam from water at 32° Fahr. The heat added to the water and steam from any higher temperature is less than the value in the table by the number of degrees above 32 from which the heating of the water commences (approximate).

TABLE IV.—HEAT REQUIRED TO SUPERHEAT ONE POUND OF STEAM.

Pressure, Lbs. per Sq. In. Absolute.	Superheat, degrees Fahrenheit.						
	50	100	150	200	250	300	350
20	25·17	50·02	74·62	99·02	123·3	147·5	172·0

80	27·10	53·39	79·20	104·5	129·7	154·5	179·1
90	27·35	53·82	79·76	105·3	130·5	155·4	180·1
100	27·44	54·25	80·33	106·0	131·3	156·2	181·0
120	28·00	55·06	81·43	107·3	132·8	157·9	182·8
140	28·41	55·78	82·42	108·4	134·2	159·4	184·5
160	28·75	56·52	83·31	109·5	135·4	160·8	186·0
180	29·09	57·05	84·17	110·6	136·6	162·1	187·5
200	29·36	57·66	85·0	111·6	137·8	163·5	189·0
250	30·2	59·07	86·9	114·0	140·5	166·4	192·5
300	30·9	60·3	88·6	116·1	142·9	169·0	195·0

Example.—The total heat of steam at 160 lbs. absolute, superheated 150 degrees, from water at 102 degrees, is approximately as follows. (There is a slight inaccuracy owing to the specific heat of water varying a little, which the reader can discover and check for himself from the third column of Table I.)

Total heat of saturated steam from 32°	= 1201	B.Th.U.
Deduct 102 − 32	= 70	,,
Net heat of saturated steam from 102°	= 1131	,,
Add heat of 150° of superheat	= 83	,,
Total heat as required	= 1214	,,

TABLE V.—TOTAL HEAT OF SUPERHEATED STEAM.

Pressure. Lbs. per Sq. In. Absolute.	Superheat, degrees Fahrenheit.

300	1244·0	1273·4	1301·7	1329·2	1356·0	1382·2	1408·1

The factor of equivalent evaporation 'from and at 212°' is found by dividing the actual total heat of steam as calculated or found from foregoing tables, by 970, which is the latent heat of steam, or heat of evaporation, at atmospheric pressure.

Example.—If the actual total heat is 1067, the factor is 1·1. This means that if the actual evaporation of a boiler is 8·0 lbs. of water per lb. of coal, the 'equivalent evaporation from and at 212°' is $8·0 \times 1·1 = 8·8$ lbs. This basis is widely used because it renders water evaporations and steam consumptions accurately comparable on a uniform basis.

TO CALCULATE THE AMOUNT OF STEAM REQUIRED TO HEAT A GIVEN QUANTITY OF WATER.

G = gallons of water; T and t = temperatures, Fah., after and before heating; $10 \times G \times (T - t)$ = B.Th.U. added to the water; H = total heat per lb. of steam (column 5, Table I., p. 1392); $H - T + 32$ = heat given to water by each lb. of steam; W = lbs. of steam required; then,

$$W = \frac{10 \times G \times (T - t)}{H - T + 32}$$

Note.—One cubic foot of water contains 6·24 gallons. The volume of each lb. of steam is given in Table I.

Flow of Steam through Pipes.

The approximate weight of any fluid which will flow in one minute through any given pipe with a given head or pressure may be found by the following formula :—

$$W = 87·5 \sqrt{\frac{D\,(p_1 - p_2)\,d^5}{L\left(1 + \frac{3·6}{d}\right)}},$$

where W = weight in pounds; d = diameter in inches; D = density or weight per cubic foot; p_1 = initial pressure; p_2 = pressure at end of pipe; L = length in feet.

This formula corresponds to $p_1 - p_2 = 0·0001306 \dfrac{W^2 L\left(1 + \frac{3·6}{d}\right)}{D d^5}$ and also to $h = f \dfrac{v^2}{2g} \cdot \dfrac{4L}{d_1}$, where h = loss of head in feet, d_1 = diameter in feet, f = coefficient of friction of the steam in the pipe, f being equa to $0·0027\left(1 + \frac{3}{10 d_1}\right)$; this coefficient is due to R. C. Carpenter, and is accepted by Unwin.

The following table gives, approximately, the weight of steam per minute which will flow from various initial pressures, with one pound loss of pressure, through straight, smooth pipes, each having a length of 240 times its own diameter. The table is calculated from the above formula.

TABLE OF FLOW OF STEAM THROUGH PIPES.

(*Morley.*)

The foregoing table is based on saturated steam. For any other loss of pressure multiply by the square root of the given loss. For any other length of pipe *divide* 240 *by the given length expressed in diameters, and multiply the figures in the table by the square root of this quotient*, which will give the flow for 1 lb. loss of pressure. Conversely, dividing the given length in diameters by 240 will give the loss of pressure for the flow given in the table.

For superheated steam multiply the values in the table by $\sqrt{\frac{\text{density of superheated steam}}{\text{density of saturated steam}}}$;

or *approximately* $\frac{1}{\sqrt{1 + \cdot 0016\, t_s}}$, where t_s = degrees of superheat.

The loss of head due to getting up the velocity, to the friction of the steam entering the pipe, and passing elbows and valves, will reduce the flow given in the table. The resistance at the opening, and that at a globe valve, are each about the same as that for a length of pipe equal to 114 diameters divided by a number represented by $1 + (3 \cdot 6 \div \text{diameter})$. For the sizes of pipes given in the table these corresponding lengths are, approximately :—

$\frac{3}{4}$	1	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3	4	5	6	8	10	12	15	18
20	25	34	41	47	52	60	66	71	79	84	88	92	95

The resistance at an elbow is equal to two-thirds that of a globe valve. These equivalents—for opening, for elbows, and for valves—must be added in each instance to the actual length of pipe. Thus a 4-in. pipe, 120 diameters (40 ft.) long, with a globe valve and three elbows, would be equivalent to $120 + 60 + 60 + (3 \times 40) = 360$ diameters long; and $360 \div 240 = 1\frac{1}{2}$. It would therefore have $1\frac{1}{2}$ lbs. loss of pressure at the flow given in the table, or deliver $(1 \div \sqrt{1\frac{1}{2}} = \cdot 816)$, 81·6 per cent. of the steam with the same (1 lb.) loss of pressure.

Flow of Steam from an Orifice or Nozzle.

A jet of steam issuing from a vessel under pressure first contracts in section, and then expands if the drop in pressure is more than about 42 per cent. of the absolute pressure in the vessel. The absolute pressure at the narrowest section, which corresponds to the neck of a turbine nozzle, varies a little, but averages about 58 per cent. of the initial pressure for saturated steam, and about 55 or 56 per cent. for superheated steam. The velocity of the steam at this narrowest section is nearly constant except at very low pressures.

For typical values of velocity and discharge see Part V., Steam Turbines, p. 1545.

When the drop in pressure is less than 42 per cent. of the absolute initial pressure, the full velocity and contraction of section do not occur, and the above data do not hold (see Part V. Steam Turbines, p. 1545).

Or the quantity discharged per minute may be approximately found by Napier's formula,

$$W = 6\, a\, p \div 7,$$

where W = weight in pounds; a = area in square inches; p = absolute pressure.

The theoretical flow requires to be multiplied by $k = 0 \cdot 93$ for a short pipe, or 0·63 for a thin opening, as in a plate or a safety valve.

Where the steam flows into a pressure more than two-thirds the pressure in the boiler, then

$$W = 1 \cdot 74\, a\, k \sqrt{p_2 (p_1 - p_2)}, \text{ approximately,}$$

where a, k are as above, and p_1, p_2 are initial and final pressures

Expansion of Steam.

It is found in practice that in engines using saturated steam the expansion line follows closely the hyperbolic law :—

absolute pressure × volume = a constant.

Hence it is usual to compute indicator diagrams on the assumption that the expansion is hyperbolic. With highly superheated steam the pressure falls more rapidly than the hyperbolic curve indicates.

Expansion of Steam.

Referring to fig. 1, the theoretical indicator diagram is A B C D O, there being no clearance and a perfect vacuum. Steam is cut off at B and exhausted at C.

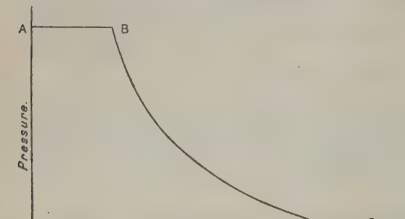

FIG. 1.

p = absolute pressure in lbs. per sq. in;

u = volume in cubic feet;

R = ratio of expansion = $\frac{OD}{AB}$;

W = area of diagram;

P = mean effective pressure in lbs. per sq. in. (M.E.P.);

pu = a constant.

then $W = ABCE + ECDO$

$= p_2u_2 \text{ hyp. log } R + p_2u_2.$

$P = p_1\left(\frac{\text{hyp. log } R + 1}{R}\right) = p_1 K.$

TABLE OF MEAN PRESSURE CONSTANTS K.

The table also gives the points of cut-off (nominal), based on assumed cylinder ratios, L.P. to H.P., in the case of multiple-expansion engines.

R.	K.	Nominal Cut-off (clearance neglected) as proportion of Stroke.

(*Morley.*)

The referred M.E.P. of compound engines is the equivalent M.E.P. if the entire expansion were to take place in the low-pressure cylinder.

The nominal ratio of expansion is the stroke volume of the L.P. cylinder ÷ volume swept by H.P. piston up to point of cut-off, or

$$R = \frac{V_L}{a\ V_H} = \frac{\text{cylinder ratio}}{a}$$

where V_H, V_L are stroke volumes of H.P. and L.P. cylinders, and a is proportion of stroke at which cut-off takes place in the H.P. cylinder.

If C_H and C_L are the clearance volumes at each end of the H.P. and L.P. cylinders, the real ratio of expansion is

$$\frac{V_L + C_L}{a\ (V_H + C_H)}$$

To determine the probable actual mean pressure (referred to the low-pressure cylinder in the case of a multiple-expansion engine) multiply the initial pressure (absolute) by K (see table on previous page), deduct the back pressure, and multiply by a suitable 'diagram factor.'

Diagram factors depend on the type of engine, type of valves and valve gear, jacketing, superheating, speed, etc. Approximate typical values are as follows :—

TABLE OF DIAGRAM FACTORS.

Triple-expansion	·65–·75
Compound condensing, superheated	·65–·75
,, ,, saturated	·7– ·8
,, non-condensing	·8–·85
Simple condensing, trip gears	·9–·95
,, ,, slide valves	·85– ·9
,, non-condensing	·9–·95

Note.—In calculating the M.E.P. the clearance is ignored. If the clearance is allowed for, the ratio of expansion for a given cut-off is lower and the theoretical M.E.P. higher, necessitating a lower diagram factor, particularly for simple and compound engines. Thus, some authorities give from 0·7 to 0·9 for simple engines.

Low revolutions, large clearance, jackets, reheaters, and low compression increase the diagram factor. These special conditions must be allowed for, as in slow-speed pumping engines

Usual Expansions in Various Types of Engines.

Single Condensing Engines	from 2 to 5 times
Two-cylinder Compound Engines	,, 10 ,, 20 ,,
Triple-expansion Engines	,, 12 ,, 25 ,,
Quadruple-expansion Engines	,, 16 ,, 30 ,,
Uniflow Engines	,, 7 ,, 12 ,,

HORSE-POWER OF STEAM ENGINES (DOUBLE-ACTING).

INDICATED HORSE-POWER.

F = Mean pressure on piston, in pounds per square inch ;
A = Area of cylinder, in square inches ;
S = Stroke of engine, in feet ;
R = Revolutions per minute.

$$\text{I.H.P.} = \frac{\text{FAS } 2\text{R}}{33000}.$$

EXAMPLE.—A cylinder 24 ins. in diameter, 3 ft. stroke, running 80 revs. per min., with 28 lbs. mean pressure on piston ; what is the indicated horse-power ?

$$\text{I.H.P.} = \frac{28 \times 24^2 \times \cdot7854 \times 3 \times 2 \times 80}{33000} = 184.$$

In the case of a compound or multiple-expansion engine it is usual to speak of the mean pressure, or mean effective pressure (M.E.P.), referred to the low-pressure cylinder. This is calculated exactly as if the low-pressure cylinder were the only one, the high-pressure and intermediate cylinders being non-existent. Thus, if two engines develop the same power at the same speed, one of them having only one cylinder and the other being a compound engine with a low-pressure cylinder equal in stroke and diameter to the only cylinder of the other engine, the M.E.P., or mean effective pressure, of the single-cylinder engine will be the same as that of the compound engine referred to the low-pressure cylinder.

Average values of the M.E.P. for high-class engines are as follows :—

TABLE OF MEAN EFFECTIVE PRESSURES AT RATED LOAD.

Gauge Boiler Pressure, lbs.	180	160	120	100	80
Triple condensing	31	30	28	—	—
Compound condensing	32	31	29	27	24
,, non-condensing	44	42	34	33	26
Uniflow condensing	38	36	33	—	—

High-speed engines are governed by throttling, the ratio of expansion being fixed. Other high-class engines have variable expansion and are capable of developing about 50 per cent. overload, but rather less at low boiler pressures.

BRAKE HORSE-POWER.

'Actual,' 'Effective,' or 'Brake' horse-power is the measured horse-power given off from the crankshaft of the engine—that is, the indicated horse-power according to the above rule, minus the power required to drive the engine itself. This latter power may be as bad as 18 per cent. for condensing engines, and 13 per cent. for non-condensing engines, but is only half these percentages for really high-class work.

STEAM CONSUMPTION.

The ideal steam-engine cycle, adopted as a standard of comparison, is the Rankine cycle. In it the steam is fully expanded adiabatically, and there are no losses due to throttling, clearance, leakage, condensation, etc.

The following tables show the work done (in B.Th.U.) per lb. of steam, and the steam consumption per i.h.p. hour in the case of ideal engines :—

(1) when the expansion is incomplete ;
(2) when the expansion is complete—*i.e.* the Rankine cycle.

TABLE OF STEAM CONSUMPTION AND WORK DONE BY STEAM.

(1)

Theoretical lbs. of steam per i.h.p. hour and work done in B.Th.U. per lb. of steam, assuming adiabatic expansion from dry steam and no compression or clearance losses, to :—

(1) 25 lbs. release pressure with 16 lbs. back pressure.
(2) 10 lbs. release pressure with 2 lbs. back pressure.

All pressures are in lbs. per square inch absolute except the approximate gauge boiler pressure corresponding to the absolute initial pressure at the engine. A pressure drop of 5 lbs. between boiler and engine is assumed.

The correction given in the table is the change in theoretical steam consumption for one pound change in the back pressure, other conditions remaining unaltered.

Boiler Pressure lbs. gauge.	Initial Pressure absolute.	Back Pressure, 16 lbs. absolute.			Back Pressure, 2 lbs. absolute.		
		Lbs.	B.Th.U.	Correction per lb.	Lbs.	B.Th.U.	Correction per lb.

50	28·6	12·0	11·2	10·2	89	211	227	249

(*Morley.*)

The steam consumption, lbs. per i.h.p. hour = 2545 ÷ work done, B.Th U. per lb.

For pressures of 100 to 200 lbs. per sq. in. and back pressures 1 to 2 lbs. per sq. in., the steam consumption of the ideal (Rankine) engine decreases about 6 per cent. for each 100° F. of superheat.

EFFICIENCY OF ENGINES.

The thermal efficiency is the ratio of the work done per lb. of steam (in B.Th.U.), to the heat required to generate 1 lb. of steam, at the pressure and temperature, at the engine stop valve, from feed water at the temperature of the engine exhaust.

$$\text{Thermal efficiency } e = \frac{\text{I.H.P.} \times 42{\cdot}42}{w\,(H_1 - h_2)} = \frac{\text{I.H.P.} \times 2545}{W\,(H_1 - h_2)}$$

where,

w = steam used, lbs. per minute; W = do., lbs. per hour;
H = total heat at pressure and temperature at boiler side of engine stop valve;
h_2 = water heat at temperature of exhaust.

It is customary to express the performance of engines in steam consumption per h.p. hour, but since the heat required to generate the steam increases with pressure and temperature, the steam-consumption figure alone is not a complete criterion of the merit of the engine.

It has been proposed to state the performance of engines in B.Th.U. per minute per i.h.p $= \frac{w\,(H_1 - h_2)}{\text{I.H.P.}} = \frac{42{\cdot}42}{e}$, or in 'equivalent feed,' which is the weight of steam which would be required per i.h.p. hour if $H_1 - h_2$ were 1100, thus equivalent feed $= \frac{W}{\text{I.H.P.}} \times \frac{H_1 - h_2}{1100}$.

Neither of these proposals has been widely adopted.

TABLE OF STEAM CONSUMPTIONS IN POUNDS PER INDICATED HORSE-POWER HOUR.

Steam Pressure, Lbs. Gauge.	Superheat, F.°	Condensing.	Simple.	Compound.	Triple-expansion.
200	100	Yes	—	10·5	10·2
200	0	,,	—	12·0	11·5
160	100	,,	14·0	11·0	10·7
160	0	,,	18·0	12·5	12·0
160	100	No	16·0	14·6	—
160	0	,,	21·0	16·7	—
120	100	Yes	15·5	12·2	12·2

120	0	,,	24·0	19·0	
80	100	Yes	18·0	15·0	
80	0	,,	23·0	17·0	
80	100	No	24·0	21·0	
80	0	,,	30·0	25·0	
40	0	Yes	28·0		
40	0	No	42·0		

Note.—The above are for highest-class engines of moderate size. For good average practice add from 5 to 10 per cent. For badly clothed or defective engines add 20 per cent. or more. For small engines add from 5 per cent. upwards according to size. The superheat is measured at the engine stop valve. The loss from the superheater may be from 20 to 100 degrees, according to steam-pipe conditions. Uniflow engines and simple (alternating-flow single-cylinder engines) vary a good deal according to the cut-off. In general, a uniflow has about the same steam consumption as a good compound engine, but with a sufficiently early cut-off beats it.

EFFICIENCY RATIO.

The ratio of the thermal efficiency of the actual engine to that of the Rankine cycle—or of the steam consumption of the Rankine cycle to the actual steam consumption (both having the same pressure, superheat, and vacuum (or back pressure))—is the 'efficiency ratio.'

The efficiency ratio varies with the pressure, superheat, and vacuum, as well as with the merit of the engine as regards freedom from condensation, leakage, and other losses.

Nevertheless the 'efficiency ratio' is useful in comparing engine test results and in predicting steam consumptions.

Typical steam consumptions are shown in the following table (*Foster*), a column of 'efficiency ratios' being added.

Typical Steam Consumptions and Efficiency Ratios.

The particulars in the table refer to high-class modern engines with Corliss or drop valves, and of about 600 i.h.p. or upwards working at normal full load.

Type of Engine.	Boiler Pressure. Lbs. per Sq. In. Gauge.	Vacuum. Ins.	Approx. M.E.P.	Super-heat ° F.	Steam. Lbs. per I.H.P. hour.	Efficiency Ratio per cent.
Compound condensing	160	26 to 27	30	nil	13 to 13·5	64

Economy of High-pressure Working.

The consumption of steam in pounds per horse-power per hour decreases as the pressure rises. The actual steam consumptions vary according to the size and type of engine.

It is estimated that the saving resulting from pressure increase from 200 lbs. to 500 lbs., keeping steam temperature constant at 600° F. and vacuum at 28 ins., would be $1,400 per annum per 1,000 kw. (assuming boiler efficiency 70 per cent., load factor 60 per cent., and cost of 14,000 B.Th.U. coal $5 per ton). Capitalised at 17 per cent., this corresponds to a saving of $8·25 per kw. compared with a probable cost of $3·50 per kw. to work at the higher pressure.

(*J. T. Foster, in 'Electrical World,' May* 11, 1918.)

Steam Saving by Superheating.

Superheating improves the efficiency ratio, so that in practice the saving due to superheating is much greater than that calculated for the Rankine cycle.

Approximate Percentage Reduction in Steam Consumption by Superheating, for Compound and Uniflow Engines.

Superheat, deg. Fahr.	50	100	150	200
Common Steam and Exhaust Ports	12	20	26	30
Separate „ „ „ „	10	16	21	25
Uniflow, about	8	12	17	21

(*Foster.*)

Superheat reduces the steam consumption most in simple engines.

See also Part III, page 1513.

Duty of Engines.

The duty of an engine is rarely spoken of except for pumping engines, and is then expressed in terms of the work done in lifting the water per 1,120 lbs. of steam used, or some other basis. Sometimes 1,000 lbs. of steam is used, especially in America; and sometimes coal or heat units is the basis.

Example.—Pumping engine consumes 14 lbs. of steam and 1·8 lbs. of coal per water, or pump, h.p. hour. The total heat added per lb. of steam is 1,125 B.Th.U.

Duty per 1,120 lbs. steam is $\frac{1,120}{14} \times 33,000 \times 60$ . . . = 158,400,000 ft. lbs.

Duty per 112 lbs. coal is $\frac{112}{1·8} \times 33,000 \times 60$ . . . . = 123,200,000 „

Duty per 1,000,000 B.Th.U. in steam is $\frac{1,000,000}{1,125} \times \frac{158,400,000}{1,120} = 125,700,000$,

The duty of winding engines is rarely measured, but is sometimes stated in terms of steam used per shaft h.p. hour, or per h.p. hour in the coal hoisted. This steam consumption increases

greatly when the cages are not fully loaded and the number of winds is below maximum. Under favourable conditions compound non-condensing engines use from 30 to 50 lbs. of steam per shaft h.p. (in the coal raised) per hour. For high-pressure engines and unfavourable conditions the consumption increases to about 100 or 120 lbs., and occasionally more.

TABLE SHOWING STEAM CONSUMPTION OF WINDING ENGINES.

Colliery.	Cylinders, ins. diam. × stroke.	Boiler Pressure.	Lbs. per Shaft H.P. Hour.

Cowper	60 × 84	20	178

(*W. C. Mountain.*)

Tests of a cross-compound non-condensing engine at Sherwood colliery gave a steam consumption of 40 lbs. per S.H.P. hour. The engine cylinders were 32 ins. and 53 ins., stroke 66 ins., pressure 125 lbs. per sq. in., superheat 65° F.

For the steam consumption of turbines *see* Part V., page 1554.

THE INDICATOR.

General Definitions.

The Atmospheric Line, AB, is a line drawn by the pencil of the indicator when the connections with the engine are closed and both sides of the piston are open to the atmosphere. This line represents on the card the pressure of the atmosphere, or zero gauge pressure.

The Line of Absolute Zero Pressure, OX, is a reference line usually drawn about 14·7 lbs. by scale below the atmospheric line. It represents a perfect vacuum, or absence of all pressure.

At any considerable height above sea level the line OX becomes nearer the line AB.

The Clearance Line, OY, is another reference line drawn at a distance from the end of the diagram equal to the same percentage of its length as the clearance and waste room are of the piston displacement. The distance between the clearance line and the end of the diagram represents the volume of the clearance and waste room of the ports and passages at the end of the cylinder.

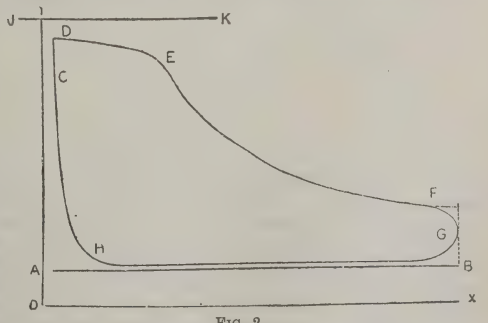

FIG. 2.

The Line of Boiler Pressure, JK, is drawn parallel to the atmospheric line, and at a distance from it by scale equal to the boiler pressure shown by the gauge. The difference in pounds

between it and DE shows the loss of pressure due to the steam pipe and the ports and passages in the engine.

The Admission Line, CD, shows the rise of pressure due to the admission of steam to the cylinder by opening the steam valve. If the steam is admitted quickly when the engine is about on the dead centre this line will be nearly vertical.

The Steam Line, DE, is drawn when the steam valve is open and steam is being admitted to the cylinder.

The Point of Cut-off, E, is the point where the admission of steam is stopped by the closing of the valve. It is difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.

The Expansion Curve, EF, shows the fall in pressure as the steam in the cylinder expands and does work.

The Point of Release, F, shows when the exhaust valve opens.

The Exhaust Line, FG, represents the change in pressure that takes place when the exhaust valve opens.

The Back Pressure Line, GH, shows the pressure against which the piston acts during its return stroke. On diagrams taken from non-condensing engines it is either coincident with or above the atmospheric line, as in fig. 2. On cards taken from a condensing engine, however, it is found below the atmospheric line, and at a distance greater or less according to the vacuum obtained in the cylinder.

The Point of Compression, H, is the point where the exhaust valve closes. It cannot be located very definitely, as the change in pressure is at first due to the gradual closing of the valve.

The Compression Curve, HC, shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

The Mean Effective Pressure (M.E.P.) is the mean net pressure urging the piston forward.

The Initial Pressure is the pressure acting on the piston at the beginning of the stroke.

The Terminal Pressure is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion curve to the end of the diagram, as in fig. 2. This pressure is always measured from the line of perfect vacuum, hence it is the *absolute* terminal pressure.

Mean Effective Pressure.

This can only be correctly determined by finding the area of the indicator diagram.

The best method of doing this is by the use of the planimeter, which, with careful manipulation, will give the exact area in square inches to hundredths of a square inch. Divide the area thus found by the length of the diagram, and the result will be the height of a rectangle having an

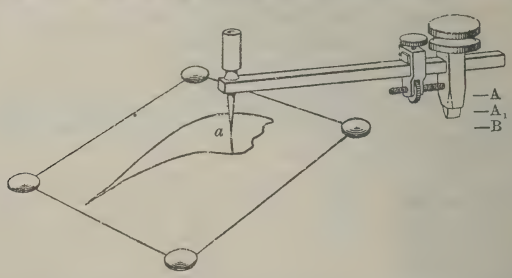

FIG. 3.

area equal to that of the diagram, and will consequently represent the average height of the diagram. Multiply this by the scale of the spring used, and the result will be the mean effectve pressure (M.E.P.).

There are several approximate methods of computing the M.E.P. It is necessary to find the mean ordinate of the diagram, and this may be done with close approximation by the application of Simson's rule for area computation (p. 143), the mean of a number of ordinates being taken. With a number of diagrams this may occupy some little time ; but if it be desired to deal with them quickly, the mean ordinate may be obtained by the application of Professor Goodman's Hatchet Averager with a remarkable degree of accuracy. This instrument (fig. 3), as usually made consists of a short, square steel rod, having at one end a tracing point similar to that on a Planimeter ; the other end is provided with a sharp steel hatchet with a slightly curved edge, so ground that the edge of the hatchet, if produced, will pass exactly through the tracing point. The distance between the hatchet and point is adjusted to the exact length of the diagram by sliding the former along the rod and there clamping it. The diagram is then laid on a level surface and fastened down ; a point *a* is chosen near the centre of the area and a line drawn there-

from to one of the edges of the diagram. The Averager is placed with its rod approximately at right angles to the line drawn with the tracing point on a and the position of the hatchet marked A. The tracing point is then moved along the line and, clockwise, around the diagram and back on the line to a. The hatchet will then have travelled to B; this is marked. To ensure a finer degree of accuracy the diagram is rotated through 180° about a, and the operation repeated in a counter clockwise direction. The hatchet will travel from B to A_1. The distance from B to a point midway between A_1 and A in inches is the mean ordinate. The whole operation occupies considerably less time than it takes to describe. The figure shows the Averager applied to an air-compressor diagram.

The mean ordinate being obtained, its value multiplied into the scale of the indicator spring used gives the M.E.P.

To Calculate the Horse Power of an Engine.

M.E.P. = mean effective pressure on piston, lbs. sq. in.,
A = net piston area (one face), sq. ins.,
S = piston speed, ft. min. (stroke × 2 × R.P.M.),

then

$$\text{I.H.P.} = \frac{\text{M.E.P.} \times A \times S}{33{,}000}$$

If a single-acting engine divide the above by two.

Approximate Steam Consumption, from the Indicator Diagram.

Draw a horizontal (constant pressure) line on the diagram so as to cut the expansion line and compression line (or compression line produced, if necessary) at a pressure just above release (exhaust opening).

If

u = volume in cu. ft. of one lb. dry steam at the pressure of this horizontal line;
a = length of horizontal line between expansion and compression lines;
b = length of stroke of diagram;

then

$$\text{Lbs. dry steam on diagram per i.h.p. hour} = \frac{13{,}750\ a}{\text{M.E.P.}\ b\ u}.$$

This is often referred to as the theoretical steam, the actual being less or greater according to the degree of superheat, jacketing, leakage, etc. Hence the theoretical consumption must be *divided* by a factor (which is approximately the dryness fraction at exhaust opening) as follows, for compound engines at normal full load.

STEAM CONSUMPTION FACTORS.

Cylinder.	H.P.	L.P.
High superheat	1·0 –1·1	0·8 –1·0
Moderate superheat	0·9 –1·0	0·75–0·95
Saturated steam	0·8 –0·85	0·7 –0·75
Badly clothed, saturated steam	0·65–0·75	0·6 –0·7

To Interpret the Indicator Diagram.

The two preceding paragraphs explain how to calculate the horse-power and estimate roughly the steam consumption from the diagram.

Other important information can be learned from a study of the diagram, as follows:—

The diagram will show the opening and closing of the valves, as explained on p. 1405, fig. 2. If the point of cut-off is fixed, as with most slide and piston valve engines, the depth of the steam admission line DE below the boiler pressure line YK is a measure of the loss by throttling. If this is invariably considerable, it may pay to shift the eccentric so as to give an earlier cut off. With a simple slide or piston valve this would make the exhaust open earlier and the compression commence earlier. These, and particularly the latter, must be watched, as too early compression sends the compression pressure above the steam chest pressure. This is not good; although the compression line should rise nearly to the admission pressure. In the case of a reversing engine having a Stephenson, Joy, or similar link motion, the point of cut-off is varied by shifting the equivalent eccentric; and thus at early cut-off the exhaust and compression are both early, but at late cut-off the exhaust and compression both become

late. Hence when studying such diagrams these changes of exhaust and compression with cut-off must always be kept in mind. The points of valve action can also be altered by changing the lap. Thus if the exhaust edge of the valve is chipped the exhaust takes place earlier and the compression later. Similarly chipping some of the lap off the steam edge of the valve makes the cut-off later and lead earlier.

If the admission line DE falls rapidly, the valve is too small or the valve travel too small.

In a multiple-cylinder engine the diagram gives the distribution of power and forces among the several cylinders. As a rule these should be roughly equal for the several cranks, but need not be equal for the two cylinders of a tandem engine. Indeed, in the latter case, the h.p cylinder may with advantage take rather more than half the load if the steam is superheated.

Valve setting should always be checked by actual indicator cards after an engine is first started to work.

It is found in practice that the expansion line (fig. 2) is closely hyperbolic when using saturated steam, the two axes of the hyperbola being the absolute zero line OX and a vertical touching the diagram at CD. These hyperbolic curves can be purchased printed on transparent paper for placing over indicator diagrams. If the expansion line rises above the hyperbola as the pressure falls it indicates leakage past the steam valve into the cylinder. Similarly, if the expansion line falls more rapidly than the hyperbola it indicates either leakage past the exhaust valve out of the cylinder, excessive condensation of steam in the cylinder, or the use of initially superheated steam. If superheated steam is used the vertical axis of the hyperbola should be about the clearance line OY in fig. 2; but the exact position depends on the degree of superheat.

The hyperbola is easily drawn more or less completely as desired when it is remembered that the absolute pressure multiplied by the volume has the same value at all points on the same hyperbolic curve.

To take an Indicator Card.

See that the indicator is in good order, the piston clean and free in the cylinder, all joints in the pencil gear free yet without slack. The pencil should fall by its own weight when the indicator is assembled without a spring. The spring should be chosen with reference to the pressure range so as to give a diagram about 1½ ins. high, or less still if the speed is high. (At very low speeds a lighter spring may be used and a larger diagram obtained.) Assemble the indicator, and see that the spring is properly secured at both ends without any slack. Couple the indicator to the cock F. Adjust the length of cord connecting the indicator drum to the reducing gear, so that there is no knock or slack at either end of the motion of the drum. At high speeds the tension of the drum spring should be considerable, so as to minimise variations in the tension of the driving cord.

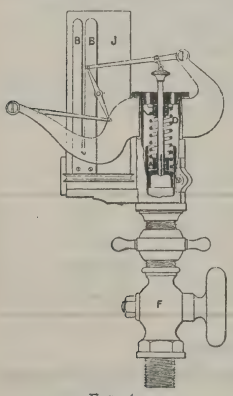

FIG. 4.

Fasten the paper on the drum *J* (fig. 4) by means of the clips BB. Draw the atmospheric line by pressing the pencil lightly on the paper and pulling the drum round by the cord.

Adjust the pencil stop so that the pencil cannot be pressed too hard on the paper. The pencil point must be kept smooth and fine. A clear, fine line will thus be drawn without excessive friction between pencil and paper.

Connect the driving cord to the reducing gear, open the indicator cock, and after allowing steam to blow through for a few seconds, apply the pencil to the paper and allow it to remain in contact for a few revolutions and then withdraw it.

Shut the cock, disconnect the cord, and remove the paper with the indicator diagram.

Mark the card with a reference number and write on it the particulars of speed, pressure, etc., unless these are separately logged.

Defects in Diagrams.

A very common and serious defect in diagrams arises from the stretching of the indicator cord. If two diagrams taken from the same engine at the same time show noticeably unequal lengths the cords are probably inaccurate. As a rule the stretch is greatest when the drum is pulled open. Thus one end of the diagram is widened and the other narrowed, giving incorrect M.E.P. and points of valve action.

The cord used should be as short and as inextensible as possible.

The reducing gear should give an accurate copy of the motion of the engine crosshead, and the cord from the reducing gear should run in a direction parallel with the line of motion of the crosshead.

If the diagram is very much to one side of the card, and if the near end is very straight and vertical, the drum is probably hitting its stop at one end of its travel. Alter the length of the indicator cord.

If the expansion line is stepped in rough terraces the indicator piston is probably sticking and the M.E.P. is too high.

If the expansion is wavy the spring is too light and should be replaced by a stiffer one.

Indicator Piston.

In any indicator the piston should always fit the cylinder loosely enough to allow the steam to blow by it. This is very important, whether the instrument is used at high or low speeds. In regard to any errors that may result from leakage by the piston, it should be distinctly understood that leakage, unless it be sufficient to add to the atmospheric pressure above the piston, cannot affect the accuracy of the indications. Absurd devices have been even patented for keeping the piston tight, while the one thing needful is absolute freedom of motion.

In order that leakage past the piston may not accumulate pressure above the piston, the space above the piston must be in free communication with the atmosphere.

Indicator Connecting Pipes.

In general, short direct connections are preferable.

The use of a long connecting pipe may cause quite an appreciable addition to the clearance volume of a cylinder, especially in the case of small engines. Where the connecting pipe has a bore of $\frac{9}{16}$ in. or $\frac{1}{2}$ in., as is usual, and suffers no contraction up to the indicator tap, however there is no appreciable error in the diagrams due to the connecting pipe being, say, 4 feet long, provided the bore of the two-way cock is quite $\frac{3}{8}$ in.; a bore of $\frac{3}{16}$ in. only, may introduce serious error. (*T. B. Morley, 'Trans. Inst. E. and S.'* 1914–15

The Simplex Indicator.

The Simplex Indicator has a spring of ⊃ form, the ends of the two legs fitting in slots in the piston rod and the resistance abutment. These springs are outside the cylinder, do not become overheated, and can be changed instantly. The Simplex indicator is excellent for gas-engine work. For high pressures, as with the Diesel engine, the piston is reduced in size.

The Crosby Indicator.

This indicator (sold by *Crosby Valve and Engineering Co., Ltd.*, 41–42 Foley Street, London W. 1) has been specially designed for use with high-speed engines, either steam, gas, or oil. Fig. 5 shows the Crosby Indicator as ordinarily made, having a drum $1\frac{1}{2}$ ins. in diameter, this being the correct size for high-speed work, and answering equally well for low speeds.

The special feature in the indicator is the use of a double-coil spiral spring, very carefully calibrated; this form of spring, which is shown in fig. 6, enables the strains to which it is subjected to be transmitted from the centre of the piston through a ball and socket joint. Each spring is made of a single piece of wire wound from the middle into a double coil, the ends of which are screwed into a head with four wings having spirally-drilled holes to receive and hold them securely in place. Adjustment is made by screwing the spring in or out of this head until it is exactly of the right strength, when it is firmly brazed.

Fig. 7 shows a sectional view of the Crosby 'New' Indicator. This has the spring mounted outside the cylinder, where it is easily detached and replaced, and where it is removed from any effect of heat—a very necessary precaution when the indicator is used with superheated steam, or on gas engines. Another novel feature in this indicator is the size and shape of the piston. The area is double that usually used, thus giving a greater active force to overcome any increased inertia due to the longer piston-rod. It is in the form of the central zone of a sphere, an arrangement which practically eliminates cylinder friction. The piston is connected to the pencil mechanism by a rod terminating in a ball-and-socket joint in the centre of the piston. The position of the pencil lever on the drum can be altered by screwing the spring up or down and locking it in place.

For the purpose of making the indicator of the utmost value to engineers, the Crosby New Continuous Drum has been designed, and this apparatus makes it possible to obtain a series of diagrams on a roll of paper. The latest form has a novel arrangement allowing the period between each diagram to be altered at will; the diagrams can be taken close together or farther

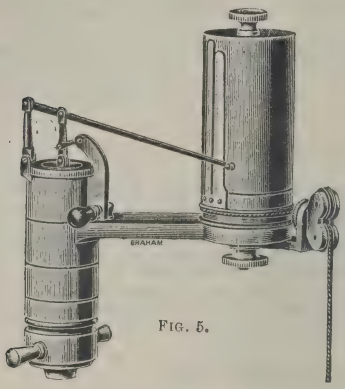

FIG. 5.

FIG. 6.

apart as desired, and the roll supplied is 12 ft. long. Such an apparatus is of great value in ascertaining variations of load in electrical tests, and in connection with rolling and winding engines.

Another useful device, which saves having a reducing apparatus added to an engine, is the Crosby Reducing Wheel. This gives a perfectly correct reduction of the stroke of any engine

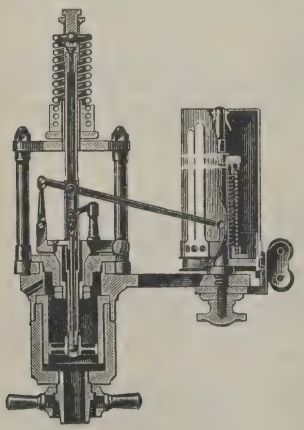

FIG. 7.

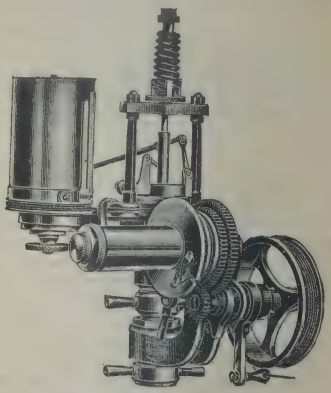

FIG. 8.

to the stroke of the indicator drum, and it is connected directly to the indicator and mounted on the indicator cock. The arrangement is portable and can be used on any engine.

The latest pattern includes a detent device which enables the indicator to be stopped to put on a fresh card without disconnecting the reducing wheel from the engine crosshead. See fig. 8.

BOILER DESIGN—BOILER SHELLS — TRANSMISSION OF HEAT IN BOILERS—STANDARD CONDITIONS FOR THE DESIGN AND CONSTRUCTION OF MARINE BOILERS—BOILER INSPECTION AND LEGISLATION — BOILER TUBES—BOILER SETTING—STEAM PIPES—PREVENTIVES OF SCALE AND CORROSION — FEED WATER SOFTENING — FEED WATER REGULATORS — STEAM REGULATORS—OIL SEPARATORS — BOILER CLEANERS —VALVES—BOILER EFFICIENCY—TYPES OF BOILERS—BOILER FITTINGS.

(Revised and largely rewritten by T. B. Morley, D.Sc., M.I.Mech.E.)

BOILER DESIGN.

General Considerations.

Simplicity and accessibility for cleaning, favour the tank type of boiler, of which the Lancashire is the best known. The ratios of heating surface to weight and space occupied are, however, necessarily low, and for large units or intensive generation of steam, the tubular boiler has advantages. In order that these advantages may be fully developed, certain problems must be recognised and dealt with, namely—

(*a*) Boiler deposits must be reduced to a minimum, and these constrained in suitable mud drums and other parts.

(*b*) Water and steam spaces must be accessible for cleaning and inspection with a minimum of time and labour for joint breaking and making.

(*c*) Combustion of coal (or oil or gas) in large bulk must be arranged for.

(*d*) Heating surface must be arranged to absorb as much as possible by radiation, and for the remainder to aim at a high ratio of heating surface to length of path of gas flow.

(*e*) Special provision made for overloads.

The first two, (*a*) and (*b*), have received more attention than the other problems. The combustion of fuel in bulk (whether coal or not does not matter, for it is all gaseous before the combustion is completed) needs, for success, a very large combustion chamber and a long path for the flame between the grate and the first tubes or plates. Combustion requires both time and space, and both these have been unduly starved in most large water-tube boiler designs. The large combustion chamber not only gives time and space for efficient combustion, but it increases the surface receiving heat by radiation, and, in general, this is the most efficient of all heating surfaces. The contact heating surface required depends largely on the speed of gas flow, but to keep the latter high involves restricted gas passages, which involve expansion troubles and maintenance difficulties. With attention, these troubles and difficulties may be gradually eliminated, and modern progress with boilers of this type seems likely to be by way of huge combustion chambers with long flame paths, large radiant heat surfaces, and relatively short gas passages between the tubes.

Grate Area—Rate of Combustion—Draught.

Depends on fuel, type of boiler, nature of firing, and draught.

Natural draught depends on temperature of gases and layout of flues. A typical figure is 0·65 in. of water per 100 ft. of chimney height, above the grate. The effective draught at the grate for a Lancashire boiler battery with economiser will be about one-third this figure, and rather less for a water-tube boiler installation with economiser.

The coal burnt per hour per square foot of grate will be about :—

20 lbs. average steam coal ; 5-10 lbs. anthracite very thinly spread.

For other chimneys and draughts the rate of combustion increases not quite in proportion to height.

Heating Surface.

Varies enormously, but typical figures for water-heating surface in square feet per square foot of grate area are :—

Lancashire boiler	25
Water tube	50–60
Water tube, marine	35
Locomotive	60-70
Scotch boiler, marine	35–40
American tubular	50-80

The economiser surface should be about equal to the boiler surface for a Lancashire boiler, and less, down to 50 per cent., for a water tube boiler with ample heating surface.

The superheating surface should be about 20 to 30 per cent. of the boiler surface: rather more for light firing and poor coal, less for hard firing and good fuel.

Evaporation.

Depends mainly on the coal burnt. A typical working figure is 25 lbs. coal per square foot grate area for good natural or moderate assisted draught for stationary boilers, and about 100 lbs. for a locomotive, but this may rise to 200.

Taking 7 lbs. steam per lb. of coal gives about 7 lbs. of steam generated per square foot boiler heating surface per hour for a Lancashire boiler, about 5 lbs. for a water tube, and about 10 or 12, sometimes considerably more, for a locomotive. Superheater and economiser surface not included in the boiler surface.

Boilers fired with blast-furnace gas have about 50-70 per cent. of the coal-fired evaporations, but improvement is being made in this direction.

In hand-fired plants, using coal for fuel, the rate of combustion should not be permitted to fall below 15 lbs. per sq. ft. of grate surface per hour. With stokers the rate of combustion may be as high as the design of the plant will permit. When firing with fine steam-size coal, the rate should not be less than 10 lbs. per sq. ft. of grate-area per hour.

Chimney and Flue Area.

Net sectional area of chimney shaft about 0·5 sq. ft. per 100 lbs. coal burnt per hour at full sustained output. For hard firing rather less. For small chimneys rather more.

Flue areas about 20-40 per cent. greater than chimney area. Sometimes fixed at one-sixth grate area.

Transmission of Heat in Boilers.

The transfer of the heat developed by the combustion of the fuel in the furnace to the water in the boiler takes place in two ways: (1) by radiation from the incandescent fuel and the hot gases ; and (2) by convection and conduction—i.e. conduction through the materials in the path of the heat flow and by the contact of the gases and water with the metal separating them.

The transmission of heat to that part of the heating surface which is directly exposed to the fire is practically entirely by radiation, and that to the remainder of the heating surface practically entirely by convection.

Transmission by Radiation.

The heat transmitted by direct radiation in most boilers is strikingly large, so that the fire-box surface is much the most powerful evaporating surface.

The amount of heat radiated from a fire of temperature T_1 (° F. absolute) to the fire-box surface at T_2 is

$$1{,}600 \times \frac{T_1^4 - T_2^4}{1{,}000^4} \text{ B.Th.U. per hour per sq. ft.}$$

or practically, since T_2^4 is always negligible in comparison with T_1^4,

$$\text{the radiant heat} = 1{,}600 \left(\frac{T_1}{1{,}000}\right)^4.$$

Whether the radiating surface to be taken into account in calculating the total heat radiated in the grate area, or a larger amount, is debatable. The formula indicates, however, the importance of the direct heating surface, and also the importance of high combustion temperature for high rates of transmission.

Transmission through Boiler Tubes.

The transmission of heat from a fluid to another fluid on the other side of a metal tube depends on a large number of factors, including, as well as the area of tube surface and the temperatures, the velocities of the fluids, the diameter of the tube, and the nature of the fluids and of the tube surfaces. The change of temperature of the fluid passing through the tube is, of course, itself dependent on the factors named, so that the factors are not all independent. Differences of conductivity and thickness of the metals of the tube are negligible, the resistance to the passage of heat through the metal being a very small portion of the total resistance from fluid to fluid.

In the case of boiler tubes with flue gases passing through them, the change of temperature of the gases, and thus also the heat transferred, can be calculated from the following equation (Lawford H. Fry, *Engineering*, Aug. 27, 1920):—

$$\text{lolog.}\frac{T_1}{t} - \text{lolog.}\frac{T_2}{t} = Mx \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1).$$

in which T_1, T_2 are the mean flue gas temperatures, ° F. absolute, at two sections of the tube x feet apart, t the mean temperature (absolute) of the tube wall, and 'lolog.' means 'logarithm of the logarithm.'

$$M \text{ is given by } \log. M = B - m \log.\frac{W}{p} \quad . \quad . \quad . \quad . \quad (2)$$

$$\log.(B + 1{\cdot}3) = 1{\cdot}71 - 0{\cdot}54 \log. d \quad . \quad . \quad (3)$$

$$\log. m = 1{\cdot}36 + 0{\cdot}37 \log. d \quad . \quad . \quad . \quad (4)$$

where d = internal diameter of tube in inches, p = perimeter of tube, and W = rate of flow of gas in lbs. per hour. Having determined the fall of temperature of the gases from the above, the heat given up—i.e. the heat transferred—is equal to

$$W \times (T_1 - T_2) \times \text{mean specific heat of gases.}$$

The following table gives the values of M for a number of tube diameters and rates of flow. These values may be used directly in equation (1).

Values of M.

d inches.	W in lbs. per hour.				
	100	200	400	800	1,600
0·5	0·133	0·117	0·104	0·092	0·081
1·0	0·074	0·063	0·054	0·046	0·039
2·0	0·050	0·040	0·033	0·027	0·022
4·0	0·040	0·030	0·023	0·018	0·014
8·0	0·037	0·026	0·019	0·013	0·009

Examples.

(1) To find fall of temperature in flue tube 2 ins. diameter and 12 ft. long, with rate of gas flow of 400 lbs. per hour, boiler pressure 180 lbs. per sq. in., and temperature of gases 2,000° F. at entrance of tubes.

The temperature of the metal of the tube is nearly that of the water in the boiler—i.e. nearly that of steam at 180 lbs. per sq. in.; thus t = 380° F., about. (Slight differences in t have very little influence as a rule.)

From the table, for 2-in. tube, and W = 400 lbs. per hour, M = 0·033

$$\therefore \text{lolog.}\frac{2{,}000 + 460}{380 + 460} - \text{lolog.}\frac{T_2}{380 + 460} = 0{\cdot}033 \times 12;$$

$$\therefore \text{lolog.}\frac{T_2}{840} = 1{\cdot}273;$$

$$\therefore \log.\frac{T_2}{840} = 0{\cdot}1875.$$

$$\therefore T_2 = 1{,}293° \text{ F. abs., or } 833° \text{ F.}$$

(2) To find the heat transferred.

The mean specific heat of flue gases at the temperature in question may be taken as 0·31. Then the heat transferred in B.Th.U. per hour

$$= 400 \times (2{,}000 - 833) \times 0{\cdot}31 = 145{,}000.$$

The tube surface is 6·29 sq. ft., and heat transferred per sq. ft. = 23,100 B.Th.U. per hour.

(3) To find length of tube required to reduce the gas temperature to 700° F., rate of flow and diameter being as before:

$$\text{log.}\frac{2{,}000 + 460}{380 + 460} - \text{log.}\frac{700 + 460}{380 + 460} = 0{\cdot}033 \times \text{length.}$$

from which, length = 15·8 ft.

Boiler Shells.

Mild steel is now almost invariably used for boiler shells. As a rule, in order to provide a margin for wear and tear, plates below $\frac{3}{8}$ in. thick should never be used.

The bending of plates should be done by rolls, and not by hammering. Rivet holes should be drilled and the rough edge removed by a countersinking tool.

Pressures Required for Riveting and Flanging.

The pressure required for riveting is 75 to 125 tons per sq. in. of rivet area, preferably the lower value. Excessive pressure causes local deformation of the plate. The riveting pressure should be maintained for a short period, so that the rivet may cool down a little, otherwise the spring of the plate may stretch the rivet while it is still hot.

The pressure required for flanging boiler plates may be found from the formula:

$$F = \frac{2{\cdot}5\,(L \times t^2}{L + 10},$$

where F = press load in tons, L = length run of flange in feet, t = thickness of plate in sixteenths of an inch. (*Mechanical World Year Book.*)

Welded Seams in Boilers.

The efficiency of welding depends essentially upon the skill and care of the workman who makes the weld; and in view of the uncertainty of the efficiency in practice as compared with tests, it is not advisable to use welds in parts of boilers subjected to tension, though parts in compression, such as furnaces and flue tubes, may be welded.

For particulars of oxy-acetylene and electric welding, see Section XXXVII, pages 2289, 2301.

Many successful boiler repairs have been effected by welding, particularly in the making up of parts that have been wasted away, and the filling up of grooving.

Welded parts should be hydraulically tested to double the working pressure, the material at and around the weld being hammered while under test.

Steel for Boilers.

The steel is usually required to be made by the open-hearth acid process. The tensile strength is about 26 to 30 tons per sq. in. for shell plates, and 24 to 28 tons per sq. in. for plates for furnaces, flue tubes, and endplates.

See page 1416 for Standard Conditions for Marine Boilers.

Strength of Boiler Shells.

Let P = working pressure in lbs. per sq. in.;
t = thickness of plate in inches;
D = diameter (internal) of boiler in inches;
E = efficiency of longitudinal joint—i.e. proportionate strength of joint to plate;
F = factor of safety;
f = tensile strength of plate in lbs. per sq. in.;

then $$P = \frac{2E\,f\,t}{DF} \quad \text{or} \quad t = \frac{PDF}{2E\,f}.$$

The factor of safety is usually between 4 and 6. Frequently rules are used in which the safe working stress is substituted for $\frac{f}{F}$ in the above.

For permissible values of f, F, or $\frac{f}{F}$ the rules of the boiler survey or insurance society concerned should be consulted.

See page 1416 for 'Standard Conditions for Marine Boilers.'

BIRCHILLS, WALSALL

Telegrams: 'Talbot, Walsall.' Telephone Nos.: 276 and 277.

The proportionate strength of joint to plate—i.e. the efficiency of the joint—depends upon the type of joint, and also on the pitch and diameter of the rivets, and thickness of plate.

Typical percentage figures for single riveted lap joints are 40 to 58 ; for double riveted lap 55 to 70 ; for double butt (a butt strap each side of the plate and double riveted) 72 to 77 ; for treble riveted butt, each alternate rivet in outer rows being omitted, 82 to 85.

For the method of calculating the efficiency of riveted joints, see page 1420.

There is a strong tendency now in favour of butt joints for the longitudinal seams, by which the circular form of the shell is maintained, and there is less liability to grooving. The butt strap also protects the joint from corrosion.

All longitudinal seams break joint, as it is termed—that is, the seam in one ring of plates comes opposite to the solid plate in the next ring.

Working Strength of Boiler Flues.

(*Modern Dimensions.*)

P = working pressure, in lbs. per sq. in. L = length, in ft., between seams or hoops.

D = diameter, in inches. t = thickness of plate, in inches.

$$P = \frac{806300t^{2\cdot19}}{D \times L} \div \sqrt{\frac{300}{L}} \text{ (Harrison).} \qquad P = \frac{50t^2}{D\sqrt{L}} - \frac{D}{L} \text{ (M. Longridge).}$$

(t being in 32nds of an inch.)

$$P = \frac{6149t^2}{\sqrt{DL}} \text{ (W. H. Booth).} \qquad P = \frac{48000t^{2\cdot2}}{D\sqrt{L}} \text{ (W. H. Booth).}$$

TABLE OF 2·19 POWER FROM $\frac{1}{4}$ TO $\frac{1}{2}$ INCH.

Details.	In.	In.	In.	In.	In.
Thickness of plate . .	·25	·312	·375	·437	·500
Power, 2·19 . . .	·04802	·07829	·116715	·16358	·21915

Every case ought to be finally examined to see that the actual pressure on each square inch of section of plate must not exceed the safe crushing resistance of the material, or $P = 30000t \div Df$. This rule may need applying to test the cases of thick furnaces. The value of f is 3 to 4. This would give, generally speaking, the flue to be about one-third the strength of the shell, but, on the other hand, the strength can be indefinitely increased by the employment of flanged seams, or corrugations.

See also page 1421.

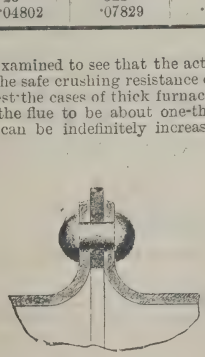

FIG. 1.—Flanged Seam.

The first form of joint in flue and furnace work was ordinary riveting, both transversely and longitudinally, but as weakness developed, the T iron hoop was tried ; this, however, though strong, was found to be too rigid, and to lead to leakage in the seams. The flange out of the solid plate (fig. 1) was then designed by Daniel Adamson, and rapidly made its way to the front. The longitudinal joints are now welded, so that when the flange is adopted, no rivets whatever are exposed to the fire in the furnaces.

BOILER RULES AND REGULATIONS.

'Standard Conditions for the Design and Construction of Marine Boilers' have been recommended by a committee of representatives of the Board of Trade, British Corporation, Lloyd's Register, and Bureau Veritas. An abstract of the rules drawn up is given in the following pages. For boilers constructed to the requirements of a particular surveying body or boiler insurance company, the rules of the body concerned should be consulted.

Standard Conditions for the Design and Construction of Marine Boilers.*

(Abstract.)

MATERIALS OF CONSTRUCTION.

(Based on British Standards.)

Process of Manufacture.—Structural steel for marine boilers shall be made by the open-hearth process, acid or basic.

Freedom from Defects.—The finished material shall be free from cracks, surface flaws, and lamination. It shall also have a workmanlike finish, and must not have been hammer-dressed.†

Tensile Tests: Plates.—The tensile breaking strength of steel plates for shells and girders, determined from Standard test pieces, shall be between the limits of 28 tons and 35 tons per square inch, but a range of not more than 4 tons per square inch shall be permitted in any one case. For plates intended for flanging or welding, and for combustion chambers and furnaces, the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of $\frac{3}{4}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 28 tons and 35 tons per square inch; and not less than 23 per cent. for material of $\frac{3}{4}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 26 tons and 30 tons per square inch.

Stay Bars.—The tensile breaking strength of longitudinal stays shall be between the limits of 28 tons and 35 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece B, but a range of not more than 4 tons per square inch shall be permitted in any one case. For steel bars for combustion chamber stays the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch, with an elongation of not less than 23 per cent. measured on the Standard Test Piece B.

Where stay bars are tested on a gauge length of 4 times the diameter (Test Piece F), the elongation shall be 24 per cent. and 28 per cent. respectively.

The tensile breaking strength of angle and tee bars shall be between the limits of 28 and 32 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece A.

For material under $\frac{3}{4}$ in. in thickness the elongation may be 3 per cent., but not more than 3 per cent., below the above-named elongations.

Wherever practicable the rolled surfaces shall be retained on two opposite sides of the test piece.

Rivet Bars.—The tensile breaking strength of rivet bars shall be between the limits of 26 tons and 30 tons per square inch of section, with an elongation of not less than 25 per cent. measured on the Standard Test Piece B or 30 per cent. measured on the Standard Test Piece F. The bars may be tested the full size as rolled.

Bend Tests: Cold Bends.—Test pieces shall be sheared lengthwise or crosswise from plates or bars, and shall not be less than $1\frac{1}{2}$ ins. wide, but for small bars the whole section may be used. For rivet bars bend tests are not required.

---

* Published by His Majesty's Stationery Office.

† The Board of Trade have more detailed instructions which they propose to retain.

Temper Bends.—The test pieces shall be similar to those used for cold bend tests. For temper bend tests the samples shall be heated to a blood-red colour and quenched in water at a temperature not exceeding 80° F. The colour shall be judged indoors in the shade.

In all cold bend tests, and in temper bend tests on samples 0·5 in. in thickness and above, the rough edge or arris caused by shearing may be removed by filing or grinding, and samples 1 in. in thickness and above may have the edges machined, but the test pieces shall receive no other preparation. The test pieces shall not be annealed unless the material from which they are cut is similarly annealed, in which case the test pieces shall be similarly and simultaneously treated with the material before testing.

For both cold and temper bends the test piece shall withstand, without fracture, being doubled over until the internal radius is equal to 1½ times the thickness of the test piece, and the sides are parallel.

For small sectional material these bend tests may be made from the flattened bar.

Bend tests may be made either by pressure or by blows.

Tests for Manufactured Rivets—Rivets selected by the Inspector from the bulk shall withstand the following tests:—

(*a*) The rivet shanks are to be bent cold, and hammered until the two parts of the shank touch, without fracture on the outside of the bend.

(*b*) The rivet heads are to be flattened, while hot, in the usual manner, without cracking at the edges. The heads are to be flattened until their diameter is 2½ times the diameter of the shank.

FORMS OF BRITISH STANDARD TENSILE TEST PIECES.

For Plates and other Structural Material.

TEST PIECE A.

X.—For thicknesses over ⅞ths in.; Maximum width allowed = 1½ ins. Y.—For thicknesses ⅝ths in. to ⅞ths in.: Maximum width allowed = 2 ins. Z.—For thicknesses under ⅝ths in.: Maximum width allowed = 2½ ins.

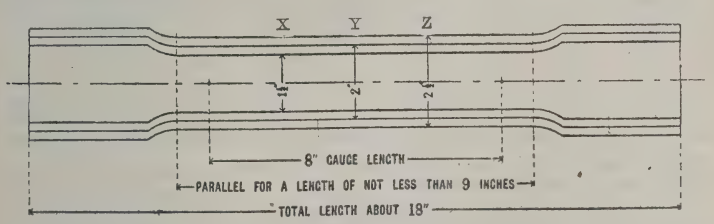

FIG. 2.

NOTE.—It will be observed that the widths given above, being maxima, do not exclude the use of the usual 1½ ins. by 8 ins. test pieces.

TEST PIECE B.

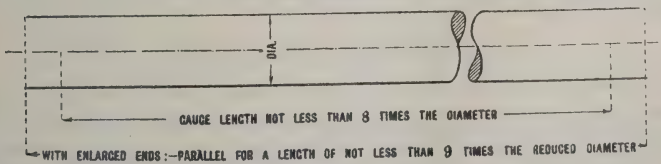

FIG. 3.

TEST PIECE F.

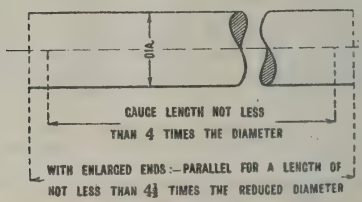

FIG. 4.

SPECIAL IRON FOR SCREW STAYS FOR COMBUSTION CHAMBERS.

In order that iron screw stays may be approved of the same size as would be required for mild steel, the iron must withstand the following tests :—

Tensile Tests.—The tensile breaking strength shall not be less than 21½ tons per square inch, with an elongation of not less than 25 per cent. measured on the Stadard Test Piece B, or of 30 per cent. measured on the Standard Test Piece F.

Bend Tests.—Test pieces either of the bar as rolled, or turned down to 1 in. diameter, shall stand bending cold until the sides are parallel and the space between the two sides is not greater than the diameter of the test piece.

Diameters and Thickness of Plain and Stay Tubes.—The following table may be worked to :—

Outside Diameter in Inches.	Standard Thicknesses in L.S.G.				Suitable for Working Pressures of Lbs. per Square Inch.			
Inches.	A	B	C	D	A	B	C	D
2	—	11	10	9	—	155	215	300
2¼	11	10	9	8	140	190	260	315
2½	11	10	9	8	125	175	230	300
2¾	11	10	9	8	110	160	215	275
3	10	9	8	7	140	190	250	300
3¼	10	9	8	7	130	180	230	280
3½	10	9	8	7	120	165	215	260

The minimum thickness of stay tubes measured under the threads shall be ¼ in. for marginal stay tubes, and $\frac{5}{16}$ in. for other stay tubes.

Thickened Ends.—If stay tubes are required to have their thickness increased at the screwed ends, so that the thickness at the bottom of thread is practically the same as in the body of the tube, the thickening is to be attained by upsetting and not by any welding process, and the tubes are to be annealed after the upsetting.

Screwed Threads to be Continuous.—Stay tubes must be screwed at both ends with a continuous thread, which should not be finer than 10 threads per inch. It is desirable, however, that they should be screwed to the standard 9 threads per inch, therefore, after 30th June, 1921, this should be the rule.

MAIN BOILERS, CYLINDRICAL TYPE.

GENERAL CONDITIONS AS TO DESIGN, WORKMANSHIP, HYDRAULIC TEST, ETC.

In the design and construction of marine boilers the following conditions should be observed :—

Riveting of End Seams.—The riveting of the seams joining the end plates to the cylindrical shell shall be not less than 42 per cent. of that of the solid plate. Where the shell plates exceed ⅝ in. in thickness the seams connecting the shell plates to the end plates are to be double riveted.

Other Circumferential Seams.—The circumferential seam at or near the middle of the length of single-ended boilers should have a strength of joint not less than 60 per cent. of the solid plates. The inner circumferential seams of double-ended boilers should have a strength of joint not less than 62 per cent. of the solid plate. In any case there shall be three rows of rivets when single-ended boilers have shell plates over $1\frac{3}{8}$ ins. in thickness, and when double-ended boilers have shell plates over $1\frac{3}{16}$ ins. in thickness. Where the shell plates exceed $\frac{1}{2}$ in. in thickness the intermediate circumferential seams of double-ended boilers are to be at least double riveted.

Welding and other Treatment of Plates.—No steel plates subject to a direct tensional stress are to be welded except where the weld is covered by a butt strap or straps. For small steam domes, by special permission where the welding is done by hammer and the plates do not exceed $\frac{1}{2}$ in. in thickness, the straps may be omitted. The strength shall, in such cases, be assumed to be 50 per cent. of that of the solid plate. All steel plates which are welded, dished, flanged, or locally heated, are to be afterwards efficiently annealed.

Butt Straps.—Butt straps must be cut from plates, and not from rolled strip.

Rivet Holes.—All rivet holes must be drilled 'fair,' and as far as possible they should be drilled in place. After drilling the plates the burrs should be removed and the faying surfaces of the plates cleaned, and the sharp outer edges of holes removed also.

Stays not to be Welded. Annealing of Fire-worked Stay Bars.—No steel stays are to be welded. If plus threads are desired, the ends of the stay bars may be upset or the bars may be drawn down in the central portions from bars originally of the size of the ends. In either of these two cases the bars must be subsequently annealed throughout.

In double-ended boilers the through longitudinal stays must be supported at or near the middle of their length.

Threads of Screw and other Stays.—All longitudinal stays and also screw stays should have threads in accordance with the British Standard Specification, and true to pitch, viz.:—

After the 30th June, 1921, all screw stays $1\frac{1}{4}$ ins. in diameter and upwards should have 9 threads per inch, and all stays 2 ins. in diameter and above passing through plates and secured by nuts on each side of the plate should have not more than 6 threads per inch.

Compensation Rings to Manholes.—Where the cylindrical shell is cut for a manhole, compensation must be provided and must be such that the strength in way of the hole is not less than that required for the longitudinal joint.

Hydraulic Tests of New Boilers.—In all new boilers working at pressures up to 100 lbs. per square inch the hydraulic test must be twice the working pressure. For boilers working at pressures greater than 100 lbs. per square inch the hydraulic test pressure must be $1\frac{1}{2}$ times the working pressure plus 50 lbs. per square inch.

RULES FOR DETERMINING THE WORKING PRESSURE TO BE ALLOWED ON VARIOUS PARTS OF CYLINDRICAL MARINE BOILERS.

Cylindrical Shells.

Formula for Working Pressure of the Shell.—For the cylindrical shells of steel marine boilers the maximum working pressure (which is designated by W.P. and is in lbs. per square inch) to be allowed shall be calculated from the following formula:—

Where the thickness of the shell plates does not exceed $1\frac{3}{4}$ ins.,

$$\text{W.P.} = \frac{(t - 2) \times \text{S} \times \text{J}}{\text{C} \times \text{D}}$$

Where the thickness of the shell plates exceeds $1\frac{3}{4}$ ins. and double butt straps are fitted,

$$\text{W.P.} = \frac{t \times \text{S} \times \text{J}}{2{\cdot}85 \times \text{D}}$$

where t is the thickness of the shell plates in 32nds of an inch,

S is the minimum tensile strength of the steel shell plates in tons per square inch,

J is the percentage of strength of the longitudinal seams calculated by the methods described below,

C is a coefficient, which is 2·75 when the longitudinal seams are made with double butt straps; 2·83 when the longitudinal seams are made with lap joints and are treble riveted: 2·9 when they are made with lap joints and are double riveted; and 3·3 when they are made with lap joints and are single riveted.

D is the inside diameter of the outer strake of plating of the cylindrical shell measured in inches.

N.B.—The factor of safety must be in no case less than 4.

Methods of Calculating the Strength of Riveted Joints.—The percentage of strength of a riveted joint (J) is found from the following formulæ (I), (II), (III): (I) and (II) are applicable to any type of joint; (III) is applicable only to that type of joint in which the number of rivets in the inner rows is double that in the outer row. The lowest value given by the application of these formulæ is to be taken as the percentage of strength of the joint.

(I) Percentage of strength of plate at joint as compared with solid plate $= \dfrac{100\,(p-d)}{p}$.

(II) Percentage of strength of rivets as compared with the solid plate $= \dfrac{100\,(S_2 \times a \times n \times C)}{S_1 \times p \times T}$

(III) Percentage of combined strength of the plate at the inner row of rivet holes and of the rivets in the outer row

$$= \frac{100\,(p-2d)}{p} + \frac{100\,(S_2 \times a \times C)}{S_1 \times p \times T},$$

where

p = pitch of rivets at outer rows in inches;
d = diameter of rivet holes in inches;
a = sectional area of one rivet in square inches;
n = number of rivets which are fitted in the pitch p;
T = thickness of plate in inches;
C = 1·0 for rivets in single shear as in lap joints;
C = 1·875 for rivets in double shear as in double butt-strapped joints;
S_1 = minimum tensile strength of plates in tons per square inch;
S_2 = shearing strength of rivets, which is taken generally to be 23 tons per square inch, and may be 85 per cent. of the minimum tensile strength of the rivet bars.

Thickness of Butt Straps.—Where the longitudinal seams are fitted with double butt-strapped joints, the outer butt strap should have at least 0·625 of the strength of the plate, and should be of sufficient thickness to permit of efficient caulking of its outer edges. The inner butt strap should be $\frac{4}{32}$ in. thicker than this.

In cases where the number of rivets in the inner rows is double the number in the outer row, this will require the thickness of the outer strap to be

$$t = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T,$$

and that of the inner strap to be at least

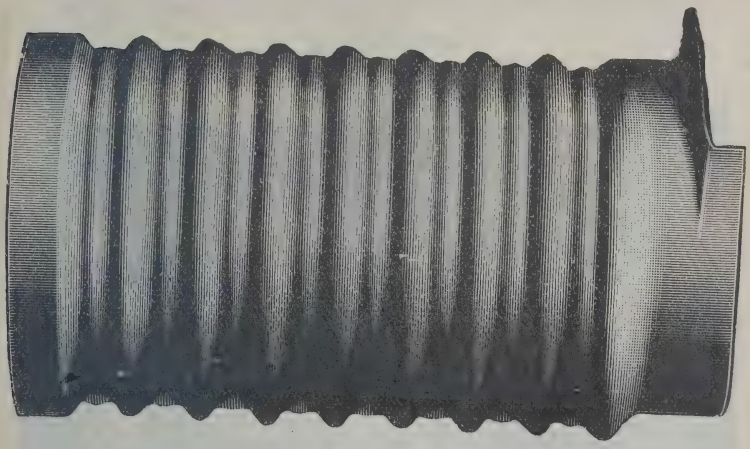
$$t_n = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T + \tfrac{4}{32} \text{ in.}$$

Distances between rows of Rivets and between Rivets and Plate Edges.—In all cases the clear space between a rivet hole and the edge of a plate should not be less than the diameter of the rivet hole—i.e. the centre of the rivet hole should be at least $1\frac{1}{2}$ diameters distant from the edge of the plate.

In joints, whether lapped or fitted with butt straps, in which there are more than one row of rivets and in which there is an equal number of rivets in each row, the distance between the rows of rivets should be not less than $0{\cdot}33p + 0{\cdot}67d$, with zigzag riveting, or $2d$ with chain riveting.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are chain riveted, the distance between outer rows and the next rows should be not less than $0{\cdot}33p + 0{\cdot}67d$ or $2d$, whichever is the greater, and the distance between the rows in which there are the full number of rivets should be not less than $2d$.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are zigzag, the distance between the outer rows and the next rows should be not less than $0{\cdot}2p + 1{\cdot}15d$. and the distance between the rows in which there are the full number of rivets should be not less than $0{\cdot}165p + 0{\cdot}67d$.



In the above p is the pitch of the rivets in the outer rows.

F. 1421

Maximum Pitch of Rivets in Longitudinal Joints.—The maximum pitch of the rivets in the longitudinal joints of boiler shells is to be—

$$\text{Maximum pitch in inches} = C \times T + 1\tfrac{5}{8} \text{ ins.}$$

where T is the thickness of the plate in inches and C is a coefficient as given in the following table :—

Number of Rivets per Pitch.	Coefficients for Lap Joints.	Coefficients for Double Butt-strapped Joints.
1	1·31	1·75
2	2·62	3·50
3	3·47	4·63
4	4·14	5·52
5	—	6·00

FURNACES.

Plain Furnaces.—The working pressure to be allowed on plain furnaces or furnaces strengthened by Adamson or other joints, and on the cylindrical bottoms of combustion chambers, is to be determined by the following formulæ, the least pressure obtained by either formula being taken :—

$$\text{W.P.} = \frac{C\,(t-1)^2}{(L+24)\times D}, \text{ or W.P.} = \frac{C_1}{D} \times [10\,(t-1) - L].$$

where D is the external diameter of the furnace or combustion chamber bottom in inches ;

t is the thickness of the furnace plate in 32nds of an inch ;

L is the length of the furnace or of combustion chamber bottom or the length between points of substantial support, in inches, measured from the centres of rivet rows or from the commencement of flange curvature, whichever is applicable ;

C = 1,450 where the longitudinal seams are welded, and 1,300 where they are riveted ;

C_1 = 50 where the longitudinal seams are welded, and 45 where they are riveted.

W.P. is the working pressure in lbs. per square inch.

Corrugated Furnaces.—The working pressure to be allowed on corrugated furnaces is to be determined by the following formula :—

$$\text{W.P.} = \frac{C\,(t-1)}{D},$$

where D is the external diameter measured at the bottom of the corrugations in inches ;

t is the thickness of the furnace plate in 32nds of an inch, measured at the bottom of the corrugation or camber ;

C is a coefficient which is 480 for the Fox, Morison, Deighton, Purves, and other similar furnaces, 510 for the Leeds Forge Bulb Suspension furnace.

N.B.—No furnace, plain or corrugated, should exceed $\frac{13}{16}$ in. in thickness.

FLAT PLATES SUPPORTED BY STAYS SECURED IN VARIOUS WAYS.

Flat Plates supported by Screwed Stays.—The working pressure to be allowed on flat plates supported by stays is to be calculated by the following formula :—

$$\text{W.P.} = \frac{(t-1)^2 \times C}{a^2 + b^2},$$

but if steel of less tensile strength than 26 tons per square inch is used the working pressure allowed shall be correspondingly reduced.

In this formula,

W.P. is the working pressure in lbs. per square inch ;

t is the thickness of the flat plate in 32nds of an inch ;

a is the distance apart of the rows of stays in inches ;

b is the pitch of the stays in the rows in inches ;

C is a coefficient which varies with the method of fixing the stays as follows : —

Where the plates are exposed to flame and the stays are screwed into the plate and their ends are riveted over C = 50.

Where the plates are not exposed to flame and the stays are screwed into the plate and their ends are riveted over, C = 57.

In these cases the thickness of the plate must be at least half the diameter of the stay required by the rule.

Where stay tubes are screwed into tube plates and expanded, C = 52. If they are fitted with nuts, C = 72.

Where the plates are exposed to flame and the stays are screwed into the plate and fitted with nuts on the outside, C = 75. Where the plates are not exposed to flame, C = 86.

Where the stays pass through the plates not exposed to flame and are fitted with nuts inside and outside, C = 96.

Where plates are stiffened by flanging, the inner radius of which is not greater than $2\frac{1}{2}$ times the thickness of the plate, for the support thus given C = 110 when the plates are not exposed to flame, and C = 96 where they are exposed to flame. The pitch is to be reckoned from the commencement of the curvature.

GIRDERS.

Girders Supporting Combustion Chamber Tops.—For girders supporting the tops of combustion chambers the following formula is to be used :—

$$\text{W.P.} = \frac{\text{C} \times d^2 \times t}{(\text{L}-\text{P}) \times \text{D} \times \text{L}} \times \frac{\text{S}}{28},$$

where d is the depth of the girder at centre in inches ;

t is the thickness of the girder at centre, when this is a forging, or the sum of the thicknesses of the plates when the girder is made of two plates, measured in 32nds inch ;

L is the length of the girder in inches, measured between the tube plate and back chamber plate inside, or between tube plates in chambers common to two opposite furnaces ;

P is the pitch of stays supported by the girder, in inches ;

D is the distance apart of the girders, centre to centre, in inches ;

S is the minimum tensile strength of the steel plates forming the girder, in tons per square inch. In the case of forged girders S is to be taken as 24 for iron and 28 for steel ;

C is a coefficient as follows :—

$$\text{C} = \frac{n}{n+1} \times 495,$$

when the number of stays in each girder is odd, and

$$= \frac{n+1}{n+2} \times 495,$$

when the number of stays in each girder is even, n being the number of stays to each girder.

STAYS.

Iron or Steel Screw Stays to Combustion Chambers.—For screw stays with threads not coarser than 9 threads per inch, made of steel or of special wrought iron tested to the requirements, the following formula is to be used :—

$$\text{W.P.} = \frac{(d - 0{\cdot}267)^2 \times 8{,}250}{a},$$

where d is the diameter of the stay over the thread in inches ;

a is the area in square inches supported by one stay.

But in no case must the stress exceed 9,000 lbs. per square inch of section.

Steel Longitudinal Stays.—For steel longitudinal stays with threads not coarser than 6 threads per inch, the working pressure is to be calculated from the following formula :—

$$\text{W.P.} = \frac{(d - 0{\cdot}340)^2 \times 9{,}500}{a} \times \frac{S}{28},$$

where d is the diameter of the stay over the thread in inches;

a is the area in square inches supported by one stay;

S is the minimum tensile strength of the steel in tons per square inch.

But in no case must the stress exceed 11,000 lbs. per square inch of section, when steel of a minimum tensile strength of 28 tons per square inch is used.

In cases where longitudinal stays are made with enlarged ends, and the body of the stay is smaller in diameter than at the bottom of the thread, and in cases where coarser threads than 6 per inch are used, the working pressure is to be calculated from the following formula :—

$$\text{W.P.} = \frac{(d_1 - 0{\cdot}125)^2 \times 9{,}500}{a} + \frac{S}{28},$$

where d_1 is the diameter of the stay at the bottom of the thread or at the smallest part of the body.

Stay Tubes.—On stay tubes, whether of wrought iron or of lap-welded steel, a working stress of 7,500 lbs. per square inch of the net sectional area at the bottom of the thread is permitted.

Dished Ends (Convex Outside).—For ends of steam chests, etc., dished to partial spherical form, the following formula is to be used :—

$$\text{W.P.} = \frac{15 \times S\,(t - 1)}{R}.$$

W.P. is the working pressure in lbs. per square inch;

t the thickness in 32nds of an inch;

R the inner radius of curvature of the end in inches, which shall not exceed the diameter of shell;

S the minimum tensile strength of plates in tons per square inch.

Safety Valves.—At least two safety valves must be fitted to each boiler. They must be arranged so that the springs and valves are cased in, that the valves cannot be overloaded when steam is up, that they can be lifted by easing gear, and turned round on their seats by hand, and in case of fracture of springs they cannot lift out of their seats.

The easing gear must be arranged to lift all the safety valves on a boiler together, and must be workable from some accessible place free from steam danger.

All the safety valves of each boiler may be fitted in one chest, which must be separate from any other valve chest and which must be connected direct to the boiler by a strong and stiff neck, the passage through which should have a cross-sectional area at least equal to one-half the aggregate area of the safety valves in the chest.

Each safety valve box shall have a means of draining it; the pipe shall lead to the bilge or tank clear of the boiler.

Size of Safety Valves.—The minimum aggregate area of the safety valves of the ordinary type in each boiler, whether coal-fired or oil-fired, and whether working under natural, forced, or induced draught, shall be found by the following formula :—

Aggregate area of safety valves in square inches

$$= \text{Total heating surface of boilers in square feet} \times \left(\frac{K}{p + 15}\right).$$

where p is the working pressure in lbs. per square inch.

For coal-fired boilers K is 1·25, for oil-fired boilers and boilers with closed stokehold forced draught K = 1·5.

Accumulation Test of Safety Valves.—All safety valves must be set to the required pressure under steam. During a test of 15 minutes with the stop valves closed, and under full firing conditions, the accumulation of pressure must not exceed 10 per cent. of the loaded pressure. During this test no more feed-water should be supplied than is necessary to maintain a safe working water level.

Superheater Safety Valves and Drains.—Where a superheater is fitted which can be shut off from the boiler it must have a separate safety valve fitted with easing gear, etc. The valve as regards construction must comply with the regulations for ordinary safety valves, but the easing gear may be fitted to be workable from the stokehold only.

The superheater must be fitted with a drain cock or valve to free it from water when necessary.

BOILER INSPECTION.

Boilers must be inspected at least once a year. The owner or user may be made responsible for the effects of an explosion.

To prepare a boiler for inspection it should be thoroughly cleaned inside, scale removed, the manhole and mudhole doors removed, the blow-off cock closed, the steam valve locked to prevent tampering and danger to cleaners and inspectors, the hot feed valve locked, the bars and bridges removed from the furnace, the flues and boiler plates in the flues thoroughly swept clean of soot and dust, and the flue doors removed and the hearth pit plates lifted away.

The special points to be observed by the inspector are the condition of the plates along the seatings and all points of contact with bricks, the dryness of the flues, the absence of lime mortar near the plates, the dryness of the top covering, leakages at seams, circularity of furnaces, blisters, signs of overheating. Internally: grooving at plate junctions, around the angle irons of shell or furnace tube connection to end plates, at the root of angle irons or flanged seams or other points of stress or flexure, tautness of gusset stays, easy slackness of longitudinal stay bolts if present, condition of plates as to cleanliness, corrosion, &c., condition of low-water appliances, scum troughs, feed pipes, gauge openings, and generally all points bearing on the safety of the boiler that may by some unlikely and hard to conceive contretemps lead to mishap of any sort. Experience is necessary to make a good inspector. He must possess judgment and sense of proportion, and be able to order a boiler not to be worked until further notice without it being possible for further enquiry to show that there were not good grounds for his fears. In old boilers the openings in the shell should be looked to in order to ascertain the weakening due to removal of so much plate, and the degree of strength given back by added rings or other reinforcements. It is also desirable to note the quality of the attendance and workings of the boiler periodically, and to test the accuracy of the steam gauge and working of the safety valves.

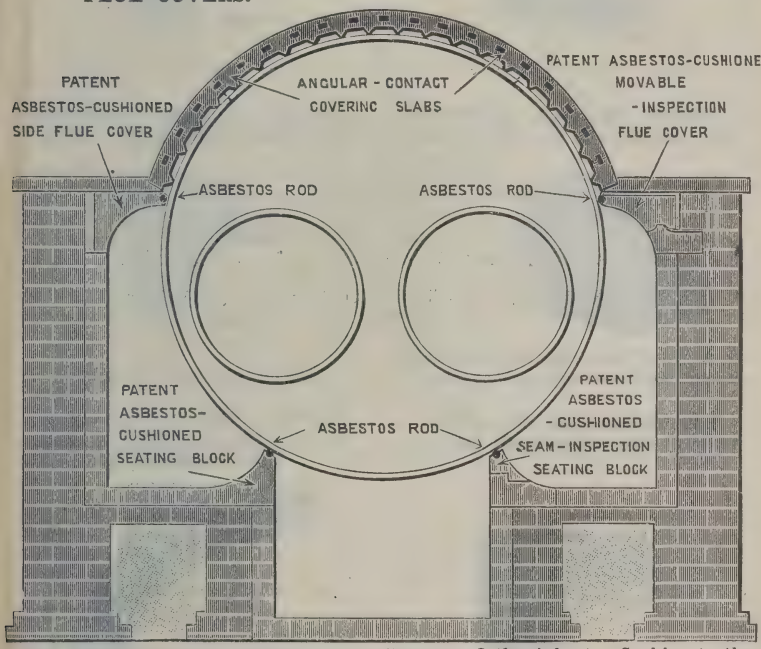
The foregoing remarks apply more particularly to shell boilers. For water-tube boilers, the caps of the water tubes must all be removed, and each tube examined and seen through for scale deposit, and as far as possible externally for blisters. Locomotive-type boilers are not easy to inspect, should never have riveted shell seams below water line, and must be largely judged by the appearance of such parts as are visible. Every few years the shell should be examined internally, the fire tubes being removed for the purpose. The accessibility of a boiler for complete inspection ought to be a considerable factor in determining the choice of a boiler, and more particularly so when the water is dirty or corrosive in quality.

BOILER LEGISLATION.

The Boiler Explosions Acts, 1882 (45 & 46 Vic. ch. 22) and 1890 (53 & 54 Vic. ch. 35) provide for inquiry into boiler explosions. The Acts extend to the whole of the United Kingdom. The term 'boiler' means any closed vessel used for generating steam, heating any liquid, or receiving steam for heating, steaming or boiling, excepting boilers used exclusively for domestic purposes or in the service of his Majesty. On the occurrence of a boiler explosion, notice must be sent within 24 hours to the Board of Trade by the owner, user, or person acting for him. This notice to state the name of premises or works, postal address, day and hour of explosion, number of persons killed and injured, description of boiler, purpose used for, particulars of failure, working pressure, by whom last inspected, and by whom insured.

The Act of 1890 makes the Act of 1882 applicable to sea and mine boilers.

The judgment of the court of enquiry into the Greenwich explosion of Christmas 1906 has made it a serious matter for engineers who have not acquired the necessary experience by training to assume responsibility for steam boilers. Steam engineers should be in charge of steam plant and machinery, is the lesson of the verdict in that case.



'MODERN METHODS OF SETTING STEAM BOILERS'

BASED ON

EFFICIENCY.

British Standard Specification for Charcoal Iron Lapwelded Boiler Tubes.*

(No. 43–1909.) (*Abstract.*)

1. The tubes shall be lapwelded and shall be made from genuine Swedish charcoal puddled iron of the best quality. 2. The tubes must be perfectly sound and well-finished, clean, and free from surface defects and rust, and the ends must be faced clean and square. They must be of the

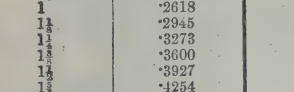

Fig. 5.

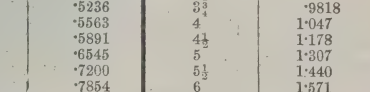

Fig. 6.

dimensions specified and of uniform thickness, and unless otherwise specified, of uniform diameter throughout. 3. Tubes shall be carefully annealed at both ends. 5. The tubes or strips cut from the tubes shall show a tensile strength between the limits of 19 and 24 tons per square inch inclusive, with a contraction of area of the metal of not less than 45 per cent. 6. The tubes

* By permission of the British Engineering Standards Association.

must stand bulging (fig. 5) both hot and cold without showing either crack or flaw until the diameter of the bulged end measures not less than 15 per cent. greater than the original diameter of the tube when tested hot and 10 per cent. greater than the original diameter of the tube when tested cold. 7. A piece of tube 2 ins. long shall be placed on end and must stand hammering down, until it is reduced to $1\frac{3}{8}$ in. high, without showing crack or flaw. 8. The tubes must when cold stand flattening (fig. 6) until the interior surfaces of the tubes meet without showing crack or flaw. 9. All tubes shall be tested by an internal hydraulic pressure of at least 750 lbs. per sq. in., and any tubes failing to stand this test will be rejected.

BRITISH STANDARD SPECIFICATION FOR COLD DRAWN WELDLESS STEEL TUBES FOR LOCOMOTIVE BOILERS.*

No. 53—1913 (Abstract).

Quality of Material.

The tubes shall be cold drawn and weldless, and shall be manufactured from steel of the best quality made by the open-hearth process. They must not show on analysis more than 0·03 per cent. of sulphur or of phosphorus. The manufacturer shall supply an analysis when required to do so.

Freedom from Defects.

The tubes must be perfectly sound, well-finished, clean, and free from surface defects and rust, and the ends must be faced clean and square. They must be of the dimensions specified, of uniform thickness, and, unless otherwise specified, of uniform diameter throughout.

Annealing.

The tubes shall be carefully annealed throughout their length after the operation of drawing.

Permissible Variation in Weight.

The actual weight of each tube must not differ from the calculated weight by more than $2\frac{1}{2}$ per cent. below or 5 per cent. above the weight calculated from the specified dimensions, allowing 489 lbs. per cubic foot of metal in the tubes.

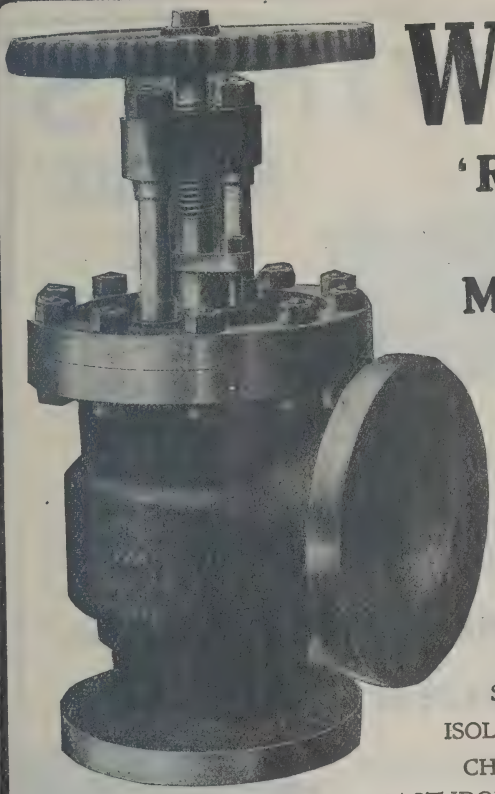
Tensile Test.

The tubes or strips cut from the tubes shall without further annealing show a tensile strength of not more than 24 tons per sq. in., with an elongation of not less than 28 per cent. in 8 ins. If strips are cut for testing from tubes over $2\frac{1}{4}$ ins. diameter, they may be annealed before testing.

Crushing down Test.

A piece of tube 2 ins. long shall be placed on end and must, when cold, stand hammering down, until it is reduced to $1\frac{1}{8}$ ins. high, without showing either crack or flaw.

Flattening Test.



The tubes must, when cold, stand flattening (fig. 6), without showing crack or flaw, until the interior surfaces of the tubes meet, or, when the tubes are over 11 S.W.G. in thickness, until the interior surfaces are brought to a distance apart equal to the thickness of the wall of the tube.

Hydraulic Test.

Every tube shall be tested by an internal hydraulic pressure of at least 1,000 lbs. per sq in., and any tubes failing to stand this test will be rejected.

BOILER SETTING.

(1.)

In ordinary practice, as developed by long experience, a boiler (figs. 7, 8, 9) is set upon two longitudinal walls, parallel to one another, and distant apart over half the diameter of the

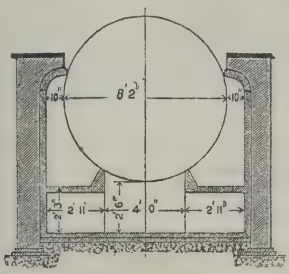

FIG. 7.

boiler. On these walls are laid specially formed seating blocks (fig. 10) of firebrick, the seating edge of which should not exceed 3 inches in width, and may advantageously be convex in

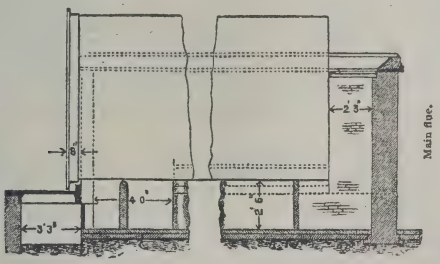

FIG. 8.

profile so as to touch the boiler plate along a line only. Where the ring seams cross the seating blocks, a rectangular gap should be cut across the seating for purposes of inspection, and specially

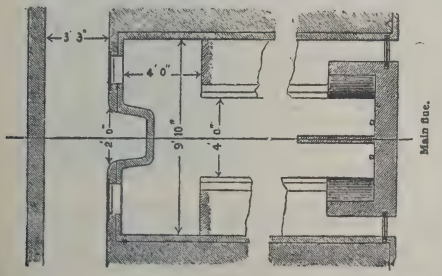

FIG. 9.

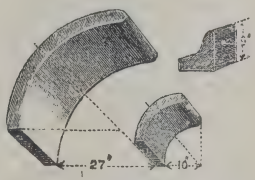

FIG. 10.—Flue Covers and Seating-block.

formed wedge pieces ought to be provided to close these gaps. These are removed for inspection and at once replaced.

Foundations.

In preparing the foundations, a matter of great importance is that good drainage should be ensured, as it is found that serious damage often occurs to boilers owing to dampness which arises from the foundation, such outside wasting not being caused by leakages from the boiler itself, but simply from being built either on wet ground or where surface water is allowed to accumulate. Care should also be exercised that the foundations are built in hard well-burned bricks, and the internal parts of the flue, where exposed to the fire, lined with fire brick; the boiler itself should be set having a fall of about 1 in 240 towards the front end, so as to ensure its being thoroughly drained of its contents when it is emptied for its periodical cleaning. The top of the side flues also should be made up by flue covers (fig. 10) of fireclay, in such a form as generally to allow a flue of about 10 inches at each side of the boiler, the flues themselves being of such dimensions as will allow of a man getting thoroughly round for the purpose of cleaning and examining the boilers from time to time.

The following materials are required to seat a boiler 7 feet in diameter by 30 feet long :—

Fire-bricks, including breakage	6,000
Downtake covers 6 inches wide	14
Seating blocks	52
Flue covers, 12-inch wide	64
Fireclay	3 tons
Common bricks for external walls	Quantity varies according to thickness.

(2.)

Some Modern Improvements.

When preparing the foundations for a boiler or battery of boilers, it is essential that the position chosen be carefully examined, for if the situation is at all damp or there is a liability of the surrounding ground getting soaked with surface water or floods, a proper system of drainage must be adopted. For this purpose an experienced engineer should be consulted. Also where the ground is of a sandy or shaley nature it may be necessary to resort to piling, and as there is no general rule to follow, experience can alone decide the laying out of the work. It is essential that there should be no sinking or warping of the foundations, which not only hastens the formation of cracks in the settings, but induces strains in the pipe work and causes other serious inconveniences.

Most boiler makers supply a general plan of the brickwork setting, which is usually of the old type, and shows broad-faced blocks and semi-circular covers in contact, with two or three courses of brickwork on top. It is far better, however, to have one's own carefully prepared drawing made for the specific installation, prepared by some firm of repute which makes a speciality of this class of work and approved by the engineers and the Boiler Insurance Co.

After the foundations are laid and brought up to the level ready for commencing the boiler setting proper, it is well sometimes to allow several days to elapse to ensure that there will be no further settlement, especially where concrete has been employed.

In the ordinary type of Lancashire boiler the path of the gases, after leaving the boiler flues, is along the bottom flues to the front, and then dividing to the side flues they pass thence into the main flue through separate dampers. There are many instances in which the gases pass first through the side flues and then along the bottom flue to the main. This system is not to be recommended, as the hottest gases should first pass under the boiler. As to the dimensions of the flue passages, these are a compromise, small flues giving difficulty when inspecting, while large flues add too much useless surface. The back downtake should not exceed 2 ft. 6 ins. from back to front, the sides tapering from the width over the furnace tubes to about 3 ft. 6 ins., and not exceeding 4 ft., with a depth of from 3 ft. to 4 ft., depending upon the size of the boiler. It is usual now to give a greater width in the downtake in order to accommodate if necessary a superheater without requiring too much reconstruction. The side flues are made with vertical sides giving 9 to 12 ins. clear from brickwork to boiler plates at the centre line of diameter, and the floor level being about on a level with the bottom of the boiler gives a convenient chamber for an inspector to crawl through while providing ample space for the accommodation of soot.

With the Paxman 'Economic' type of boiler (page 1479) the arrangement is somewhat different. The gases pass from the main iron flues into the back chamber where they divide right and left and return through the internal boiler tubes into two front smoke boxes from whence they pass downwards to two underneath flues separated by a mid feather upon which the boiler rests. These flues meet at the back, and the products of combustion pass out through a single damper or dampers to the main flue.

All parts of flues in direct contact with the hot gas should be lined with firebricks, neat fireclay being used between the joints. All other bricks not subject to a high temperature should be

of a close-grained quality, well burned, of regular dimensions and free from warp, set in with fire-clay unless entirely free from heat, when a good quality of mortar will suffice.

A number of firms make special firebrick blocks for boiler setting. These include mid feather and side seatings, large and small segment blocks for the top of the side flues and back chamber, besides flat blocks and other shapes less commonly employed but often required. However well the brickwork, as constructed on the older plan, may be cemented together, the constant movement of the boiler under steam and the changes of temperature soon begin to cause cracks and crevices to appear, especially between the boiler shell and the brickwork. The result is a loss of draught and short circuits in parts of the flue causing a considerable reduction of thermal efficiency. Further, the blocks being cemented in position the work of the boiler inspector, who has to thoroughly examine the boiler plates on the outside, is not an easy one, and to remove the permanent brickwork entails a very considerable amount of trouble and expense.

(3.)

The 'Pearson Patent' Asbestos Cushioned Seating Blocks and Flue-Covers (*E. J. & J. Pearson Ltd., Stourbridge*) have been specially designed to remedy sources of waste caused by (*a*) corrosion of the plates, due to the presence of moisture in the brickwork; (*b*) short circuiting of the hot flue-gases; (*c*) leakages of cold air into the flues; and at the same time to be readily removable and replaceable when an inspection has to be made.

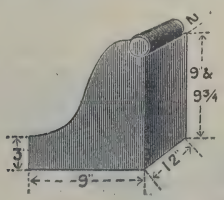

FIG. 11.—Patent 'Asbestos Cushioned' Seating Block.

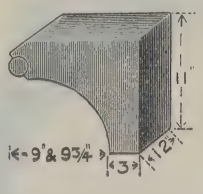

FIG. 12.—Patent 'Asbestos Cushioned' Flue-Cover.

The arrangement, as shown by figs. 11 and 12, consists of a specially prepared cushion of hard asbestos, compressed into a groove formed on the face of the blocks, in such a way that the boiler-plates are completely insulated from all contact with the blocks themselves.

The plates are thus secured against the rubbing caused by the expansion and contraction of the boiler, and also against any risk of corrosion through contact with damp brickwork or blocks, which alone has been the cause of very many serious explosions.

Owing to the non-absorbent nature of the material, and also to the high pressure to which it is subjected, the hard asbestos-cushion does not take up moisture, as is the case with ordinary clay blocks, consequently there is no possibility of corrosion. No corrosion has ever been found in boilers set with these seatings, and boilers can be inspected which have been running for several

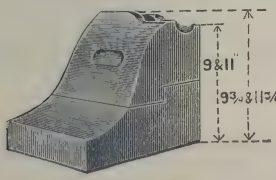

FIG. 13.—Patent 'Asbestos Cushioned' Seam-Inspection Seating Block.

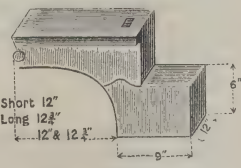

FIG. 14.—Patent 'Asbestos Cushioned' Seam-Inspection Flue Cover.

years. In addition to this advantage, the presence of the compressed asbestos cushion ensures an absolutely gas-tight joint between the boiler plates and the blocks, so that not only is there no risk of any short circuiting of the flue-gases, but (an even more important consideration) no danger of cold air finding its way into the flues from the outside, there being no necessity to fill up large spaces with ashes or sand in order to ensure air-tightness. The arrangement gives a specially large heating surface. Under the old system, 10 per cent. of the external surface of the

boiler was covered up by, and in contact with, brickwork; while in a boiler set with the Patent Asbestos Cushioned Blocks, less than 1 per cent. of the external surface is covered, and at no point are the seating blocks or covers in contact with the boiler plates.

The 'Patent Asbestos Cushioned Seam-Inspection Blocks and Covers' (figs. 13 and 14) are designed to meet the requirements of the Board of Trade and the insurance companies. The Board of Trade now require a proper inspection at least once in fourteen months, and the removal of the brickwork, wherever necessary, is compulsory. These blocks enable complete examination of the ring-seams, without any need to remove more than the block or cover opposite the seam. This means a great saving of time and expense at each inspection. The lower half of the block is built and bonded into the side wall of the flue, rendering it a part of the permanent structure, and enables the upper half to be removed with utmost ease, admitting daylight to the flues and facilitating inspection. The upper part of the block turns slightly on the knuckle joint, and is thereby safe from cracking under boiler expansion. Handholes are inserted in upper half of each cover for lifting purposes.

It is probable that no part of a boiler setting of the old types gives more trouble than the back downtake. The constant expansion and contraction of the boiler causes the blocks or slabs, used to cover in the downtake flue, to crack and fall down into the flue. The 'Pearson Patent Interlocking Downtake Arch' (fig. 15) is an arrangement of great simplicity and reliability. It

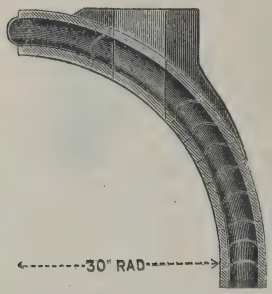

FIG. 15.—'Pearson Patent Interlocking Downtake Arch.'

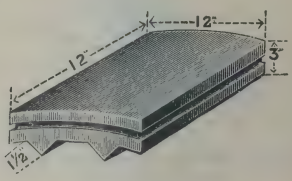

FIG. 16.—'Angular Contact Slab.'

consists of an arch, of the required span, built up of interlocking bricks, so shaped that while they are as easily built up as an ordinary brick, when once in place they cannot be dislodged, and however much the arch may give to the movements of the boiler, no displacement of the brickwork can occur. Each set is fitted with two manhole blocks with lids, by means of which easy access is obtained to the flues, without disturbing the brickwork.

For the covering in of the boiler the 'Angular Contact Slabs' (fig. 16) may be used. In these coverings, advantageous use is made of the well-known fact that an envelope of stationary air is one of the best non-conductors of heat known.

Recent tests, of which particulars are given below, show the efficiency of this method of covering, there being a difference of over 90° C. between the temperature under the covering and the external air temperature.

Tests.

(1.) Report on test of Angular Contact Boiler Covering Slabs with layer of hair felt between slabs and boiler plates:—

Type of boiler, 'Lancashire'	30 ft. × 7 ft. dia.
Working pressure at time of test	40 lbs.
Temperature of atmosphere	8° C.
Shaded temperature taken 3 ins. above surface of bare boiler shell	83° C.
Shaded temperature taken 3 ins. above surface of covering slabs	21° C.
Temperature under covering slabs	107° C.

Boiler housed in shed open both ends.

(2.) Report on test of Angular Contact Boiler Covering laid on boiler shell without felt or silicate cotton :—

Type of boiler, Cylindrical	26 ft. × 6 ft. 6 ins. dia.
Working pressure at time of test	40 lbs.
Temperature of atmosphere	10° C.
Shaded temperature taken 3 ins. above surface of bare boiler shell	81° C.
Shaded temperature taken 3 ins. above surface of covering slabs	15° C.
Temperature under covering slabs	109° C.

Boiler set in the open and not housed.

The covering slabs are quite distinct, and have no connection with the flue-covers, the compressed asbestos cushion preventing any leakage of flue-gases : consequently while radiation of heat from the boiler is prevented, there is also no possibility of the temperature under the slabs being raised by the infiltration of hot flue-gases.

The covering slabs form a surface hard enough to be worked on, and can easily be removed for the inspection of the boiler plates at any time, and as easily replaced, the covering being in no way damaged by the removal.

Leaky Boiler Settings.

Leakage through boiler settings of brick can be lessened by giving the walls two coats of Portland cement wash and then one coat of cold water paint to brighten them up. Or the brick settings may be sealed by applying cement with a covering of canvas pasted over and then painted.

Another method is to build with mortar in which a certain quantity of cement has been mixed, the amount to be gauged by the tenacity of the mortar, which must not hold bricks so that they will be destroyed if it is found necessary to take the brickwork down : a 5 per cent. cement will give this, but may be increased or decreased ; the greater the percentage of cement the tighter the setting, but with the above disadvantage.

Washing the bricks with the liquid cement when building will give best results ; the brickwork should then be coated with the thin pure cement liquid afterwards, the cement being used as a wash. (*Horóbin.*)

Fusible Boiler Plugs.

There are six primary causes for the rejection of fusible plugs, which may be roughly divided into two classes. Under the first class, rejections are included due to mechanical defects of casing material. The second class includes rejections due to lack of purity in the tin filling. The impurities in the latter case may be those either present in the original tin or those introduced during the manufacture of the plug.

The following conclusions have been reached as to the precautions to be taken in the manufacture of fusible plugs :

1. The pig tin should be at least 99·7 per cent. pure, containing not more than 0·1 per cent. lead, or 0·1 per cent. zinc, which are the requirements of the Steamboat Inspection Service.

2. The casing should be of bronze, an alloy the major constituents of which are copper and tin. Small amounts of zinc and lead increase the ease of casting and machining, and are not objectionable if not present in greater amounts than in the following compositions :

	I.	II.
Copper	88	87
Tin	10	7
Zinc	2	5
Lead	—	1

3. The pot or crucible for melting the tin should not be used for melting other metals, thus doing away with the liability of contaminating the good tin when these are not thoroughly cleansed.

4. Casings should be tinned on the inside with the same grade of tin used for filling, but the tin left over from this process should not be added to the filling to be used. Zinc-chloride flux may be used, although hydrochloric acid is preferred, though no flux need be used during the filling process.

5. The casing should be preheated to not above 250° to 275° C. (482° to 527° F.), and tin should be poured at a temperature not above 275° to 300° C. (527° to 572° F.).

(*' Bulletin of the American Institute of Mining and Metallurgical Engineers.'*)

STEAM PIPES.

The ring main should be avoided ; it is no longer employed, and was always bad practice.

The pipes if possible should not rise from the valve on the boiler to the main steam pipe, as this causes a dangerous water pocket and, if suitably drained, only automatic steam traps should be used ; these should be tested by blowing to atmosphere at least twice a day.

The best steam pipe arrangement between engine and boiler is that the boiler stop valve should stand at the top of a vertical pipe on the boiler and there should be a steady, if small, slope from that valve to the engine separator. Rupture from water-hammer occurs from failure of pipe drains, and if possible all drains should be unnecessary by design. The closing of no valve should be able to cause water to accumulate against it. Where it is impossible to avoid drainage points, these should be carefully arranged, and unduly small drain pipes must be avoided lest they choke with rust or dirt. New pipes and drains especially should be well blown through before fixing traps.

Long lengths of drain piping, from steam mains to traps, should be avoided ; they are a continual source of waste, and with superheated steam they more often drain away the water which they have been the means of condensing. Therefore the pipes from steam main to traps should be as efficiently lagged as the main steam line.

Idle parts of the steam range should be isolated when not in use, and carefully drained, as valves often leak when shut, through scoring of faces and grit wedging in, preventing tight closing.

All live steam drains should be returned to the feed tanks.

(See also Manchester Steam Users Association Reports 1907, 1908.)

Steam pipes, where supported on brackets or columns, should be carried on rollers or rubbing-plates, which should be riveted to the pipe, to allow of free contraction and expansion.

The connecting pipes from the boilers to the main steam pipe, and from the main steam pipe to the engines, should be preferably of steel, with half (not 'full,' which would form a 'water pocket') swan-neck bends, to allow for expansion.

When erecting new steam pipes, attention should be given to the thorough cleaning of the pipes, as otherwise fine particles of grit, driven by the steam into the faces of the valves, cut into the seats, causing considerable trouble and expense.

The centre of a main steam pipe should be anchored, to divide the longitudinal expansion. Where engine and boiler room are in line and steam mains are of considerable length, a $\cap$ or Ω shaped bend should be inserted between the engine and boiler room ; the horizontal position is best and should in no case be downwards. Anchor-plates should then be fixed in the centre of the engine-room main and in centre of boiler-room main.

Riveted pipes and flanges may be used from 6 ins. diameter upwards.

The branch-pipes from boilers and engines to steam main having full swan necks of as large a radius as possible (*see* Table of Standard Radius, page 1433), give the greatest amount of play, but necessitate careful draining. They should preferably be of solid-drawn steel.

If the pipes are of riveted steel the necessary thickness must be secured for caulking. It is not the practice to make these plates less than $\frac{1}{4}$-inch ; it is better to use $\frac{5}{16}$-plates. To avoid risk of rivet-heads springing off during caulking, rivets should not be less than $\frac{5}{8}$ in. in diameter.

Copper pipes (although not advisable), if used for steam, should be solid drawn, and not brazed. Flanges to be screwed and brazed should be of brass in all cases. On no account should copper or brass be used for superheated steam, owing to loss of strength at these high temperatures, which to obtain the full benefit of superheat is raised to 650° or 700° F. (*Horobin.*)

Copper pipes above 5 ins. bore should be annealed by slinging them up within easy access of about a 2-in. blast pipe. Charge end of pipe nearest blast connection with light pieces of wood, lighting same with hot cinders or gas blow-pipe, then blow blast through, the wood being repeatedly replenished. The effect to aim at is the emitting at opposite end of pipe of good supply of flame. Too much wood results in dense volumes of smoke, too little wood causes lack of flame and discharge of merely sparks and burnt wood. A little experience soon enables the operator to decide upon the happy medium. In a few minutes the pipe becomes a uniform red heat throughout its whole length. A 12 in. bore or even larger bend, 12 ft. or so long, can be heated by this means from end to end to a good annealing heat in a quarter of an hour or so, at an expenditure of a few pence in wood. This method removes the possibility of any part not being properly heated. Copper will attain to a degree of hardness by mere exposure to the atmosphere, the degree depending upon the time of exposure. It is advisable to re-anneal any pipes that have lain about for over twelve months, especially if any bending or working is required to be done to them.

Brazed copper is apt to be unreliable, and copper steam pipes ought to be wound with steel wire.

Copper should not be used for superheated steam.

Serviceable and reliable steam pipes may be made up of lap-welded mild steel with heavy wrought-iron flanges, the flanges being screwed on hot and the ends brazed. The flanges must be faced up to enable good joints to be made.

The radius of curvature measured to the centre of pipes should not be less in solid drawn pipes than three times the diameter of pipe; even this radius of curvature causes a reduction in thickness of 20 to 25 per cent. on the outside of the bend, and a corresponding increase in thickness on the inside. Sharper bends can, if necessary, be made by working the pipes out of two plates with a brazed joint along each side. The latter construction is more expensive than the former.

Spigot and socket pipes should not be employed for steam or for hot-water, under any condition.

Bolts in pipe flanges should be in multiples of 4.

Pipes often vibrate under the pulsating demand of steam by an engine. This requires that they should be anchored at one or more points.

The pipes should be marked when cold opposite marks on the walls, and again when hot. Anchors should be at the points where least movement is shown. Pipes are best carried on brackets. Where they rest they should have rubbing pieces firmly attached, and they should not rest on rollers, as the friction helps to check vibration. In long mains there may be an anchorage at or near each end, with a telescopic expansion joint between.

Expansion bends are best arranged to project horizontally from the line of pipe, in order to allow a free passage for water. If they stand vertically upwards they prevent water flowing, and if hung downwards they form water pockets. In both cases they necessitate careful drainage.

Steam pipes between 32° and 212° F. expand by heat 0·0000111 per degree C. = 0·00000618 per degree F., if of cast iron. For wrought iron these figures become 0·0000118 and 0·00000656. Between 60° F. and a pressure of 190 lbs. or a temperature of 383° F. the expansion is about $4\frac{1}{2}$ ins. per 100 ft. The coefficient for steel is 0·000006 per degree F.

With superheated steam, pipes may expand nearly $6\frac{1}{2}$ ins. per 100 ft. of their length. At higher temperatures the coefficient of expansion is considerably larger.

In fixing pipes the expected movement when hot should, if possible, be half provided for in the opposite direction, in order to minimise stresses.

Pipes may be best bent by filling with thoroughly dry sand and plugging the ends. They will then bend without buckling.

Copper pipes are bent by being filled with melted resin, or with solder, the pipe bent cold, and the filling then melted out.

(Power).

Exhaust Pipes.

These may be of cast iron and should be free from blow holes. The flanges should be faced and jointed with soft rubber rings. Exhaust pipes should be painted while under vacuum, preferably with several coats of red lead paint well brushed in until all the pores are filled. It has been suggested that exhaust pipes, especially if long, might be laid in a concrete trench under water so as effectually to prevent air leakage. *(W. H. Booth.)*

(*Philip Dawson.*)

Joints of Steam Pipes.

Pipes for steam and hot water should not be jointed with socket and spigot; this is dangerous.

Steam pipes may be screwed and socketed. This is neat and is easy to cover.

Flanges should have not less than 8 bolts if possible, and bolts should thus number 4, 8, 12, and so on, in multiples of 4.

Faced flanges may be jointed simply with a ring of copper, preferably corrugated. In first-class work, faced flanges and a little paint has sufficed.

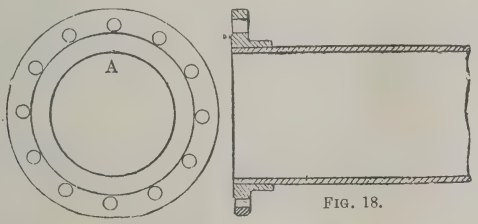

FIG. 18.

In large-sized steam pipes it will be found that the joints can be kept tighter by having the flanges made with a slight boss, which is faced up for the joint, instead of the whole of the flange being faced up for that purpose, as shown at A in fig. 18; from $\frac{1}{16}$ inch to $\frac{1}{8}$ inch is sufficient for the thickness of the boss.

Rubber prepared with plumbago makes a good sound joint, which requires taking up when steam is admitted to the pipe, as the material softens with the heat, although it sets into a hard permanent joint when tightened up.

A cement for pipe joints that is said to be as good, in a faced or rough flange joint, as red lead putty, at one-tenth the cost, consists of a mixture of ordinary pine tar and dry oxide of iron. It is stated that it does not harden so soon as red lead, and is very adhesive under pressure.

The Use of Metallic Gaskets.

The ordinary corrugated copper gaskets are approximately $\frac{1}{16}$ in. thick, and are generally used as a ring inside the bolt circle, two in a joint, because when only one is used the flanges are apt to spring enough under the strain of the bolts to touch, iron to iron, outside the bolts, permitting a leak. In other words, one thin copper gasket is not enough for the ordinary commercial flanges to 'get a bite on.' When two gaskets are used they should be meshed the same way of the corrugation. Metal gaskets should be coated with pipe cement, graphite and oil, or lead and oil, and bolted up before the coating has dried, so that each corrugation flattening under the pressure forces a ring of this filler concentrically around the flange, and the copper gasket practically acts as a binder. There are, however, exceptions to this rule of two gaskets, especially on low-pressure work. Copper gaskets should be annealed soft and pliable at the final process, because in the process of corrugating it becomes hard, stiff and springy. This is because, in corrugating, the fibres of the metal are strained and thrown out of harmony and mesh. Annealing brings these fibres back into harmony and restores the strength of the metal; therefore orders for soft gaskets should always be marked 'to be annealed after making.'

The ideal gasket is one that covers the pipe ends as well as the flange if the pipes are faced off flush with the flange, because such a gasket will save thread leaks. If, however, the pipe does not come out flush with the flange, this cannot be accomplished with any gasket.

(*Power.*)

For jointing purposes the corrugated copper gaskets in common use have not been very successful with superheated steam. The reason lies in the fact that the annealing temperature of copper lies in the neighbourhood of 600° F., corresponding with a boiler pressure of 180 lbs. to a superheat of 220°. Corrugated gaskets, moreover, used by careless pipe fitters are always likely to give trouble owing to the danger of the bolts and flanges being overstrained. Joints of asbestos and of rubber preparations have often been used, but they last but a short time. It is fairly certain that the high temperature of superheated steam at the usual boiler pressures prohibits the use of organic material for jointing purposes if results of any permanence are desired. A satisfactory joint has been found to be one in which a gasket of thin steel of a radial width not exceeding $\frac{5}{8}$ in. has been used, the steel being soft annealed. The comparatively small area of the gasket enables great pressure to be brought to bear by bolts of ordinary size, with the result that the soft steel is thoroughly pressed into the rough surface of the flange. Such a joint will, although simple and cheap, give all the permanence that could be desired.

(*Times Engineering Supplement.*)

'Dexine.'

This material (*Dexine, Ltd.*) is a very suitable substance for making joints. It does not stick to the flanges, nor does it press out, blow out, or burn out; and it can be used over and over again. It is made in sheets from $\frac{1}{64}$th inch upwards.

'Universoline.'

By the use of this substance, which is in the form of a paste (*Sterns Ltd.*), the materials used for making joints (asbestos, rubber, millboard, cardboard, spunyarn, etc.) are prevented from adhering to the metal surfaces. Consequently the materials can be removed undamaged as often as necessary, and thus used over and over again. Scraping and cleaning of the metal surfaces are also rendered unnecessary. It is a rust preventive, so that the formation of rust in the threads of screws, bolts, nuts, etc., is obviated, and the articles can be unscrewed with ease at any time, even should they have been exposed to water.

Asbestos Fibre Rings and Joints.

Compressed asbestos fibre rings and joints are made in any required shape, in thicknesses from $\frac{1}{64}$ in. upwards, by *Turner Brothers Asbestos Co. Ltd., Rochdale.*

Leaks in Steam Pipes.

Leaks in steam pipes that cannot be stopped by caulking or plugging may be stopped with a cement made by mixing black oxide of manganese with enough raw linseed oil to form a thick paste. The steam pressure should be relieved in the pipe, but the pipe should be kept warm enough to dry the oil.

Loss of Heat from Uncovered Steam Pipes.

The large amount of heat lost from bare steam pipes, and the consequent waste of coal, is frequently not fully appreciated. One square foot of uncovered pipe surface, the pipe containing steam at 100 lbs. per sq. in., will dissipate about 3 B.Th.U. per hour per degree of temperature difference between the steam and the atmosphere, or about 850 B.Th.U. per hour at ordinary atmospheric temperatures. The steam condensed per hour due to this square foot of bare pipe will be ·96 lb. In a year of 3,000 working hours the steam wasted will amount to 2,880 lbs., corresponding to a coal consumption of about 410 lbs.

A single 9-ft. length of 6-in. pipe, if uncovered, will waste by heat loss about 2·5 tons of coal per year.

80 to 90 per cent. of this loss may be avoided by the use of suitable coverings, the expense of which is amply counterbalanced by the saving in coal.

It is important that flanges, valves, etc., as well as the body of the pipe lengths, should be covered.

The loss of heat per hour per sq. ft. of surface, in the case of bare pipes, depends principally upon the difference of temperature between the pipe—i.e. practically, that of the steam in the pipe—and the surrounding atmosphere, but also is influenced to some extent by the diameter of the pipe, its position—whether horizontal or vertical—the presence of air currents about the pipe, the nature of the pipe surface, and the velocity of the steam in the pipe.

Complete data on all these factors is lacking.

It is usually assumed that the loss is proportional to the difference of temperature, but careful experiments show that the rate of loss, B.Th.U. per sq. ft. per degree F., increases at the higher temperature differences. Thus from 1·95 at 50° difference, it becomes 2·4 at 150°, 3·26 at 300°, 4 at 400°, and 5·26 at 460°. (*McMillan.*)

There is little experimental data on the effect of pipe diameter, but it appears that the loss per sq. ft. decreases as the diameter increases, and this is in accordance with theory.

The following table shows the heat loss from pipes covered with various thicknesses of 85 per cent. magnesia composition, and the approximate loss from uncovered pipes is given for comparison.

LOSS OF HEAT FROM STEAM PIPES, WITH STEAM 300° F. ABOVE ATMOSPHERIC TEMPERATURE. LOSS IN B.TH.U. PER HOUR PER SQUARE FOOT OF PIPE SURFACE.

(*Based on tests by McMillan, 'Trans. Am. Soc. M.E.'* 1915.)

The 'efficiency' of the covering in preventing loss of heat is taken as the ratio (heat loss from bare pipe — loss from covered pipe) ÷ heat loss from bare pipe. The table shows that this 'efficiency' varies with the thickness and the pipe diameter, hence to compare different covering materials, the comparison must be made under the same conditions of thickness, etc. if the comparison is to show the relative insulating properties.

The coverings may also be compared on the basis of cost per foot run—i.e. taking a greater thickness, in the case of the cheaper materials.

The relative properties of various pipe coverings are shown in the following table, the thickness being about 1·4 ins., diameter of test pipe 1 in., steam pressures in pipe 50, 100, and 200 lbs. per sq. in.

RELATIVE VALUE OF PIPE COVERINGS.

Material.	Weight per foot run, lbs.	Insulating Efficiency per cent.		
		At 50 lbs. per sq. in.	At 100 lbs. per sq. in.	At 200 lbs. per sq. in.

NOTES ON COVERINGS FOR PIPES AND BOILERS.

As well as having good heat insulating properties, it is important that pipe coverings be durable. A material which easily disintegrates under vibration will not long remain an efficient insulator, nor will a material which cannot stand high temperature. For example, hair felt is a good insulator, but will not stand contact with pipes carrying high pressure or superheated steam.

Eighty-five per cent. magnesia has proved to be very durable. Recent trials on coverings which had been eight years in service showed no deterioration, and after further test for two months at the high temperature of 800° F. the covering still showed the average conductivity value, and when removed was in such a condition that it could be re-applied.

Tests with locomotive-type boilers, first uncovered and then covered with 2 ins. of 85 per cent. magnesia, showed in the second case 2·5 per cent. additional evaporation for 13·8 per cent. less coal, or a total coal saving of 16 per cent.

(*'Chem. and Met. Eng.,' Feb.* 16, 1921.)

NOTES ON LAGGING.

The surface temperature of a lagging, when in use, is commonly supposed by engineers to furnish a clue to its efficiency, and conclusions are often formed from the sensation of heat experienced when the hand is placed on the surface. Another test, frequently employed, is to make a small hole in the lagging, into which the bulb of a thermometer is inserted; and it is then assumed that the material in which the lowest reading is obtained possesses a superiority in respect to insulating power. Whilst a correct measurement of the temperature of the surface is of value in conjunction with other tests, if taken alone an entirely erroneous opinion of the merit of the material may be formed.

The important factor which is not taken into account in the above rough-and-ready test is the nature of the surface with respect to its radiating power. A lagging with a rough exterior radiates heat with much greater freedom than one which is finished smooth, and the latter which is superior as an insulator, owing to retention of heat by the surface, will feel hotter than the former when touched by the hand. Hence it follows that a given non-conducting coating, if improved by painting and varnishing the surface, would appear to have suffered in insulating power if judged by its surface temperature only. To avoid such a fallacious conclusion, it is evident that the radiating power must also be taken into account, and only when this is done can a correct inference be drawn.

HEAT RADIATION

from Boilers and Pipe Lines can be most effectively prevented by

F. 1439

When the radiating surfaces are identical, the surface temperature furnishes a reliable and delicate guide to the insulating powers of different materials. A smooth metallic surface, such as aluminium paint, may be hotter than an unprepared surface, and yet radiate less.

On reference to a test in which a thermometer bulb is placed in a hole made for the purpose in the outer part of the lagging, into which it is customary to pour mercury to secure a good contact between the material and the bulb of the thermometer, it is difficult to say what the reading indicates, as the temperature recorded will be the mean of that existing between the end of the bulb and the surface; and, moreover, the normal condition of the lagging at this part is entirely changed by the introduction of the mercury and thermometer bulb. One thing is certain: that the reading affords no clue to the surface temperature it is supposed to measure; and in this respect the test is inferior to the application of the hand. The thermal-junction method is undoubtedly the best for obtaining a definite reading of the surface temperature; and as it is now possible to obtain cheap portable indicators for use with a junction, other so-called measurements should be definitely abandoned.

The relations between surface temperature and efficiency may be summarised as follows:—

1. When the surface of a given insulating material is treated so as to reduce its radiating power, the temperature is higher, although the heat escaping is less.

2. If two different materials possess identical surfaces, that which has the higher surface temperature, under given conditions, is the worse insulator.

A recognition of these two points will prevent engineers from being led astray by the extravagant claims frequently put forward for compositions, based entirely on imperfect surface temperature measurements. The advantage of finishing the surface with aluminium paint, instead of ordinary paint and varnish, should be recognised, as not only is the insulating power improved, but the finished work has a better appearance. The fact that such a surface feels warmer to the touch is in this instance not a proof of inferiority, but of the contrary.

(*C. R. Darling*, '*Engineering*,' *Sept.* 22, 1911.)

The holding of slag wool to pipes or boilers (to which asbestos composition has been applied) is best effected by means of wire-bound split laths, so spaced that the finishing overlay of cement may not only be keyed in between them but may also afford a means of locating any leakages, in addition to preserving a favourable density estimated at from 10 to 12 lbs. per cubic foot.

A cheaper but decidedly less effective way of holding slag wool together is by means of wire netting into the meshes of which an overlay of plastic cement is impacted. When, therefore, disintegration takes place and the wool settles down by its own gravity, the upper surface is reduced to a mere shell of wire and cement by which the bulk is held in suspension.

Silk waste, although almost equal in efficiency to slag wool, is wanting in durability.

Hair-felt is one of the finest non-conductors known, but is quickly consumed by direct contact with heated surfaces. (*E. Kenyon.*)

'Crown' Boiler Coverings

(*Sutcliffe Bros. & Bryce, Ltd.*)

These coverings are specially useful for extreme pressures and superheated steam. Official tests show over 96 per cent. saving in condensation, even in long lengths of steam piping. The coverings being almost indestructible will last practically as long as the boiler and piping.

For piping, patent spiral springs (2 ins. or more in diam.) are fixed about every 16 ins., and on these rest specially turned steel sheeting, the space between the piping and the sheeting being filled with 'Crown' slag wool, the whole being firmly bound together by bands at uniform distances. For boilers, steel bridges 3 ins. or 4 ins. high are fixed as saddles on the boiler at distances of 32 ins. from front to back, with short intermediate bridges; 'Crown' slag wool is then used to fill up the space level with the bridges, and covered with steel sheeting secured by strong brass screws to the bridges; any portion of the covering to boilers or piping can thus be removed and refixed with great facility.

Messrs. Sutcliffe Bros. & Bryce, Ltd., Park Works, Godley, near Manchester, are the sole makers of these coverings, as also of the 'Crown' Magnesia, 'Crown' Asbestos, and 'Crown' Telluric Cement Coverings.

Loss of Heat Conductivity.

The loss of heat conductivity in a boiler due to soot on the heating surface has been calculated at 9·5 per cent. for a layer of $\frac{1}{16}$ in. of soot, 26·2 per cent. for $\frac{1}{16}$ in. layer, 45·2 per cent. for $\frac{1}{8}$ in. layer, and 69·0 per cent. for $\frac{3}{16}$ in. layer.

Priming.

The most successful way of separating water carried along by steam is to cause the latter to impinge against a plate interposed at right angles to its course, so that it has to turn down and pass under the edge of the plate and continue its course on the other side.

Preventives of Scale.

As a result of experiment it is stated that $\frac{1}{10}$ in. of scale requires 16 per cent. more fuel to transmit a certain quantity of heat, that $\frac{1}{4}$ in. of scale requires 50 per cent. more fuel, and that $\frac{1}{2}$ in. of scale requires 150 per cent. more.

In regard to the increase in temperature of the plates as scale accumulates, all authorities are in agreement and practical experience confirms the fact. Stromeyer states that with clean plates the plate temperature is only 400° F., with a water temperature of 380°, when the usual quantities of heat per sq. ft. of heating surfaces are being transmitted. With $\frac{1}{4}$ in. of scale he states that the temperature of the plate may go up to 700° F., which, of course, may result in strains being set up which are highly dangerous. Especially is this so if deposits of oil in addition to scale are allowed to accumulate on the water side of the tube, and even a very thin coating of grease may result in the boiler furnace being brought down.

The loss of efficiency for a given thickness of scale will depend on the type of boiler and on the nature of the scale. In a Lancashire boiler the effect of a certain thickness of scale will be much less than with a water-tube or fire-tube boiler, nor will the resistance of a hard fine scale be the same as that of one having a soft porous nature.

Actual experience with Lancashire boilers in industrial concerns confirms the statement made by Stromeyer that, taking the boiler and economiser as a whole, the drop in efficiency will not be more than 5 per cent. with an average accumulation of $\frac{1}{8}$ in. thickness of scale. It will be found also that as the boiler becomes more scaled the outlet water from the economiser will increase in temperature, showing that this portion of the plant is absorbing the heat rejected by the unclean boiler surfaces.

With water-tube boilers in central station work it is a generally accepted figure that after a run of 1,000 hours the scale accumulation will have reduced the efficiency at least 10 to 12 per cent., even when fairly good feed-water is being used.

For sea-water a mixture of 1 part slaked lime to 3 parts soda, and for fresh water containing salts some organic compound, such as Harris's composition, should be placed in the boiler, about $\frac{1}{4}$ lb. per indicated horse-power per month. For muddy water, particularly if it contains salts of lime, no preventive of incrustation will prevail except filtration.

Dr. Joseph G. Rogers has proposed two methods of preventing boiler incrustation. One consists of introducing into the boiler a sufficient quantity of *sodium oxalate*, which converts the scale-forming impurities of the feed-water into insoluble oxalates as soon as they enter the boiler. These oxalates are precipitated as a mushy sediment, which has no tendency to form scale, and which may be blown out from the mud drum from time to time. The other consists in the use of *sodium tannate*, which is kept constantly present in the boiler in solution. It decomposes the calcium and magnesium carbonates as they enter, tannates being precipitated in a light, flocculent, amorphous form, which gradually accumulate in the mud drum, from which they may be readily blown out from time to time. The sodium carbonate formed in the reaction remains in solution, becoming bicarbonate by appropriation of the free carbonic acid in the water. This reacts upon the calcium sulphate, forming sodium sulphate and calcium carbonate, which latter in turn is acted on as above by fresh portions of the sodium tannate. The constant presence of the alkali protects the iron from any injurious action of the tannic acid. A similar reaction will take place between the tannate and the already-formed scale, though the action will be a gradual one.

When boilers are coated with a hard scale difficult to remove, it will be found that the addition of $\frac{1}{4}$ lb. caustic soda per horse-power and steaming for some hours, according to the thickness of the scale, just before cleaning, will greatly facilitate that operation, rendering the scale soft and loose. This should be done, if possible, when the boilers are not otherwise in use.

The chief engineer of a private plant in Brooklyn states that a mixture of graphite and caustic soda in the proportion of 50 ozs. to 30 lbs. has been found effective in preventing boiler scale. His conclusions have been drawn from experience with two 264 horse-power Babcock and Wilcox boilers operating at 110 lbs. pressure. The boilers are treated alternately, the mixture being fed gradually to one boiler, and during that time it is not blown down. The other unit, however, is blown off to 80 lbs. every morning.

Boilerine.

This is a viscous fluid, consisting chiefly of a carbon compound which has no action upon iron, steel, or other metals, but which has the property of rendering all water impurities innocuous and incapable of forming scale, while it also works its way through the interstice of

the scale, the rate of this percolation depending on the porosity and degree of compactness of the same, and when the preparation reaches the underlying plate of the boiler it there diffuses and insinuates itself behind the incrustation, causing it to crumble and flake, so that when the boiler is opened it can readily be removed. The preparation as a preventive of scale differs from the old style of boiler composition, inasmuch as it absorbs the gaseous carbonic anhydride from the water, forming an intermediate salt which throws the scale-forming salts out of solution, suspending them in the water in a non-crystallisable and powdery state. Incrustation is thus forestalled and prevented. Steam generated from sea water containing 'Boilerine' is free from ammonia. Boilerine is not only a preventive, but also a disuniter of incrustation in boilers; it is absolutely non-volatile, and does not affect the purity of the steam produced from water treated with it; it does not discolour the water in the boiler, and it will not cause priming. It is guaranteed free from arsenic, acids and poisonous substances, and is a neutraliser of grease and acids.

The boilers should be blown down and treated with Boilerine *daily*, as by this system greater efficiency is obtained. With average feed waters the cleaning out should be done at intervals not exceeding 150 to 300 hours for vertical and locotype boilers; 500 hours for watertube and marine dry-back boilers; 300 hours for the two bottom rows of tubes of Babcock boilers; 1,000 hours for Lancashire, Galloway, and Cornish boilers.

'FOLIAC' BOILER GRAPHITE.

(Graphite Products Ltd.)

The use of this material enables scale in a boiler to be easily and safely removed, a wire brush being used for the purpose. The graphite does not attack the metal of the boiler, nor, it is claimed, does it cause the metal to be attacked; it is not affected by any acid in the water or by the heat generated in the boiler. Particles of the graphite work through the minute fissures existing in the old scale and gradually penetrate between the scale and the metal. The scale thus loosened may be rapped off or removed with regular cleaning tools with little trouble. If the scale is very hard and thick it may require as long as three or four months for graphite to loosen it, but once removed the scale can never again adhere firmly to the metal as long as the graphite treatment is continued. The graphite also becomes thoroughly intermixed with new scale as it forms, rendering it soft and friable.

The graphite is introduced in the form of fine powder with the boiler feed, about half a pound being used per day for a 250 h.p. boiler.

Preventives of Corrosion.

The outsides of boilers should be well painted and lagged as a protection from moisture.

Ashes should never be cooled in the ashpits.

When the boiler is not at work, corrosion can be effectively prevented by filling quite full (to the top of a small filling pipe if necessary) with water in which soda (about 50 lbs. of common soda to 100 cubic feet of water) has been dissolved. A bright nail should be placed in sample to note if it rusts. No more soda need be used than will make the water alkaline.

In boilers using water over and over again from surface condensers extensive internal corrosion generally occurs. To prevent it, add soda to the feed sufficient to make the water alkaline in the boiler, and place rolled zinc plates in good metallic connection with the inside of boiler, under water, so that no part of the boiler is more than about 6 feet from zinc, and renew them when wasted.

It is of great importance that an analysis should be made of all feed waters and each case treated separately, so that the proper treatment may be determined.

A boiler at a chemical works at Derby was in 1911 dismantled after sixteen years' service for steam-raising purposes with the local water. The boiler was found to be in a perfect state of preservation, and had never required any repairs to the shell during the period named. The method of treatment adopted consisted in adding sufficient soda-ash to the feed-water daily to show faint alkalinity in the boiler, and to blow off daily 1 in. or 2 ins. of water containing the loose deposited salts in the form of mud from the lower blow-off cock. About 1 lb. of soda-ash per day sufficed to bring about this result.

THE CUMBERLAND ELECTROLYTIC PROCESS FOR PREVENTING SCALE AND CORROSION.

This process whilst primarily intended for the prevention of corrosion, when applied to boilers not only arrests corrosion, but owing to the mechanical action of the hydrogen given

off from the negative surface will loosen scale and precipitate it in the form of sludge, which is easily washed or blown out.

Where only the question of corrosion has to be dealt with in boilers, it is found that considerably less current is required than 1 amp. per 300 sq. ft.

One of H.M. cruisers having twelve Yarrow water-tube boilers, with a total heating surface of 49,500 sq. ft., or 4,125 sq. ft. per boiler, was fitted with the process, and it was found in actual practice that all corrosion was arrested and heating surfaces kept clear of scale by using about 1 amp. for 800 sq. ft. of heating surface. The anodes in these boilers consisted of two 7-ft. lengths of 3 ins. × ¾ in. bar iron, fitted in the steam drums of each slightly below the water level, and their life, it is estimated, will be considerably more than two years.

FEED-WATER SOFTENING.

Softening and Purifying Water for Boiler Purposes.

(W. H. Booth.)

To get over the difficulty of incrustation in boilers, the surface condenser as used at sea has been introduced into land practice. Condensed steam is practically free from all scale-forming salts, and as such cannot form scale, but between the feed-water pumped into a boiler and the water delivered by the air pump from the surface condenser there is a discrepancy of 5 per cent. more or less. This is compensated for by the addition of unsoftened water, and some little scale is still deposited in the boiler or in the economiser. Unfortunately, in its passage through the engine, the steam picks up the lubricating oil and carries it to the condenser, in which it is found in the form of an oil-water emulsion of such a perfection that no separation is completely possible by ordinary gravitation. Very fair separation is possible by increasing the gravitational effect by rotary whizzing as in a de Laval cream-separator. There is an electrical process by which the oil emulsion is made to coalesce in drops of a size that will separate out. Another process employs sulphate of alumina as a coagulant of the oil, which can then be removed by filtration. Wood wool, sawdust, finely broken coke, and cloths are variously employed for filtration purposes with fair success. The oil separation is often combined with a softening process introduced for the purpose of dealing with the 5 per cent. of make-up feed-water. But the surface condenser is not only costly ; it is liable, also, to scale and to become inefficient through the coating with scale or oil of its surface : it is apt to leak at its tube ends, and its repairs and maintenance are often considerable. It does not obviate softening if the make-up water is hard. For these and other reasons it would be wise to employ jet condensers in place of more costly surface condensers, and to soften the feed-water in place of removing oil from the water of the surface condenser discharge. Every case must be considered on its merits. Hard waters are rendered so by various salts of lime or magnesia, namely, the carbonates of both and the sulphate of lime. Carbonates are only soluble freely in water when they exist in the form of bicarbonate. Lime bicarbonate is known by the formula $CaCO_3 + CO_2$. The additional molecule of CO_2 may be driven off by boiling, and this explains why it so often happens that carbonate of lime is found to have passed through the economiser to be deposited thickly about the feed inlet of the boiler. Water hardened by carbonate of lime is said to be of temporary hardness only, implying that it will be rendered soft by boiling. Permanent hardness is caused by sulphate of lime, a salt which does not deposit until the water is heated to 400° F. But it will of course deposit from solution when concentrated beyond a certain percentage. In cold water calcium sulphate is soluble to the extent of 0·23 part per 100 of water. At 212° F. it is still soluble to the extent of 0·21 part. Lime carbonate is only soluble in cold water to the extent of 0·0036 part per 100 of water, or about 25 grains per gallon. Deprived of the presence of free CO_2 the solubility falls to only 2·1 grains per gallon, and this is the point down to which a carbonate water may in theory be softened. According to Taveau the solubility per 1,000 parts of water is 0·03 of lime carbonate free from CO_2 in excess, and 2·12 of sulphate at 34° C. down to 1·62 at 100° C.

Water containing iron in solution is obtained from some wells. The iron can be removed by aeration and deposit or filtration. When aerated under pressure the water will corrode iron badly, and should be heated before it is allowed inside a boiler. Heating drives off the air and removes the corrosive quality. It is not generally understood that oxygen is doubly as soluble in water as is nitrogen, so that the air dissolved in water is abnormally rich in oxygen. The iron exists as a carbonate in the form of FeO, CO_2. In addition to oxygen, caustic lime should be added, to absorb the carbonic acid which keeps the iron in solution, thus $FeO, CO_2 + CaO = FeO + CaCO_3$. Then to peroxidise the iron, air is forced into the water, when the following reaction takes place : $2(FeO) + O = Fe_2O_3$; this peroxide being quite insoluble. The process can be carried out at atmospheric pressure by first mixing the water with milk of lime and allowing it to fall through the air or over and through coke so as to expose it to air very fully. The oxide will settle out, after which the water can be passed through a sand filter. When carried out under pressure, particular care must be taken that the entry of the milk of lime is regular, a small quantity being pumped in with every few gallons. Without lime the residual iron may amount to 0·035 grain per gallon. With lime it may be reduced to 0·01, and this will no longer deposit rust after filtration. whereas with 0·035 the water will deposit down to 0·014 grain. The omission of lime

LIME.

The Purest Lime known in Commerce.

THE LARGEST OUTPUT OF LIME AND LIMESTONE IN THE WORLD.

'Old Buxton Lime'

Pure Limestone for Chemical Purposes

In Lump (any size) or Powder.

The Purest Lime for Chemical Work.

Special Trades Catered for Specially.

WHY do the leading Municipalities, Gas Engineers, and Metallurgists use ONLY 'Old Buxton Lime'? BECAUSE IT HAS NO EQUAL.

WHY does a ton of **'Old Buxton Lime'** go farther and give better results as a carrier and as a re-agent than a ton of any other Lime? **Because** of its high degree of **Purity** and its extraordinary property of **Diffusion.** Its intense activity and uniform action are not only due to its **Chemical Purity,** but also to its having a **Physical Character** possessed by no **other** Lime in the Market. To be had **only** from

The Buxton Lime Firms Co. Ltd., Buxton.

Telephone: 312 Buxton. *Telegraphic Address: 'Buxton Lime.'*

for a few minutes will cause trouble in the shape of a length of unlimed water in the main between two lengths of good water. The insufficiently treated water, when it mixes with the other, will in a few hours discolour the whole. An amount of iron only 0·02 per 70,000 will cause water in a tank to be turbid, yellow, and non-transparent. A final filtration through hard lump chalk will remove the last trace of iron and should, if possible, be applied as a safeguard against the occasional passage of insufficiently limed water.

Magnesium carbonate is a little more soluble than lime carbonate. Carbonate of lime may be almost entirely removed by the aid of caustic lime, while lime sulphate may be removed by carbonate of soda with the formation of very soluble soda sulphate as described under 'Hardness of Water.' Magnesia is not recommended for water containing even a feeble amount of chlorides, for hydrochloric acid may be produced and serious corrosion may ensue. This acid reaction is more liable to be produced at high temperatures, hence the fact that feed water good enough for low-pressure boilers may develop virulent corrosion in high-pressure boilers.

Since caustic soda will also destroy carbonate of lime with the formation of carbonate of soda, and carbonate of soda will destroy sulphate of lime, it follows that a water containing both carbonate and sulphate of lime will be purified by caustic soda instead of by caustic lime and carbonate of soda. This of course assumes that the two salts of lime are present in certain equivalents, or the difference must be equalised by a suitable addition of more carbonate of soda, if necessary to destroy more lime sulphate.

It is not probable that anything cheaper than caustic lime can be found for temporary hardness reduction, but no lime is needed if waste heat is properly applied to drive off the carbonic acid gas. Other salts used as softeners are silicate of soda, which gelatinises carbonate of lime and sets free CO_2, leaving carbonate of soda in the water to destroy its equivalent of lime sulphate if present. Oxalate of soda is good but costly, forming a very insoluble calcium oxalate. Oxalate of potash has a similar reaction ($K_2C_4O_8$).

There are many apparatus sold for the carrying out of the Clark process and its variants. One method is to use alternate tanks, weighing into one the correct weight of caustic lime or soda necessary, in a state of solution. The whole is well stirred and allowed to settle. Meantime the other tank of softened water is drawn upon for use.

In the continuous process the water is divided into two streams of a determined ratio, one of which is made to saturate itself with lime in a separate tank. The two streams are re-mixed and agitated and passed through settling tanks. A final filtration is often added, and in one process the hydrate of magnesia that may be left in the water is recarbonated by carbonic acid gas from a coke stove. This renders the water more palatable and prevents deposit of hydrates in pipes. Water fully charged with CO_2 will dissolve 70 grains per gallon of lime carbonate or 0·10 per cent., whereas distilled water will only dissolve 1·3 grain per gallon Caustic lime rapidly absorbs CO_2 from the air; it should be stored in tight metal receptacles.

All the reactions in softening are aided by heat, and some apparatus is specifically provided with heating pipes. Well water is more easily treated than river water. The latter contains organic matter, and precipitation will be helped by using a trace of alum. This coagulates the organic matter and hastens precipitation. In the testing of water for hardness certain standards are employed. Standard hard water is pure water to which has been added 1·11 gramme of fused calcium chloride per 1,000 c.c., or 1 gramme of pure lime carbonate is dissolved in HCl, evaporated to dryness, dissolved in 50 c.c. of water, and neutralised by ammonium hydrate. These solutions are, in brief, the equivalent of 1 gramme of carbonate of lime per litre, or 1 per 1,000. Standard soap solution is a solution of white curd soap in alcohol, 100 grammes of soap to 1,600 of alcohol with heat. The filtered solution is added to 1,000 of water; 22 parts of soap solution should neutralise 40 of standard hard water, that is, should just create a lather permanent for 10 minutes. The above is French.

English standard soap solution consists of 13 grammes of Castile soap dissolved in 500 c.c. of methylated spirits and 500 c.c. of pure water. 1 c.c. of this solution should neutralise 0·001 gramme of carbonate of lime or be equivalent to one degree of hardness. Thus a water of 20 degrees of hardness will call for 20 c.c. of standard solution per gallon. Laboratory tests of course involve much smaller quantities in test tubes only. Usually 12 c.c. of the water to be tested are diluted to 70 c.c., and the soap solution is added 1 c.c. at a time, and shaken until a five minutes' lather persists. Then if, say, 13 c.c. have been added, the water is said to be 12 degrees hard, for even pure water requires 1 c.c. of the solution to show a permanent lather.

Water from various sources varies in hardness from nil to above 114 degrees. A few samples have been taken from 19 to 114 degrees, and the cost of chemicals found to vary from 0·2*d.* to 4·2*d.* per 1,000 gallons, depending much on the ratio of lime to soda required.

As a guide to the value of softening, it may be added, one pound of lime will soften as much water as $4\frac{2}{3}$ lbs. of carbonate of soda or 17 lbs. of hard soap, the relative cost of the three reagents being 1 : 50 : 500.

Filters are charged variously with sponge, wood wool, cloths, crushed quartz, sand, broken coke, or sawdust, suitably packed.

Artesian waters from sand rocks are usually soft, those from limestone rocks or the red marls are hard. Superficial gravels often give hard waters, and the clay rocks, such as the lias, are often productive of hard water. Coal measures often give very bad water, even from sandy strata. Ancient rocks such as granite yield soft supplies, and the moorlands of the north country, being chiefly of millstone grit, yield remarkably soft water. Chalk yields hard water, but where covered with London clay the hardness is very much reduced, often falling to 6 degrees.

Water Softening by Means of Zeolytic Exchange Process.

('Permutit' Process—United Water Softeners, Ltd.)

The 'Permutit' system comprises filtration through a bed of granular material of pearl-like appearance, which is employed in a granular state and which has the property of giving up its sodium base to any water which is flowed through it, in exchange for any calcium or magnesium contained in the water.

This action takes place irrespective of whether the calcium or magnesium in the water is in the form of carbonate or sulphate, i.e. quite independent of whether the hardness is temporary or permanent.

Such a method affords a means of presenting to the hard water a large supply of the softening element in readiness to be drawn upon by the water itself in exact proportion to its quantity and hardness; in other words, Permutit contains, in large excess, the active softening element, which however is effective in precisely the degree required to completely effect the softening of the water, and no more.

This action continues for so long as there remains in the Permutit active material (sodium) available for exchange; the total softening capacity of Permutit being represented by the multiple of the hardness and the quantity of any water, so soon as this quantity of water of the specified hardness has passed through the bed of Permutit, the sodium will become replaced by calcium or magnesium (or both), extracted from the water; thereafter, no further effect takes place either in respect of the Permutit, or of any further water passed through it. A fresh charge of the sodium is then transferred to the Permutit by flowing through it a weak solution of common salt (NaCl), when a similar exchange action takes place."

In this stage revivifying, or in its technical term 'regeneration,' takes place, by an exactly similar process. The bases of the hard salts (calcium or magnesium) are replaced in the Permutit by the sodium contained in the salt solution; and the calcium and magnesium combine with the chlorine of the salt forming the chlorides of these bases, which as a clear liquor may be run into any drain. Any slight excess of salt solution remaining amongst the granular particles of the Permutit after complete regeneration has been effected is washed out by a short rinse with clean water.

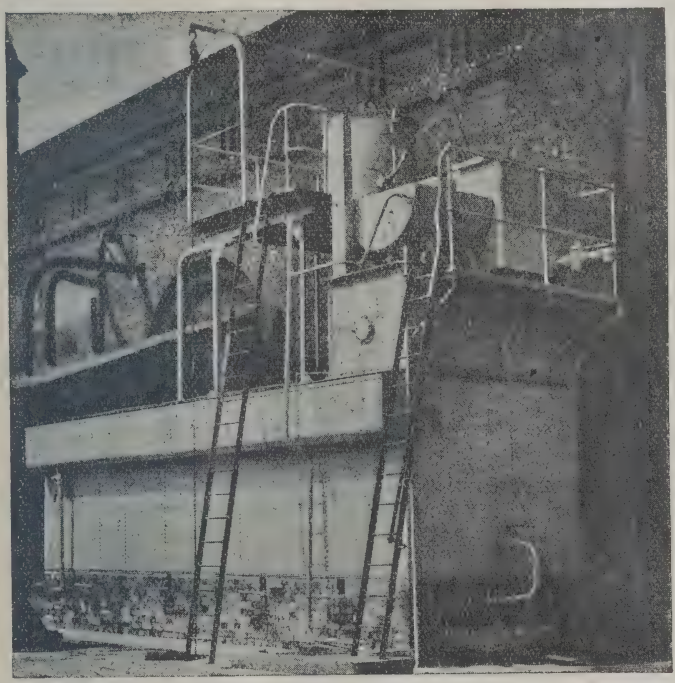
A complete cycle of operations has then been completed, when hard water can again be passed through the filter, softening being complete as before, and continuing until the maximum quantity for which the filter is designed has again been treated.

During this to-and-fro softening action, the Permutit itself suffers no damage or wastage, it being merely a vehicle for the zeolytic exchange action which is the peculiar property of the substance. There is, therefore, afforded an extremely simple, though entirely scientific means for completely softening water of any hardness without any deposit of solid matter; any necessity for settlement and subsequent sludging away of precipitates, as was the case in the previous lime and soda systems, is thus completely obviated.

Another important feature attaching to the 'Permutit' system is the valuable means which it affords for treating water as it passes through the mains under pressure; and it has thereby become possible to treat any supply for industrial or domestic purposes as it enters the building in which it will be used, and to deliver the same in a completely softened condition to storage tanks in the top of the building, without any break in the pressure or consequent necessity for repumping.

The process is equally effective when operated cold. Running expense depends mainly upon the relative local cost of lime and salt, or soda and salt according as the hardness in the water is principally temporary or permanent. Elimination of any necessity for repumping, as also for the removal of sludge constituting the by-product of the lime-soda treatment, are, however, features which considerably affect the relative running costs of the two methods of treatment; and in a large number of cases these compensate for any advantage which may exist in favour of the lower price of lime than that of salt in any particular locality.

Absolute uniformity in the final water, as well as elimination of any necessity for skilled control of the treatment by a chemist, are also features of importance attaching to the Permutit system.



In cases where temporary hardness preponderates heavily, and the difference in cost of lime and salt is also in favour of the lime treatment, a Permutit filter may with advantage be arranged to supplement a preliminary lime treatment.

Elimination of Iron and Manganese from Water Supplies.

By means of a special type of Permutit, prepared and oxydised by the use of manganese salts and permanganate, all traces of iron and manganese can be eradicated from a water supply the treatment being effected under pressure and without calling for any extra pumping.

Large installations for some of the leading public water supplies throughout Europe have been laid down with conspicuous ssucess for this purpose, as well as for the softening of the water as above described.

The Permutit system constitutes practically the only one of certainty and success for the removal of manganese.

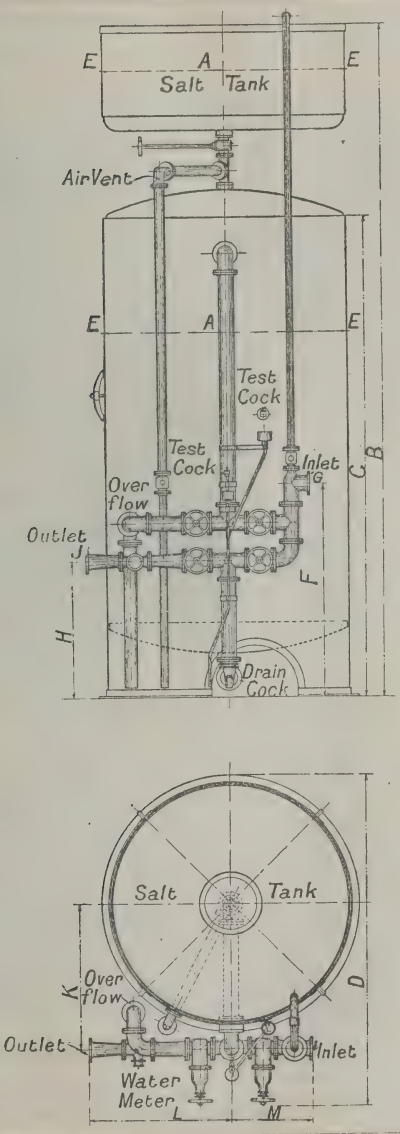

FIG. 19. PERMUTIT WATER SOFTENER.

General Design of Permutit Plant.

The type of plant utilised for effecting Permutit treatment of water is of a standard design, and is shown by fig. 19, page 1445.

A mild steel cylinder of such proportions as are requisite accommodates the proper quantity of Permutit.

Provision is made by means of suitable pipe connections and valves for agitating the Permutit bed by means of a flow in the opposite direction to that of filtration. By this means any uneven action due to air pockets or channels in the bed of the Permutit is prevented.

In the case of single units, the filter carries above it a shallow tank for dissolving the salt for regeneration—which is usually arranged to be effected once in each day.

In the case, however, of multiple-unit plants, these overhead salt tanks are dispensed with : and a common tank in steel or ferro-concrete provided, in which the salt solution is made up for the entire battery of the filters.

A complete plant of this description is in operation for both iron removal and softening at the Hooton Pumping Station of the West Cheshire Water Company.

Plants upon similar lines have been installed by a very large number of the leading industrial concerns both in England and on the Continent, as also by the Municipalities of Breslau, Dresden, and other leading cities.

For ' Lassen-Hjort ' Patent Water Softening system, see page 1450.

The Kennicott Type ' K ' Water Softener.

(Kennicott Water Softener Co., Wolverhampton.)

The Kennicott Type ' K ' Plant is so designed as to be very simple to operate, and at the same time extremely accurate. The plant is absolutely positive in its action, and there are no oscillating parts to get out of order, and no valves or cups to get made up with lime. Fig. 20 shows the general construction of the plant, the action of which is as follows :—

The calculated quantity of chemicals required for a day's supply are run into the chemical tank B, which is filled to a definite level. The hard water enters the plant by way of the pipe E into the hard-water box F, whence it flows through an adjustable slot over the water wheel D and out of the chute G at the bottom of the water wheel casing into the top of the downtake H. The incoming water, passing over a water wheel, provides all the power required for operating the plant. It drives the main shaft, and this shaft drives two vertical shafts, one in the downtake and the other in the chemical tank B. The shaft in the chemical tank B has a 4-bladed agitator at the bottom, and this keeps the chemicals constantly and homogeneously mixed. The shaft in the downtake has an agitator fixed to it, and this ensures that the chemicals added are thoroughly mixed with the water, a most essential feature. In order to proportion the chemicals, a small quantity of hard water from the hard-water box F is bye-passed to the dividing box I, where the small quantity of bye-passed water is divided, a portion running into the regulating tank K, and the rest down the drain. The dividing box is set so that the amount of water run into the tank K fills up this tank in a definite number of hours, generally sufficient for a day's run, and as this tank fills, the float riding on the water in this tank gradually rises and at the same time lowers the weir L in the chemical tank B, the float in the tank K being connected with the weir in the tank B by means of a flexible cable passing over two pulleys. It will thus be seen that the chemicals are added in an absolutely definite proportion to the quantity of water entering the plant. Immediately the chemicals come into contact with the water, the whole is thoroughly mixed by means of the mechanical agitator in the downtake, and the water passes down to the bottom of the downtake H, and finally flows upwards in the direction of the arrows, at a very slow rate, and is finally filtered at the top of the plant.

Any mud contained in the water, and the bulk of the precipitated hardening salts, settle on the bottom, and it is very necessary that this sludge should not be allowed to accumulate, otherwise the moving water will very quickly wash it up into the filter. By means of the *Kennicott Patent Revolving Sludging Gear*, however, the whole of the sludge settled on the bottom can be removed, the action of the sludging gear being very similar to a vacuum cleaner.

No Kennicott plant is made with less than three hours' settling, this being the minimum time that should be allowed for the complete precipitation of the hardening salts. With all Kennicott plants the mixing tank A is supplied. This tank is sufficiently large to hold a full day's supply of chemicals, so there is always a charge in readiness when the proportioning tank B is empty.

As the main tank always stands full of water, the clear soft treated water discharges from the overflow at the side of the main tank at a point above the filter as fast as the water to be treated enters the top of the downtake ' H.'

The machine is continuous and wholly automatic in its operation. The flow of the water furnishes all the power necessary for mixing the chemical reagents with the water and for operating the mechanism.

KENNICOTT TYPE 'K' WATER SOFTENER.

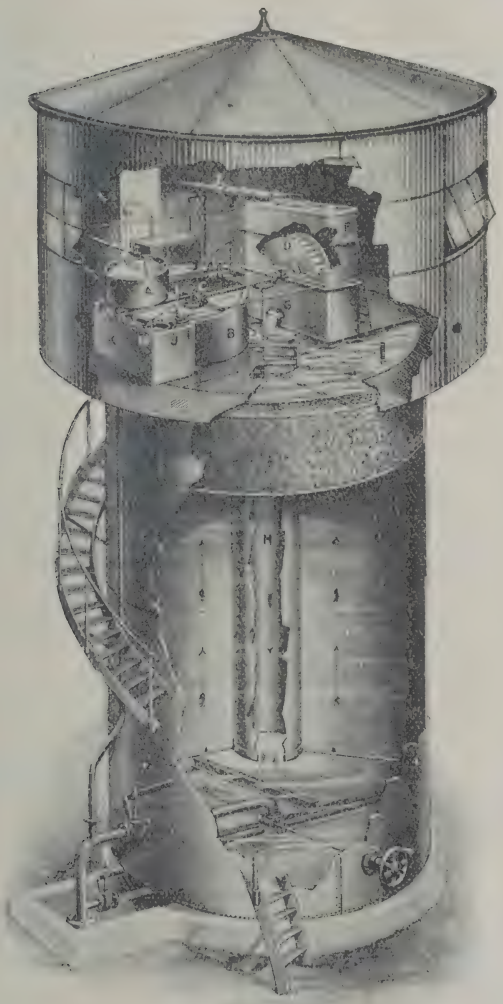

FIG. 20.

Every installation is designed for the work it has to perform, and to suit the site it must occupy. The chamber can be made either cylindrical or rectangular in shape. When a supply of exhaust steam is available, great economy can be obtained by installing a Kennicott Patent Type 'K' combined Heater and Softener.

The operation of this type of plant is exactly similar to the Kennicott Cold Water Softener described above. In addition to the chemical proportioning gear, there is fitted a very substantial heater, fitted with removable trays, over which the water passes. Steam is admitted at the bottom of this heater after passing through an oil separator, and passes upwards through the water. This raises it to boiling point, a considerable proportion of the hardening salts being at the same time deposited in the trays, which are from time to time removed for cleaning purposes. Practically the whole of the hardness originally present in the water is by this system removed, and at the same time a soft feed water of high temperature is available for boiler purposes.

Plants of the latest Type 'K' design of all sizes from 500 to 150,000 gallons per hour capacity are actually in operation.

The Royles Automatic Water Softener and Purifier.

(*Reisert System.*)

In this apparatus, fig. 21, p. 1449 (*Royles, Ltd., Irlam, near Manchester*), the bicarbonate of lime is precipitated by hydrate of lime (lime water), and the sulphate of lime by soda. The softened water is then filtered and discharged.

The apparatus, which acts entirely automatically, consists essentially of an automatic lime saturator and decanter B, a soda chamber D, a water-distributing tank E with a lime-slaking division A and soda-mixing division C, a reaction chamber F, and an automatic self-cleansing filter K.

The *Lime Saturator* B requires no stirring contrivance, and lixiviates the lime completely; and owing to its upward widening shape, it turns the saturated lime water into a clear fluid.

By a constantly uniform water supply through the micrometer valve 3 from the distributing tank E, which is conducted dnwaowrds through the central pipe O, the lime paste at the bottom is stirred up and thoroughly impregnated, and rises, at first partly with the water, until the rapidity of the rising water diminishes so much, owing to the upward widening shape of the saturator, that the undissolved lime particles are no longer able to follow, so that the saturated lime-water, clarified, then leaves the saturator B at the top, and is carried into the reaction chamber F by way of the mixing pipe E^1.

As lime possesses the property of dissolving in a definite proportion in water until the latter is saturated, it is possible to continually keep a uniform stream of saturated lime-water supplied as required, for the precipitation of bicarbonates of lime and magnesia. Upon this uniform addition of lime depends the degree of purification of the water.

In the *Soda Apparatus* D, a quantity of soda (which unlike lime, is very soluble), one gallon of water at 60° F. dissolving up to 1¼ lb. of dry sodium carbonate that will suffice for one of more days, is dissolved in the chamber C and let down into D through cock Q.

The action of the soda apparatus is based on the fact of the soda solution having a greater specific gravity than water, and thus the water flowing from the distributing tank E through the small micrometer valve 1—which is adjusted in accordance with the amount of soda required—into the soda chamber D, remains always on the surface of the soda solution (no mixing taking place), and displaces the same, it being carried through the small pipe from the bottom upwards, and into the mixing pipe E^1, and finally into the reaction chamber F.

The water-distributing tank, E, is supplied with the hard water to be treated, by pipe and cock as shown; it is also provided with an overflow pipe.

It is further provided with three micrometer valves at an equal height, viz.—(1) for the supply to soda tank; (2) for the supply of untreated water to the reaction chamber; and (3) for the supply to the lime saturator B. By arranging these three valves at an equal height the quantities of water flowing from them are always proportionate in the event of less water being supplied to the apparatus than corresponds to the capacity; or in the event of the water supply ceasing altogether, they cease simultaneously.

A *Lime-Slaking Division*, A, is arranged in the distributing tank. In it, once a day, the required quantity of lime is slaked by means of a supply of water obtained from the water inlet pipe. The lime paste is then conveyed in bulk to the bottom of the lime saturator B, through the short depending pipe illustrated, by opening cock R. The *Reaction Chamber* F thus received through the mixing pipe E^1, the untreated water, lime-water, and soda-water, which remain in this chamber until the chemical reactions have been accomplished.

The continuous inflow of the water and chemicals above described overflows *via* the pipe J into the filter chamber K, following the course of the arrows downward through the filter bed and upwards through pipe S into the tank L, the rest flowing away, at M, to reserve or for use. The height of the column of water in the pipe J will vary with the resistance of the filter bed, and as the latter fouls, the water will rise higher and higher in J.

Similarly it will rise to an equal and corresponding height in the syphon pipe L^1, and as soon as the resistance through the filter bed reaches such a point as to cause the water to over-

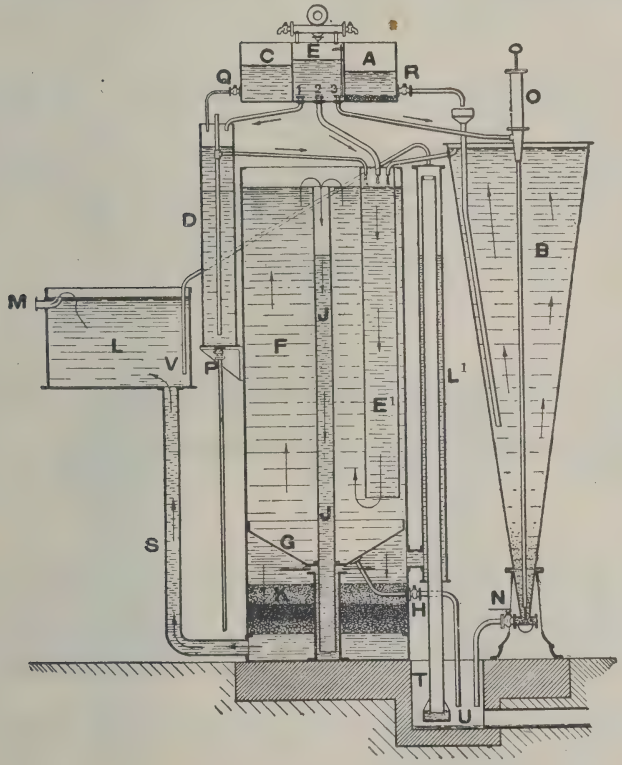

FIG. 21.

flow this pipe, it forms a syphon and instantly reverses the current through the filter bed, drawing backwards the clear water held in the small tank L, thus thoroughly and automatically cleansing the filter, the sediment being discharged at T into the gully U. The small tank L is proportioned to hold sufficient water to thoroughly flush the filter K, and as soon as the tank is empty air enters *via* the pipe V, and destroys the syphonic action.

The filter then resumes its normal working, and so continues until the fouling is again such as to cause the pipe L to overflow, when the cleansing action is repeated. The loss of water in reflushing is very trivial. The filtering material rarely requires renewal.

The Lassen-Hjort Water Softening and Purifying Plant.

(United Water Softeners Ltd.)

A special feature of the Lassen-Hjort patent automatic water softener, fig. 22, is the device it embodies for the separate and exact measurement, in small, absolutely definite, and predetermined quantities, of both hard water and softening reagents. This device (termed the Lassen-Hjort patent measuring apparatus) renders it possible to treat water or effluents of any character with any reagent or combination of reagents, in rigidly proportionate quantities, which can be varied at will and adjusted with the utmost precision.

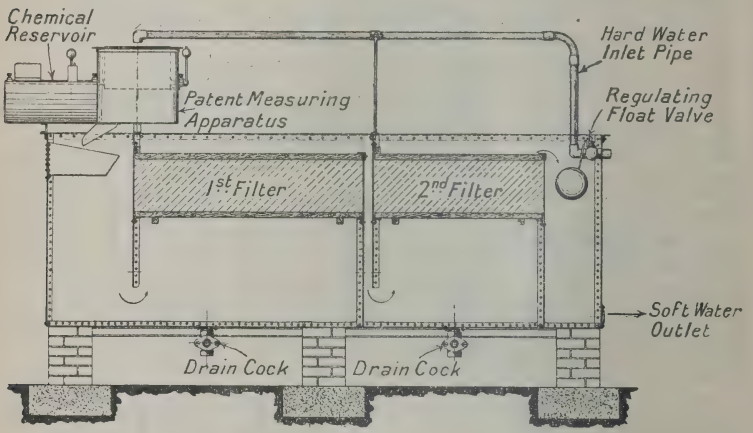

Fig. 22.

The hard water to be softened is ed into the plant by a pipe which alternately fills each of the compartments of a two-chambered tipper oscillating on a shaft carried in bearings. When one of these compartments is full of water the disturbance of equilibrium causes the tipper to over-balance, and, by doing so, to discharge its contents of water into the tank in which it is suspended : at the same time the other compartment of the tipper is brought under the orifice of the inlet pipe and filled in its turn with hard water, to be discharged in the same manner when full. A counter affixed to the tipper shaft registers the number of oscillations, so that the quantity of hard water to be treated is thereby accurately measured.

An important feature of the apparatus is the recently introduced patent locking gear, by means of which the oscillating receiver is prevented from tipping until it contains a predetermined quantity of water. This ensures absolute precision in the measurement and delivery of the water to be softened.

The apparatus, fitted with this locking gear, has been tested as a water meter pure and simple, at the National Physical Laboratory, Teddington, and certified to be correct within 1 per cent.

At each discharge of water from the tipper into the tank in which it works, a corresponding amount of water is displaced from this tank through a standpipe and shoot into the reaction chamber of the softener, and here it receives at the same moment the requisite charge of chemical solution from the semi-circular chemical container affixed to the side of the tipper tank. This is effected by means of a 'positive discharge valve' (patented) placed in the bottom of the chemical container, which is opened at each movement of the tipper, and caused to deliver into the reaction chamber the exact amount of softening reagent (in the majority of cases a mixture of lime and soda ash) required to soften it to the guaranteed figure.

The valve can be adjusted (with great ease and over a wide range) to discharge any specified quantity of reagent required by the volume of water in the tipper compartment, so that the plant can be easily regulated while working without any necessity for altering the strength of the chemicals or changing the solution in the container. The precision with which the chemicals and water are measured and mixed makes for speedy completion of the reaction.

A special feature of the tipper gear is the fact that all the working parts are in sight, whilst the whole gear is simpler (it is claimed) than that of any other water softener plant in use.

The average results obtained with the Lassen-Hjort plants show a hardness of the water after treatment of 2° Clark, while the residual alkalinity (i.e. excess of lime and soda remaining in the water after the conclusion of the softening process) averages only 1·5 grain per gallon, or one and a half parts in 70,000 parts by weight, i.e. practically no excess of alkalinity.

The plant being primarily designed for adding lime automatically to water in exactly measured quantities, is very suitable for carrying out the Houston 'excess lime' process of water sterilisation.

The Lassen-Hjort process has been adopted by Messrs. Babcock & Wilcox, who supply it throughout the world under license from the makers.

Over 6,000 Lassen-Hjort plants are at present in use.

See also 'Purification of Boiler-Feed Water,' No. 4, 1921, *Proceedings Inst. Mech. Engrs.*

THE ROW FEED-WATER HEATER.

FIG. 23.

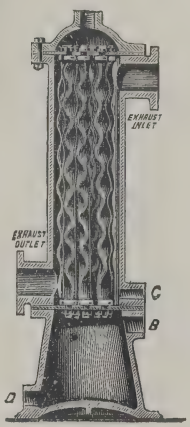

FIG. 24.

In Row's Patent Feed-Water Heater, figs. 23 and 24 *Royles, Ltd., Irlam, near Manchester*), a peculiar form of indented tube is used, which it is claimed is *twice as efficient as an equal amount of plain tube surface*, giving great *compactness* and *efficiency*. The tube is also elastic in the direction of its length, thus avoiding liability of fracture or breakage when fixed between tube plates.

The Heater (fig. 24) shown is intended for good water—i.e. water not liable to scale—in which case the water is sent *through* the patent tubes. For bad water the order is reversed, i.e. the exhaust is sent through the tubes and the water circulates in the casing.

FEED-WATER REGULATORS.

THE CROSBY PATENT FEED-WATER REGULATOR.

The action of this regulator (*The Crosby Valve and Engineering Co. Ltd.*, 41–42 *Foley Street, London, W.* 1) is in no way dependent upon the rising and falling of a float, and there are very few parts which are liable to give trouble and so to cause the apparatus to work in an erratic manner.

In fig. 25, A is a chamber which is put into communication with the steam space of the boiler, the steam being led in through the pipe H. A pipe L also puts the chamber in connection with the boiler, but in this case with the water space. If, for example, the apparatus is fitted to a Babcock boiler it might be placed at the side of the drum, so that the top of the chamber A is in line with the required water level. If the pipe L be then connected to the drum G, about 12 ins. below the water line, and the pipe H to the top of the drum, the level of the water in the chamber A will be dependent upon the level of the water in the boiler. When the water in the boiler rises, that in the chamber A will rise, and when this chamber is full of water steam will be prevented from entering from the pipe H. When the water in the boiler falls it will also fall in the chamber A and steam can enter, which causes an immediate rise in pressure in the system above the chamber A.

The part of the apparatus above the chamber A is partly filled with water and is connected to the chamber M of a regulating valve by the pipe O which acts as a cold water column. When the apparatus is used for regulating the supply of water to boilers working on a common steam main, the double-beat balanced valve T is connected in circuit with the feed pipe, each boiler being provided with one of these regulating valves. Where there is only one boiler, however, the valve T can be made to control the supply of steam to the feed pump, the latter automatically starting and stopping according to the slight variations in the water level.

There is a diaphragm in the chamber M, this being connected to the double-beat balanced valve by means of a spindle. When the water level in the boiler falls, the pressure formed in the apparatus as described below is exerted on the diaphragm, causing the valve to open against the action of the spring. When, however, the water rises, this pressure falls and the spring causes the valve to close, thus shutting off the supply of water to the boiler.

When the apparatus is first put into use, both the cocks on the boiler are closed, so that neither steam nor water can enter the chamber A. The air valve B is removed, and water is poured in. At the same time the union, or plug, on the diaphragm chamber is loosened, in order to enable the water to drive out the air in the pipe connecting the two pieces of apparatus. This having been done, the union on the chamber M is again tightened up, and more water is poured into the chamber at B when the air valve is closed. Steam from the boiler is then admitted under the partition G and the water in the system above is boiled up, the air valve B being loosened to let the air escape. This process is repeated several times, and on each occasion the apparatus is allowed to cool. In this way a vacuum is created in the apparatus above the partition G, and when a gauge to the left of the upper chamber registers a vacuum of at least

10 ins. the device is ready for use. The gauge serves for registering both pressure and vacuum, the latter being to the left of the zero mark and the former to the right of it.

The vacuum having been obtained, the two cocks on the boiler are opened, and the device commences to work. When the water in the boiler falls and steam is admitted to the chamber A through the pipe H, the heat of the steam is transmitted through the plate G. This heat boils the water in the chamber D. The pressure of the steam so generated, acting on the surface of the water in the top chamber, gives rise to a pressure above the diaphragm in the chamber M. This diaphragm is depressed, and the valve (which is in a battery of boilers arranged in the feed-pipe to each boiler) is opened, a supply of feed-water is admitted to the boiler, and in this way the water level is raised. As the water rises in the drum of the boiler, it also rises in the chamber A, and when the proper level in the boiler has been reached, steam ceases to enter from H. The chamber A then contains nothing but water. Under these conditions the water in the chamber D is no longer evaporated, and the steam condenses, the pressure in the top chamber consequently falls, and the valve closes. The supply to this particular boiler then ceases for

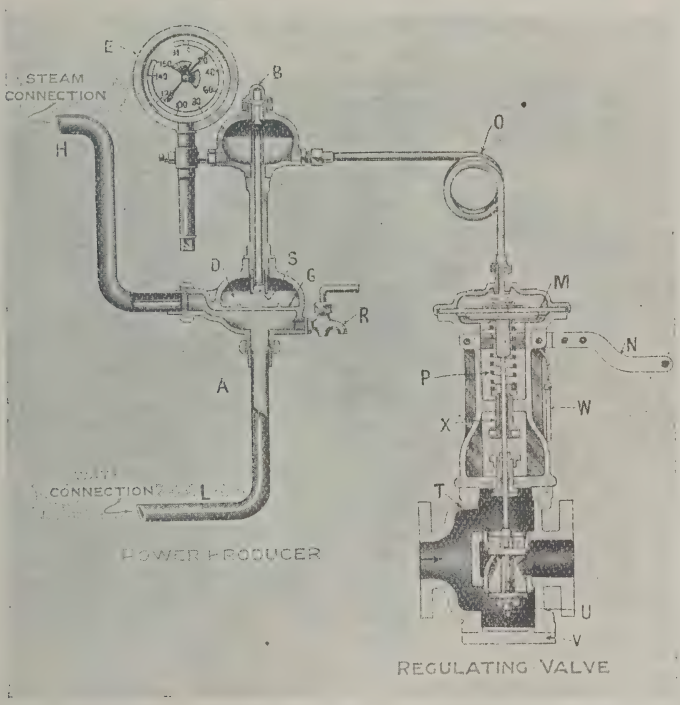

FIG. 25.

the time being. The pressure gauge indicates whether the apparatus is working properly, and in this way the stoker is provided with a means of guarding against low water even should the device get out of order, which, however, is not at all likely to occur.

When the apparatus is working properly the pressure rises and falls slightly in accordance with the fluctuations in level in the boiler, opening the regulating valve wider or allowing it to close, thus increasing or reducing the feed supply to the boiler. It does not constantly open and shut, but regulates the feed so as to keep the water level constant within close limits. A lever is provided on the regulating valve for testing its operation or to keep the valve open if desired and an adjustable device is provided to keep the valve always open a limited amount if required

The principal advantages claimed for the apparatus are the following:—(1) It enables a lower water level to be maintained with perfect safety, thus increasing the steam space in the boiler and ensuring a supply of dry steam; (2) it reduces coal consumption by reason of maintaining a regular feed proportionate to the evaporation of the boiler; and (3) it ensures a greater regularity in the steam-raising, and so tends to prevent fluctuations in the pressure. (4) It will work continuously without requiring attention or repair.

The Warner Hydraulic Automatic Feed-water Regulator.

(Patent.

With this regulator (*Robert Warner & Co.* (*Engineers*), *Ltd.*, 14–16 *Cockspur Street, London, S.W.*), which is shown fitted to the drum of a water-tube boiler, fig. 26, no additional valve

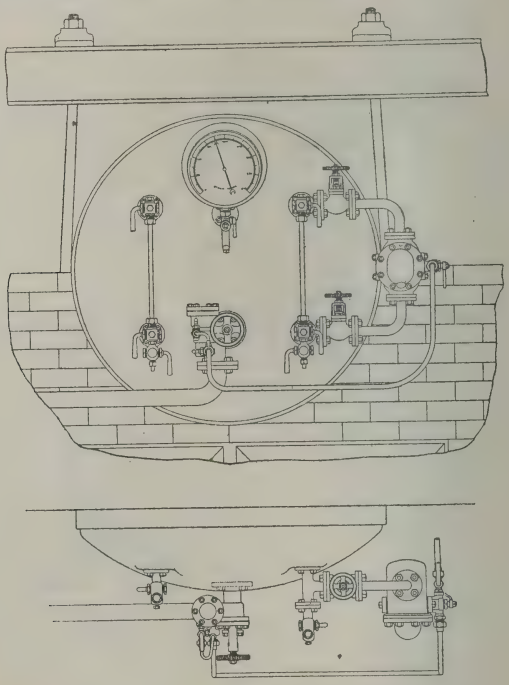

FIG. 26.

for regulating the feed water admission to the boiler is used, but the boiler check valve itself is made to do its own throttling and opening automatically. To the underside of the valve is attached a small piston working in a cylinder, and a definite amount of water is by-passed into a space underneath it.

The way the valve operates is as follows:—The feed water is delivered from the pump as usual underneath the check valve and above the small piston. The pressure exerted by the feed water therefore acts both ways, viz., up and down, while at the same time the pressure in the boiler is holding the valve shut, and the pump cannot lift the check valve, which remains closed. But a small quantity of water is continuously passing to the space underneath the piston. As long as this is allowed to escape, the check valve remains closed. If, however, it is prevented, from escaping, the water instantly fills the space and exerts the same pressure underneath the

F. 1455

piston as above it; the piston therefore becomes balanced and inoperative, and the feed water pressure raises the check valve, and the pump forces water into the boiler in the usual manner. As soon as the water is allowed to escape from the space, the check valve again closes and stops the pump. The control of the escape of the water from the space therefore constitutes a complete hydraulic control of the check valve.

By this system, instead of its being necessary to control the whole of the water entering the boiler, it is only necessary to control the small quantity passing to the underside of the piston, or about one per cent. of the total feed.

The space below the balance piston is connected by means of a pipe to the control valve situated on the side of the control box. The control box is connected to the boiler in any convenient manner which ensures the same water level in the control box as in the boiler.

The control box contains a displacement float which rises and falls with the water level in the boiler; the float operates the control valve, which controls the by-pass water.

The control valve proper is a semi-rotary barrel valve of such design as to eliminate the danger of jamming up by accumulation of scale.

As the water level in the boiler rises, the float rises and opens the control valve, thus allowing the water under the balance piston to escape. Consequently, the check valve closes. Conversely, as the water level falls, the float also falls, closes the control valve, thus preventing the escape of the water from the underside of the balance piston. It will be seen, therefore, that the piston being balanced, the pressure exerted by the feed pump will raise the check valve and water enters the boiler in the usual manner.

Suitable levelling valves are provided with the control box, and by closing these valves, the whole of the working parts may be taken out and examined whilst under steam, and without stopping the feed.

Provision is made for varying the water level above or below the normal working level, should this at any time be considered desirable.

STEAM REGULATORS.

The Hulburd 'Servo' Patent Regulator.

This regulator, fig. 27 (*The Hulburd Engineering Co. Ltd.*), consists of a single-seated main valve C, formed with a cylindrical throttle valve extension D on its outlet side and a piston on its steam side, containing an auxiliary relief or balancing valve K, which terminates in a slender conical plug and is attached to the valve spindle E. There is no direct connection between the valve spindle and the main valve. The piston, which is rendered steam-tight by an ordinary piston ring, works in a cylindrical extension of the valve casing, forming with it a balancing chamber A. This balancing chamber is in permanent communication, by means of the small hole P in the valve casing cover, with the boiler, and is thus kept under steam pressure, which so long as the auxiliary valve K is closed presses the main valve firmly against its seat S. The regulator is operated by drawing the balancing valve K from its seat within the main valve, thus allowing steam from the chamber A to escape past its conical point until the rate of flow out of the chamber past the valve K is in excess of the steam supply to it through the orifice P, and the pressure in A is thereby reduced. When the pressure in A is thus reduced to a certain point it is insufficient to keep the main valve closed against the steam pressure constantly exerted in an opposite direction on the other or valve side of the piston; the piston, therefore, is forced inwards into its cylinder and draws with it the main valve from its seat. The main valve now takes up a definite position in relation to the auxiliary balancing valve, and so adjusts itself with regard to it that the outflow of steam from A past the small valve K exactly equals the supply admitted through the passage P, which is in permanent communication with the boiler. The main valve, in fact, may now be said to float upon the steam, and in this condition responds instantly to the slightest movement of the auxiliary valve and spindle. When the auxiliary valve is at rest in any given position, the main valve is rigidly held by the steam in that position, and if the auxiliary valve is advanced or withdrawn, the main valve follows it as though the two were one, automatically re-establishing the condition that inflow and outflow of steam in A are equal, without the slightest indication of oscillation or 'hunting.' Indeed, so sensitive and absolute is the control afforded that, as has been demonstrated by experiment, a driver is able to raise his steam chest pressure at will, and with the greatest certainty, by regular increments of

2 lbs. throughout the whole range of pressure. The effort required to manipulate even the largest valve on this system is altogether insignificant, for the auxiliary valve, which is the only one to be moved by hand against steam pressure, does not in any case much exceed one inch in diameter; and the steam itself supplies the necessary power to move the main valve, being set in operation and controlled by the auxiliary valve acting as a sort of relay, so that the least possible exertion is necessary on the part of the driver, who has, in fact, only the friction of the working parts to overcome, and thus is able with a touch to keep his regulator absolutely under control. *It is important to note that the main valve does not in any position exert the slightest pull on the spindle, there being no mechanical connection whatever between the two.*

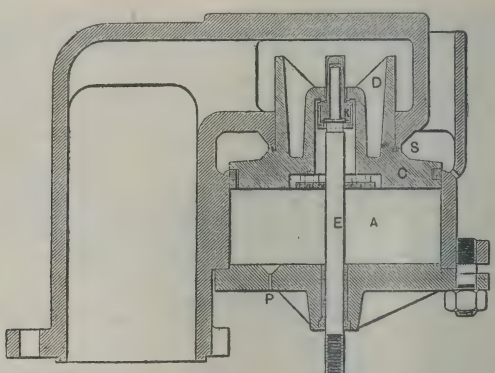

FIG. 27.

The special construction of the valve seat and face is such that the faces are protected by a projecting lip or edge from the cutting action of steam at high velocity at the moment of opening or closing. The design of the throttle valve also prevents any appreciable rush of steam past the main valve faces before they are separated by a considerable interval.

The 'Servo' Regulator forms part of the standard equipment on many leading railways. The principle is also adapted to valves for stationary use, such as winding, hauling, etc., and for marine purposes where a variable speed is required; in such cases it gives excellent results.

OIL SEPARATORS.

Lubricating oil, if allowed to pass into boiler feed-water, constitutes a danger to boilers so serious that means for its separation and removal are now invariably insisted upon by insurance companies. The method generally employed is that of the mechanical separation and extraction of oil and grease from the exhaust steam before it enters the condenser.

The fitting of high-pressure boilers with superheaters has increased the difficulty of the removal of the oil, while rendering the necessity of the complete separation all the more imperative.

For *small* quantities of greasy water, finely-broken coke placed in a perforated-bottom pail and hung below the greasy drip of an exhaust pipe has been found efficient in separating oil.

THE 'BAKER' PATENT OIL SEPARATOR FOR EXHAUST STEAM.

(*Bakers* (*Leeds*), *Ltd.*, *Hunslet, Leeds.*)

This separator is designed to eliminate the lubricating oil from the exhaust steam of all classes of reciprocating engines, it being immaterial whether such engines are exhausting into l.p. turbines, condensers, or heating installations. The steam is cleansed to such a degree that the condensate may be used for boiler feeding or manufacturing purposes without further treatment, a recent analysis of a sample of condensed steam after passing through a 'Baker'

A FEW REASONS WHY

WE CLAIM THAT

THE BAKER OIL SEPARATOR

FOR EXHAUST STEAM

IS THE BEST

We have specialised in this class of apparatus for 26 years and are in possession of exclusive information.

We have made it our business to watch the working of each apparatus supplied and have from time to time improved our designs with the result that we can guarantee maximum efficiency.

We calculate the capacities of our Separators in accordance with the properties of the steam to be dealt with and not merely to fit into a certain size of exhaust pipe.

We can invariably refer you to apparatus in operation in your district, so that you may prove our claims to your own satisfaction.

We are the original Patentees and Manufacturers and can quote competitive prices for apparatus to fit into new or existing installations.

And remember there is a type of

'SKATOSKALO'

For every Scaling Purpose.

F. 1457

Patent Oil Separator showing ·03 grain of oil per gallon of condensate, which is equivalent to one part of oil in 2,330,000 parts of condensate. Such results as this can be obtained without any expenditure on the separator in upkeep and attention.

For the larger installations the makers claim that a very considerable saving in oil can be shown, as from 50 per cent. to 75 per cent. of the lubricating oil can be recovered and rendered suitable for use again after passing through the special oil filter which they make for the purpose.

BOILER CLEANERS.

The Hulburd Mechanical Boiler Cleaner.

Excellent results have been obtained with the Hulburd mechanical boiler cleaners, apparatus which, although suitable for all classes of boilers, are especially recommended for locomotives, in which reduced efficiency of the heating surfaces, due to formation of scale and obstruction of the water spaces by accumulations of deposit, are above all things to be prevented if possible.

As almost invariably fitted, the cleaners, fig. 28, consist essentially of two portions; one in the boiler barrel, placed in such a position near the forward end as to collect all scum-forming matter in a kind of skimmer-trough, or basin, to which it is brought by the natural circulation of the water and from which it is discharged, while running, by a suitable cock worked from the cab; the other in the water spaces surrounding the firebox, immediately above the foundation ring, to evacuate by means of blow-off cocks the sediment which otherwise inevitably accumulates there. Both front and back portions are in the form of draw-off heads having openings or suckers on their undersides spaced so as effectively to scour the whole of the surfaces with which they have

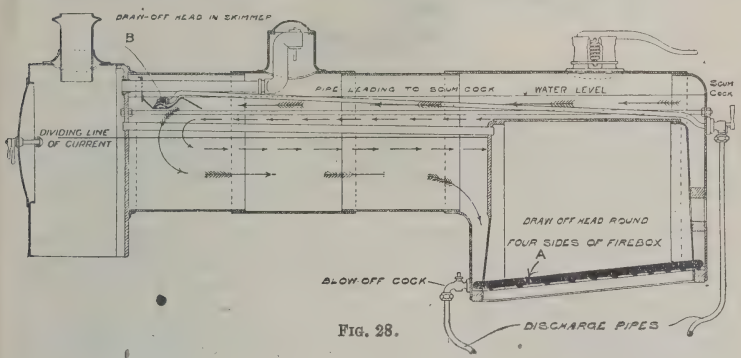

Fig. 28.

to deal, and their efficacy is such that an engine fitted with the apparatus, working on water which may previously have necessitated opening up the boiler and washing out every four or five *days*, can with the Hulburd cleaners be run 5, 6, or even 8 *weeks* without being laid off a single day for cleaning in the ordinary sense.

Among the advantages obtained by the use of the cleaners are:—

1. The immediate stopping of priming by the use of the scum cock in connection with the forward fitting.

2. The preservation of the boiler tubes, firebox sheets, stays, etc., in a clean condition through the removal of all scale-forming matter as soon as it is deposited. The cleaners' action may be advantageously assisted in some cases by the use of a suitable boiler composition, which together with other resultant solid matter is evacuated as soon as it becomes inert.

3. Immunity from leaky tubes, stays, and strained tube plates, owing to the less frequent necessity for cooling down and washing out boilers.

4. Saving in washers' wages, cost of repairs, and depreciation of boiler fabric.

5. More efficient steaming, owing to the entire boiler being kept clean and a consequent saving of fuel.

THE WILLCOX-RAMONEUR BOILER-TUBE SOOT REMOVER.

This apparatus, fig. 29 (*W. H. Willcox & Co. Ltd.*), consists of a 10-foot length of specially-constructed flexible Trellis Metal tubing tested to 375 lbs. per sq. in., attached to the following parts:—*For Smoke Tubes*: a specially-designed, cone-shaped head, made in either of three

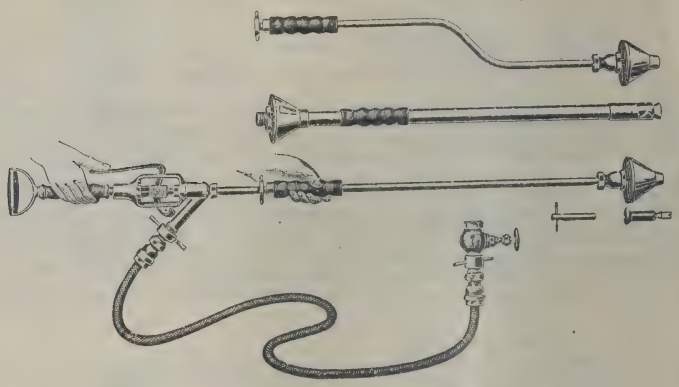

FIG. 29.

sizes, viz.:—*large*—to suit tubes above 2⅜-in. bore; *small*—to suit tubes up to 2⅜-in. bore; *extra small*—for loco. tubes; this cone head is provided with an internal interchangeable nozzle, spiral partitions or webs, and a disc throttle for regulating the admission of air. Steam lance of finest quality steel tube. A sliding hand-hold, also protector on handling end of tubing. Lever regulating valve. Steam valve for fixing to steam pipe on boiler.

A special type is made for locomotives fitted with superheaters. This superheater type is arranged for cleaning both the fire tubes and the superheater tubes from the fire-box end, and is supplied with various cranked lances to reach the nest of tubes. For water tubes a slightly different pattern (for blowing around the outside of the tubes) is supplied.

The action of the apparatus is as follows:—On the steam valve being opened the steam passes through the flexible tube into the nozzle. This nozzle is made in various styles to suit the type of boiler and the existing steam pressure. Passing from the end of this nozzle, the steam meets with ten times its own volume of hot air drawn in from the surrounding flues of the boiler, and is thoroughly mixed with same. The combined hot air and steam strike against spiral-shaped partition webs inside the cone head, and, by the united action of the nozzle and the partitions, emerge at an increased velocity through the mouth of the cone into the boiler tubes in spiral form. The steam at this point has become completely dried by the admixture of hot air, and, further, it is now joined by an additional current of warm air from the exterior of the cone; the whole ærated mass then assumes what is best described as a 'whirlwind' movement, which sweeps with great force through the boiler tube, and drives all deposits out at the opposite end, in a similar manner to that of a projectile from a gun. As the steam is thoroughly dried in the process, there is no coagulation, and formation of sooty incrustations is avoided.

In the water-tube pattern the apparatus is fitted with a tubular end-piece, joined at its base to the form of cone head shown. The opening at the tubular end is provided with a spreader which creates a fan-shaped spray, which is directed upon the outside of the water-tubes. With this arrangement it is possible to sweep away thoroughly, and with equal velocity, the soot and ash dust which collect on the surfaces of these tubes.

For works using both types of boilers the '*Combined Ramoneur*' is supplied. This is arranged with interchangeable heads, so that either the smoke or water-tube pattern may be utilised as required. The head suitable for the particular type of boiler requiring to be cleaned can be readily screwed on, and the apparatus is thus rendered immediately applicable for use.

Steam Turbines and Turbo-Compressors.

A Treatise on their Design and Construction.

By FRANK FOSTER, M.Sc.

Contents.

Descriptions of Turbines—Steam Nozzles—Disc Friction—Blades—Rotors—Governing—Bearings—Gyroscopic Action—Deflection of Discs—Critical Velocity—Balancing—Condensers—Steam Turbine Performance—Marine Turbines—Turbo-Compressors—Gas Turbines—Diagrams and Calculations—Construction—Miscellaneous—History, with an Appendix of Useful Tables.

Press Opinions.

'The book fills a want which all those who are interested in the subject of steam turbines should be grateful to see supplied. It contains some valuable original contributions to the literature of the subject.'—*Engineering News.*

'This work is a step in the right direction. The mechanics and construction of the steam turbine are considered at considerable length and quite practically. We can recommend the book as an attempt to place the steam turbine properly before mechanical engineers. Considering the amount of original work in it, the book is cheap.'—*American Machinist.*

'The descriptive and historical sections of the book are comparatively brief, and on the whole well executed and illustrated; the sections dealing with "the design of details" are relatively full, practical in form, and suited to the requirements of men engaged in the work of designing steam turbines. The scheme of the book is good.'—*Times Engineering Supplement.*

'The book is not merely a popular description of existing machines, but takes the subject up in a common-sense sort of way, giving a great many practical details which affect the efficiency. The work appears to be well worthy of careful consideration.'—*International Marine Engineering.*

'In every particular the book has been made to appeal to the practical engineer. Most of the subject matter is original.'—*Iron Age.*

Simplex Patent Boiler Tube Brushes and Scrapers.

(W. Crockatt & Sons., Ltd., Glasgow.)

The 'Simplex Boiler Tube Brushes' are made with short hardened steel wires which, being comparatively unyielding, are capable of removing deposits which softer brushes will not readily attack. The necessary spring of the brushes is obtained through the action of the arms, which are made of spring steel of sufficient strength to put a reasonable pressure on the tubes being cleaned. The filling of the brush plates is done in a special machine, and in such a way that it is impossible for the bristles to come out, unless they are worn quite away.

Two designs of brush are made, the 'Self-Adjusting Brush,' which depends for its action entirely on the spring of the arms, and the 'Adjustable Brush,' which also has a certain amount of spring in the arms, but which has also a central spindle with a wing nut at each end, by which the diameter of the brush can be increased within a limited range.

The 'Simplex Patent Tube Scraper' is made of drop forgings and will remove harder deposits than will the brushes. It is arranged to scrape only on withdrawal from the tubes, so that the soot, etc., is brought to the front of the boiler, and not shoved into the back ends. This tool also is adjustable by means of a nut which is easily operated as required.

The 'Simplex Condenser Brushes and Scrapers' are for use in marine work as well as on shore.

VALVES.

The large valves on the steam mains should each be provided with a small by-pass valve to enable a length of cold steam pipe to be warmed up, and the pressure balanced before the main valve is opened. This will prevent the straining of the joints caused by sudden expansion, and likewise accidents due to water hammer.

The outlet valve from the boiler should be at the highest point possible, so that there may be a fall from the valve towards the engine. There should not be a vertical pipe rising from the valve since this affords a pocket for water which will be dangerous should the drainage fail.

It has been suggested by W. H. Booth that since the loss of pressure in steam pipes is due to friction, there would be no very serious loss caused by a short length of less diameter placed in the course of a long pipe, and he suggests that the valves might be much smaller than the pipes, being connected to them by conical ajutages. These cones should not be isosceles but scalene, so that the floor of the valve should be in one level with the lower side of the pipe, thus allowing free flow of water. These small valves would greatly reduce the cost of the valve installation, especially where valves are numerous, as in the needlessly complicated pipe systems so much in vogue.

Stop-Valves.

The Hopkinson-Ferranti Patent Stop Valve.

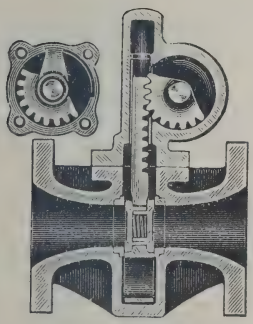

Fig. 30.

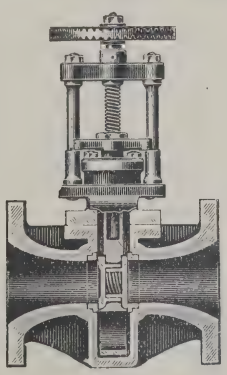

Fig. 31.

This valve, figs. 30 and 31, is designed to pass an amount of steam equal to the full carrying capacity of the pipe. The working parts of the valve are similar to those of the Patent Parallel Slide Valve, and are placed in the throat of a converging-diverging nozzle. The construction allows a large reduction in size, weight, and first cost, as compared with ordinary fullway valves.

The design is such that a part of the pressure energy of the steam is converted into kinetic energy in the converging nozzle, the steam increasing in velocity and dropping in temperature and pressure. With the high velocity thus acquired the steam passes through the valve proper and enters a diverging nozzle in which the kinetic energy is reconverted with an increase of pressure and temperature. The steam thus leaves the valve at the pressure, temperature and velocity with which it entered the converging cone on the inlet side, the loss of pressure under normal conditions being negligible.

The Hopkinson-Ferranti Valve for steam is made in all the standard sizes from 4 inches to 24 inches diameter, with cast-iron or cast-steel body and cover in accordance with the pressure and temperature and with 'Platnam' disc and seats in all cases. Steam can be passed in either direction as required the old pattern with unequal nozzles having been superseded.

The principle is also applied to valves for water and air, and a number of special patterns are manufactured.

United Brassfounders Gun-Metal and Cast-Iron Stop Valves.

A large variety of stop valves are made by *United Brassfounders and Engineers Ltd., Manchester.* The valves, which are all specialised products, are made in large quantities by means of special automatic and semi-automatic machinery, the principal types being as follows: Ordinary gun-metal wheel valves (fig. 32) and renewable disc valves of the well-known 'Fearnought' type (fig. 33). A regrinding type has a special union attachment of the stuffing box to the body, enabling the valve to be taken apart and the parts reassembled with great ease. The special feature of the latter type is that the valves can be reground without the necessity of removing them from the pipe line. Light, medium, and heavy ranges are made to suit various working pressures up to 300 lbs. per sq. in., and they are supplied with screwed or flanged ends and of the straight through or angle patterns as may be required.

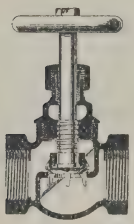

Fig. 32.

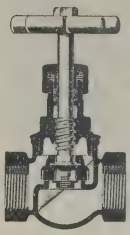

Fig. 33.

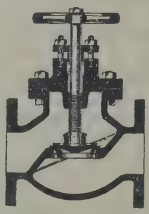

Fig. 34.

Another leading speciality is cast-iron globe stop valves of improved design (fig. 34). In these valves the spindle is of nickel steel and the inner valves of the rotating type, so that every time it is opened it can rotate and find a new position, thus keeping the working faces quite even. The valves are of sturdy proportion and give a very large area through the passages.

Valves are also supplied arranged to act for check and feed. In the cast-iron parallel slide stop valves, which are suitable for 300 lbs. pressure, the seating rings are carried in a manner which prevents the possibility of damage, and dispenses with the use of small diameter springs, the only spring used being of large diameter and made of phosphor bronze wire.

Fig. 35.

Cast-Iron Fullway Sluice Valves.

These valves, fig. 35 (*United Brassfounders and Engineers Ltd.*), are made in three strengths to suit all pressures up to 225 lbs. per sq. in., and embody recent improvements, which give strength and reliability under working conditions. The valve faces on either side of the wedge valve are locked securely by means of an improved dovetailing device, which effectually prevents loosening of the facing rings and consequent leakage, so usual in the case of valves with faces secured by setscrews. All valves have working parts carefully machined to gauge, thus ensuring sound mechanical construction and working. The wedge taper is so designed that the wedge does not touch the faces in the body until the valve is almost closed, which results in easy operation of the spindle and immunity from sticking or jamming of the wedge.

Alley & MacLellan, Ltd.
Sentinel Valve Works. WORCESTER.

The No. 7 Crane Valve.

(With Union Bonnets and Renewable Discs.)

(*Crane-Bennett, Ltd., London.*)

These valves, fig. 36, are designed to be used in plants where continuous service is required and where discs must be changed quickly without injury to the valve. As wheels, stuffing-box nuts, and union bonnet rings receive rough treatment, these parts are made of malleable iron, which is stronger, tougher, and stiffer than brass.

The disc holder slips on to the stem, and is accurately guided in the body, whether the valve is open or closed. The disc may be easily removed from this holder.

Besides the quick change features, and the malleable iron parts, these valves have glands in the stuffing boxes, the stems have bevelled shoulders, which make tight seats against the bonnets, allowing the valves to be repacked while under pressure, and the bodies are heavier than many standard valves.

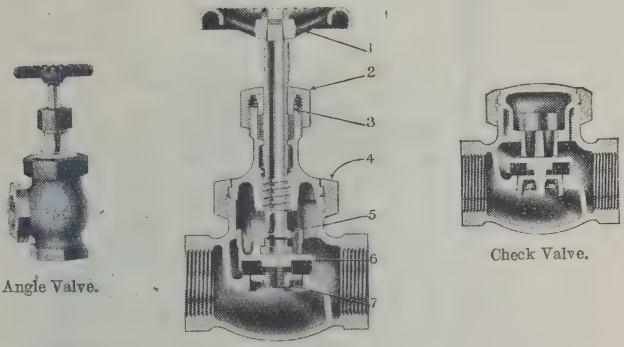

Fig. 36.

Seven Features of the Crane No. 7 Valve:—

1. Malleable iron, non-heating wheel, enamelled red.
2. Malleable iron nut, enamelled red.
3. Brass gland.
4. Malleable iron nut, enamelled red.
5. May be packed under pressure, when valve is wide open.
6. Removable disc holder for quick change.
7. Removable nut for changing discs.

A special feature is the adaptability of the valves to many services, such as compressed air hot and cold water, oil, etc., by the use of different discs.

For ordinary steam service, a composition disc is used, and this is the disc furnished on all orders, unless a different one is specified: a special high-pressure composition can be supplied if required.

For extreme conditions, such as steam throttling, a metallic disc is supplied.

The valves are recommended for working pressures up to 150 lbs. on steam, air, and hot water. They may be used on cold-water lines, not subject to shock, up to 200 lbs. water pressure.

The valves are made with screwed ends in sizes ¼ in. to 2 ins., and with flanged ends, ¾ in. to 2 ins., also horizontal or angle check valves.

Seven other special features are:—Wheel easily removed; heavy brass stem; long and strong stem threads; disc accurately guided; large, heavy hexagons; more than full area everywhere; strong, heavy body—pleasing proportions.

Cockburns' Positively Controlled Regulating and Emergency Throttle Valve.

This valve, fig. 37, p. 1462 (*Cockburns Ltd.*), is a balanced double beat valve fitted with a flexible disc, making it absolutely steam-tight. It is positively opened and closed by a hand wheel. When the valve is to be used as a throttle the locking gear for the positive opening and closing is detached, allowing the valve to be steam operated through the medium of the control valve.

COCKBURNS' POSITIVELY CONTROLLED REGULATING AND EMERGENCY THROTTLE VALVE.

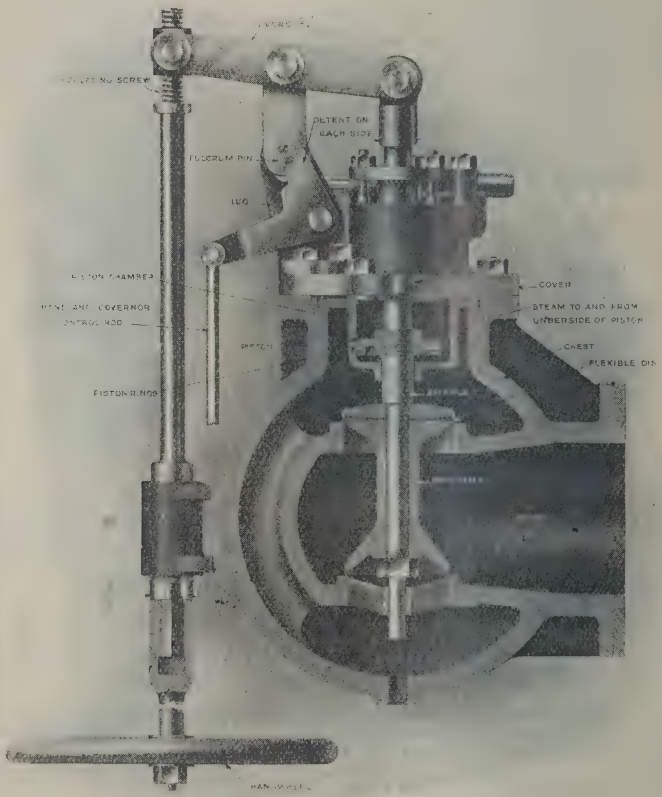

FIG. 37.

Action of Valve.

For ordinary positive opening and closing as a regulating valve the fulcrum pin is locked by the detents as shown. The detents thus allow the valve to be positively opened, as the valve is balanced ; this requires a minimum of power. On closing the valve and hardening down, the fulcrum pin bears against top of lug. During these operations the control valve is in neutral position, preventing steam passing to condenser. The operating piston has also inlet pressure steam on both sides of it, thus effecting a balance.

When the valve is opened to any degree of regulation it can be shut and opened again by the emergency gear in the following manner :—

The throttle lever is moved from open position to shut. The control valve during this operation moves through an intermediate position which allows the control valve to hold the main valve open till detents have cleared themselves from fulcrum pin—then with throttle lever in shut position the main valve closes—the levers (A) swinging from pin on nut of regulating screw. On the throttle lever returning to intermediate position the main valve opens up, and when this occurs the throttle lever, due to the weight of pull rod, drops back again into open position, again locking the fulcrum pin and shutting off all communication from control valve to condenser, thus placing main valve in a position for positive control.

The valve can, if required, be taken adrift in a few minutes.

THE JENKINS' BLOWER VALVES.

These valves, fig. 38 (*Jenkins Bros. Ltd.*), are for use in railroad roundhouses, where they have to be connected to down pipes, which, when not in use, become filled up with water.

The valve is practically a non-return valve, with one size smaller bonnet screwed into a neck which is formed on the bottom of the body. The bonnet carries a spindle with a small collar on the end, which, when the valve is opened, strikes the underside of the check clapper and lifts it from the seat. There is a second collar on the spindle, which strikes the inside or bottom of the bonnet when the valve is closed. The spindle has a left-hand thread, and an

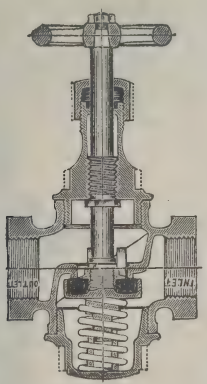

FIG. 38.

extension attached to the wheel end. This extension spindle is carried down to easy reaching distance from the floor. As the valve is *pushed* open by the spindle, instead of pulled, the wheel turns in the same direction as an ordinary wheel valve, and can go only the distance between collars in either direction, consequently it is 'fool-proof.' When the spindle is turned until the collar brings up on the bonnet, the valve closes itself positively, as a non-return valve would, and remains so until it is desired to open it again. The result is, that if it is tight, as it ought to be, there is no dripping, as only steam is on top of the disc-holder, any condensation running back into the main pipe.

The valve is fitted with a renewable composition disc, and all working parts are interchangeable.

Valve Refacers.

The Brooke Valve Refacer.

(Patent.)

The trouble caused by leaky valves, owing to wear or bad cutting of the surfaces, is often a source of great annoyance, and the possibility of refacing the same without removal of the valve is a very important point. This refacing can effectively be carried out by Brooke's valve seat refacer. This machine, fig. 39, is very simple in all its parts, and is capable of standing a fair amount of rough usage without getting out of order, and should last the life-time of any steamer, with ordinary care.

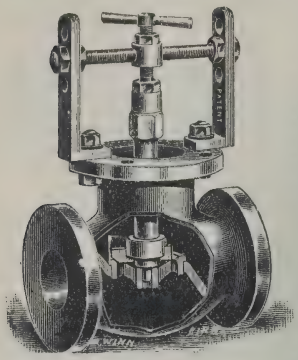

Fig. 39.

In the arrangement, the legs are reversible on the crosshead, the feet being turned inwards for small flanges, and outwards for large, also, whether fastened one way or the other, there is no part that prevents the operator from seeing the cutter. When once the machine is set in position, it need not be disturbed to change the cutter, as the mandril (which may be of any desired length) can be unscrewed from the box nut and taken out, while any extra cutters are easily made by the engineers, if required.

Disc steadies are provided for plain bore seats, and leg steadies for star-ribbed seats, which not only centre the end of the mandril at once, but obviate any tendency to vibrate—so that the machine will reface a valve-seating true, and leave it without jars or riffles.

The machine is operated with an ordinary spanner, and is made complete with five cutters and necessary guides for dealing with all sizes of valves from 1¼ in. to 4½ ins. Larger sizes are made for valves up to 10 ins. diameter. *(Charles Winn & Co. Ltd.)*

The Simplex Patent Valve Reseating and Facing Machine.

(W. Crockatt & Sons, Ltd., Glasgow).

(1)

This tool, fig. 40, has been designed to avoid the necessity of using the studs in the valve chest as a means of steadying. At the same time it is simpler and stronger than the machines which are secured and centred by means of a chuck operated by a scroll.

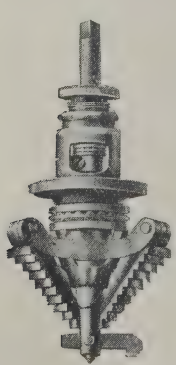

Fig. 40.

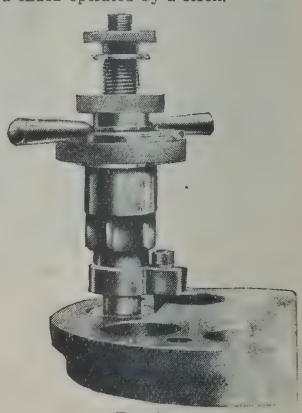

Fig. 41.

The tool is fixed in the valve chest (which may be either plain or screwed) by means of three stepped arms, pivoted at their upper ends. These arms are expanded by a cone which is depressed downwards by means of the hand nut. The action of expanding these arms both centres the tool in the valve and fixes it securely in position. This is ensured by the manufacture of the tool, the arms being turned up truly central with the spindle, after assembling. The cutters

COAL SAVING

By Scientific Methods in the Boiler-house

OUR UNIQUE SERVICE.

We are a firm of Technical Chemists and Engineers, who have been engaged continuously for the past 10 years in Coal Saving by modern methods of steam generation. Our Engineering department attends to the designing and carrying out of schemes of reorganisation for boiler-plants of every description, including the services of our trained engineers to "tune up" the plant when completed. Our Chemical department undertakes, in our own laboratories, all the chemical analyses necessary, particularly boiler-feed water and fuel (including coal, refuse coal, coke, coke-breeze, oil, blast furnace gas, waste heat, and refuse of every description). Our Building department prepares all Architects' drawings and negotiates the building contract.

The whole forms a unique service for Coal Economy, and as a result we can give you a boiler plant running on the highest degree of efficiency. We are not interested in the sale of any particular plant, machinery or appliances, and no other firm can give you such a service or has had anything like our experience of this business. We also make a speciality of the design and erection of new Boiler and Power plants. Finally, we can produce the highest references from firms for whom we have saved 15-35% of their coal bill.

It is difficult for us to explain our proposition in detail in a short advertisement, and we shall be pleased to send you our literature and full particulars on application. We are also prepared to visit your Works **free of charge,** and give you our opinion of the working of your boiler-plant, or to inspect the site of a proposed new plant.

Laboratories & Testing Station—Church St., Cheetham, Manchester.

used are made of flat steel, and one end is arranged for flat and the other for bevelled seats. The simplicity of this type of cutter is found to counterbalance any slight advantage the milled type of cutter may have. Also a very much smaller number of cutters can be employed to deal with a large range of valves, as each cutter is adjustable. In order to prevent chattering of the tool, the feed is against the action of a strong spring, which keeps an upward pressure on the tool, so that feeding only takes place when the cutter is forced down by the action of the nut. This prevents the cutter following any irregularities in the face of the seat.

A simple attachment is provided when desired for trueing up the valves themselves. The valves are centred in this part of the tool and faced up by a movable tool, which can deal with either flat or bevelled valves. The arms and lower part of the body of the tool are made of cast steel, so that the machine will stand hard wear. Ball-bearings are fitted throughout, to ensure smooth working and to avoid jarring.

The machine is made in three standard sizes to deal with valves from ¾ in. to 8 ins. diameter, but has been supplied and can be easily adapted to do valves up to 12 ins. or more.

(2)

In order to meet the demand for a tool which will face up the seats of the group valves in Weir's and similar feed pumps, the Simplex No. 3 machine has been introduced. This tool, fig. 41, is secured in position by the expansion of three segments, which are turned concentric with the central spindle, and which are expanded hard against the inside of the bore of the valve seat by the action of the tapered end of the spindle. It can easily be adapted to flat or bevelled seats by simply changing the cutter used.

If it is desired to face up the valves in the bottom seat of the pump without drawing the complete seat, a special tool with an extended body can be supplied.

Besides being suitable for the type of valve mentioned, the tool is equally adaptable to dead-weight safety valves, or indeed, to any design of valve in which the inside of the bore is a plain cylindrical surface. Ball bearings are fitted to ensure smooth and easy working.

WILLCOX'S 'ELLIPTIC' FULLWAY COCKS. (*Allen's Patent.*)

This cock (*W. H. Willcox & Co. Ltd.*) has an absolutely full bore throughout. By its special construction the bore gradually changes from circular at the flanges to an ellipse in the centre

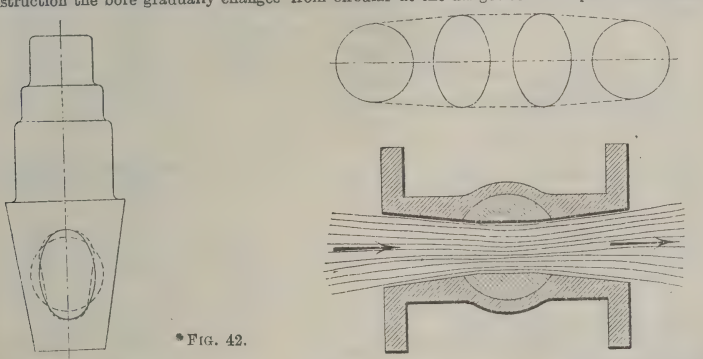

FIG. 42.

or plug, as indicated by fig. 42, and, in doing so, maintains full equal area of the circle right through. The interior is entirely smooth from end to end, there being no projections whatever. The cocks are made from ½ in. up to 6 ins. bore, and are suitable for water as well as for steam.

BOILER EFFICIENCY.

Typical figures are :—

	Per cent.		Per cent.
Small cylindrical boiler, no economiser	45–55	Large water-tube boiler with economiser	70
Large cylindrical boiler with economiser	60–70	Do. highest class	70–75
Do. well fired and maintained	75	Locomotive boiler, moderately fired	65–70
Small water-tube boiler with economiser	50–60	Marine boiler, well fired	60–70

The actual evaporation in lbs. of steam per lb. of coal is a common, but somewhat unscientific, standard of efficiency. It obviously varies with the heat value of the coal, the steam pressure, and the superheat. When stated as the equivalent evaporation 'from and at' 212° F. it is a better basis, but is still dependent upon the quality of the coal. Thus, best Welsh coal will evaporate 25 per cent. more than an inferior slack with the same boiler efficiency. To convert actual evaporations into 'from and at 212' multiply by the B.Th.U. given to each lb. of

water in heating, evaporating and superheating it, and divide by 966. Thus starting with water at 102° and superheating to 150° at 160 lbs. absolute, the B.Th.U. is 1,205, so that the equivalent evaporation factor is 1·25.

Efficiency of Steam-Boiler Plant.

(*Contributed by* ***David Brownlie, B.Sc. Hons. (Lond.), F.C.S., A.M.I. Mech.E.***)
(Brownlie & Green, Ltd., 10 Church Street, Cheetham, Manchester.)

(1)

The following are the true average figures for the performance of 250 steam-boiler plants in 27 different industries, comprising 1,000 boilers with an annual coal bill of 2,166,000 tons. Each test, comprising a day test and a check test of one week, was carried out with the greatest care on the plant as actually working from week to week all the year round. Nearly 2,000 boiler plants were inspected and it was found that all were being worked on the same general lines—that is to say, these average figures apply to the burning of 75–100,000,000 tons of coal burnt per annum in Great Britain for steam generation :—

AVERAGE WORKING FIGURES OF 250 TYPICAL BOILER PLANTS.

TESTS.

Average of 250 *Typical Boiler Plants.*

(A) *Working Day's Test.*

Type of boiler	'Lancashire'	Water evaporated per sq. ft. of grate area per hour	137·4 lbs.
Number of boilers	4	Water evaporated per lb. of fuel	6·56 lbs.
Grate area	152·6 sq. ft.	Equivalent evaporation from and at 212° F., per lb. of fuel	7·46 lbs.
Duration of test	9·43 hours	Equivalent evaporation from and at 212° F., per 1,000,000 British thermal units	631·0 lbs.
Amount of fuel used	30,131·72 lbs.	Temperature of feed-water before economisers	116° F.
Analysis of fuel used :		Temperature of feed-water after economisers	193° F.
British thermal units	11,822	Percentage of fuel bill saved by economisers	7·1 per cent.
Ash	11·5 per cent.		
Fuel burnt per boiler per hour	798·8 lbs.		
Fuel burnt per sq. ft. of grate area per hour	20·9 lbs.		
Water evaporated	197,776·0 lbs.		
Water evaporated per boiler per hour	5,243 lbs.		

(B) *Long Check Test* (one week of 7 days).

Duration	167·5 hours	Water evaporated per lb. of fuel	6·42 lbs.
Amount of fuel used	128·25 tons		
Water evaporated	184,435·0 galls.		

DETAILS.

Draught in side flue	0·40 in. W.G.	Temperature of superheated steam	346·5° F.
Draught in main flue at exit of economisers or chimney base	0·80 in. W.G.	Steam or power used as auxiliary to the production of steam	2·4 per cent.
Temperature of flue gases before economisers	598° F.	Thermal efficiency :	
Temperature of flue gases after economisers	478° F.	(A) Net working efficiency complete, after deducting 2·4 per cent. steam or power used as auxiliary to the production of steam	60·09 per cent.
Percentage of CO_2 in flue gases from side flue of boilers by means of combustion recorder	7·6 per cent.	(B) Boilers only	56·71 ,,
Steam pressure :		(C) Economisers only	4·35 ,,
Pounds per sq. in. (gauge)	89	(D) Superheaters only	0·51 ,,
Pounds per sq. in. (absolute)	104		
Temperature of saturation of steam	330·5° F.		

The installations from which the above average is derived comprise all sizes of plants with annual coal bills of from 750 tons to 70,000 tons ; whilst the average working pressure varied from 12 lbs. to 200 lbs. per sq. in. The fuels used were of every possible description, from the highest qualities of washed nuts, beans, peas, and fine slack, and large and small screened coal, down to inferior fuels of all qualities, including refuse coal mixed with shale, pit sweepings, washer settlings, etc., as well as coke and coke breeze.

The 250 plants had a total of 1,000 boilers, comprising 935 'Lancashire' boilers, 36 modern 'tubular' boilers, 17 'egg-ended' boilers, 6 'Cornish' boilers, 1 'marine' boiler, 2 'vertical' boilers, and 3 'patent' boilers. The plants varied in size from one small 'vertical' boiler to 35 'Lancashire' boilers, 30 ft. by 8 ft.

The total grate area of the 250 boilers was 38,158·6 sq. ft., corresponding to 152·6 sq. ft. per plant, or 38·1 sq. ft. per boiler, which, on the assumption that all the boilers were 'Lancashire,' would give an average grate-area length of approximately 6 ft.

The average figure shows 20·9 lbs. of fuel per square foot of grate area per hour, referring to the average amount burnt per hour per working day, and not to the amount for any particular hour. This figure is considerably below what is possible on a boiler plant run on modern lines, which would give something like 25 lbs. to 30 lbs. per square foot grate area per hour with the average quality of fuel. The boiler plants of the country are working under very easy conditions in this respect, and much more fuel could be burnt per boiler. Figures for fuel consumption depend very largely on the quality of the fuel. Thus a good quality washed coal of, say, 13,000 British thermal units and 7 per cent. to 8 per cent. ash could easily be burnt economically at the rate of 35 lbs. per square foot per hour, whereas purely refuse coals would only give about 15 lbs. Coke of good quality can be burnt at the rate of 22 lbs. per square foot grate area per hour and coke breeze about 15 lbs.

The average for the 250 plants shows 11,822 British thermal units and 11·5 per cent. ash, which includes almost every description of coal and coke varying in quality from 7,000 British thermal units to 14,000 British thermal units.

As regards coke, a good average sample of coke shows about 12,000 British thermal units to 12,500 British thermal units with 12 per cent. ash, whilst a good sample of coke breeze shows 9,000 British thermal units to 10,000 British thermal units and 15 per cent. to 20 per cent. ash. The great trouble with coke and coke breeze is the amount of moisture contained in them. Good samples should only contain about 5 per cent. and certainly not over 8 per cent. Many samples, however, contain regularly 20 per cent., which is a most serious matter from the point of view of economy.

In a well-managed plant with average quality of coal a 'Lancashire' boiler, 30 ft. by 8 ft., can evaporate easily 850 gallons per boiler per hour, an increase of 62 per cent. of steam output as compared with average figures.

Efficiency of Steam Boiler Plant.

(2)

The following are the figures for two separate industries, namely, collieries and chemical works:—

(1) *Collieries.*—Representing average figures for the complete investigation of 100 boiler plants, 570 boilers, annual coal bill 1,250,000 tons.

(2) *Chemical Works.*—Representing average figures for the complete investigation of 60 boiler plants, 236 boilers; annual coal bill, 620,000 tons.

Essential Figures of the Tests.	100 Colliery Plants.	60 Chemical Works Plants.
1. Duration of test	9·68 hrs.	9·20 hrs.

26. (D) Due to superheater only	0·62 "	1·3 "

TYPES OF BOILERS.

LANCASHIRE AND CORNISH BOILERS.

The distinction between these two general types is that the Cornish has one and the Lancashire two internal flues.

These boilers were originally made with iron plates, and had flat ends (often in two or three pieces), the flat surfaces being strengthened with rod and gusset stays.

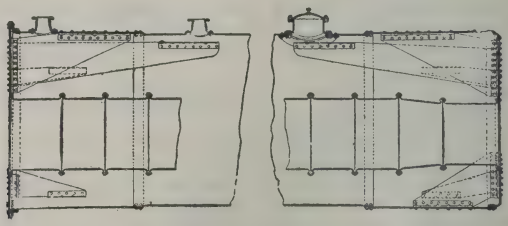

FIG. 43.—Lancashire Boiler (ordinary type, with flat end plates).

When steel took the place of iron, and boiler makers were able to obtain larger plates, the end plates of the largest boilers were then made in one piece, and the shells constructed of seven or nine belts, each in one plate. Fig. 43 shows a section of one of these Lancashire boilers as it is still being made by some firms.

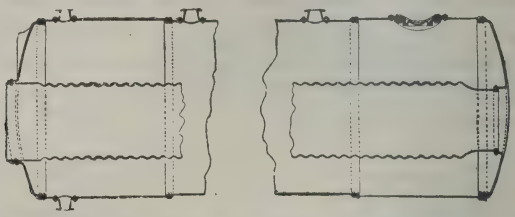

FIG. 44.—Thompson Type, with dish end plates and corrugated flue tubes.

All internally-fired boilers are subjected to straining due to unequal expansion and contraction, the flue tubes and furnace tubes becoming hotter than the shell while the boiler is at work.

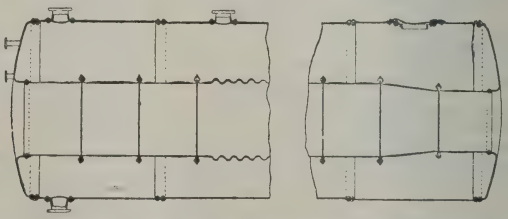

FIG. 45.—Thompson Type, with flue tubes corrugated for part of their length.

Makers of boilers having flat end plates provide for expansion by the flexibility of the end plates.

Some makers avoid the staying required in the case of flat end plates by using dish-end

plates (fig. 44), and provide for the relief of expansion stresses by making the flue tubes corrugated, either for their whole length (fig. 44), or for part of their length (fig. 45).

A length of corrugated flue tube is used by makers of flat end boilers also, for high pressures.

The Galloway Boiler.

The general design and details of the Galloway Boiler (*Galloways, Ltd., Manchester*) are shown by fig. 46. The boiler has two furnaces at the front, joining behind the bridges into one flue of special shape, containing the well-known Galloway cone tubes, and side pockets: otherwise, and in general appearance it is somewhat similar to the two-flued or Lancashire boiler.

The advantages claimed for the Galloway boiler are:—

Increased heating surface—about 10 per cent. additional.

Improved circulation, giving more uniform temperature and reduced expansion strains. This circulation, also, largely prevents the deposit of solid matter upon the furnaces and adds to the durability of the boiler.

Improved heat transmission, owing to good circulation and to sinuous path of flue gases past the cone tubes.

Increased output and higher efficiency.

THE THOMPSON LANCASHIRE BOILER.

(John Thompson (Wolverhampton), Ltd., Wolverhampton.)

This is a boiler (fig. 47, p. 1475) of the dish-end type (figs. 44, 45). The end plates are dished to a convex form and increased in thickness to give the same factor of safety (as obtained with the stayed surface), thereby dispensing with all gusset and longitudinal rod stays. The inside, being free from stays, can be easily cleaned, particularly over the fire-boxes, where the steam is so largely generated.

The table on page 1474 gives some particulars of these boilers, which have been made for working pressures up to 230 lbs. per sq. in.

MULTITUBULAR BOILERS, LOCOMOTIVE TYPE.

THE ROBEY BOILER.

Fig. 48 shows a boiler, locomotive type, by Messrs. Robey & Co. Ltd. of Lincoln. It is rated at 8 h.p. nominal, with enlarged grate suitable for burning inferior fuel, having a grate area of 6·43 sq. ft., and a total heating surface of 164·8 sq. ft. Its working pressure is 150 lbs. per sq. in. The tubes are of steel solid drawn.

The figure shows Messrs. Robey & Co.'s patent roof fire-box girders, which, being supported by the archplate of external fire-box, take all compressive strains off the fire-box front plate and tube plate.

FIG. 48

LOCOMOTIVE BOILER FOR 6 FT. 6 IN. 4-WHEEL COUPLED BOGIE ENGINE, GREAT NORTHERN RAILWAY.

FIG. 49.

The Essex Tubular Vertical Boiler.

This is a type of boiler (figs. 50, 51) introduced by Messrs. Davey, Paxman & Co., Ltd., Colchester, and is yielding excellent results.

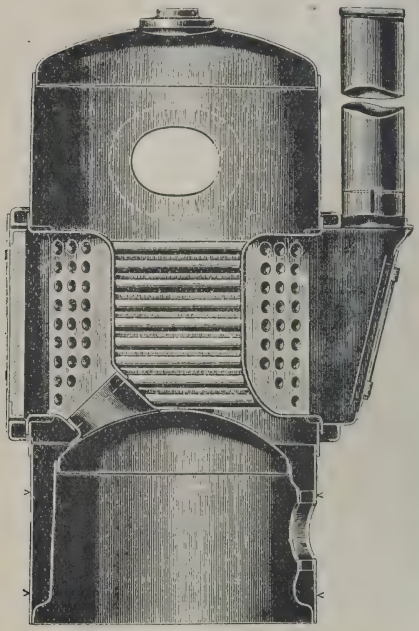

Fig. 50.

A flanged riveted neck, secured to the top of fire-box, conveys the products of combustion into a chamber to the left. This chamber is of a triangular shape (see fig. 51), and has an outer flange by which it is riveted to the shell of the boiler, and to which a door is fitted. An exactly similar chamber is in like manner secured at the opposite side and is fitted with a door, the whole forming the smoke-box, which can be arranged with either up-take or down-take.

These two chambers have a number of tubes, of a semicircular shape, uniting them. The curve of the tubes being of a greater radius than that of the boiler, enables them to be easily put in or withdrawn in a small space.

The chambers (of fine quality steel) are formed, while hot, in a special hydraulic pressing machine,

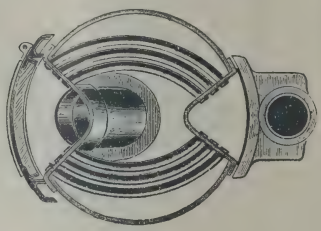

Fig. 51.

and are then annealed. The shape of the flues causes a centrifugal action in the hot gases, which brings every portion of them into direct contact with the tube surface.

Principal Dimensions of Standard Sizes of Paxman Essex Vertical Boilers.
For a Working Pressure of 90 Lbs. per Sq. In.

* The figures given for the evaporative capacity of each boiler are with feed at 212°F., when burning good coal, and with good draught and stoking. It is of course possible to obtain a much greater evaporation when the draught is ample, and the user is prepared to sacrifice economy to increase the evaporation.

The Paxman Economic Boiler.

This boiler (fig. 52) consists of a cylindrical shell, with one or more internal flues, and a number of small return tubes running from end to end. A combustion chamber of brick receives the products of combustion at the back of the boiler; they then pass through the small tubes to the smokebox in front, and finally return to the back, outside the boiler shell, through the brick flues in the setting, to the chimney.

Whilst the temperature of the waste gases which leave the boiler on their way to the chimney ranges from 600° to 700°F. with many boilers of the Cornish, Lancashire, or similar types, it is only from 450° to 475°F. in the case of the Paxman 'Economic'; with the latter boiler, on account of its large heating surface, there is about 30 per cent. less waste of heat, the temperature named being just sufficient to create a natural draught, indicating that the utmost possible degree of heat has been abstracted from the fuel burnt, and rendering an Economiser unnecessary.

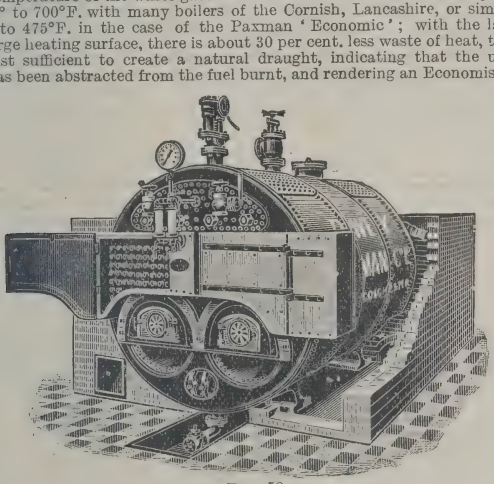

Fig. 52.

An independent test of this boiler by Sir Alexander W. B. Kennedy showed an evaporation of 12·2 lbs. of water from and at 212°F. per lb. of coal.

The operation of sweeping the tubes (preferably daily) can be effected by the stoker, using an ordinary wire tube brush, during any interval of thirty minutes; or, if there is no such interval, a steam cleaning device can be supplied, enabling the operation to be completed in ten minutes.

A Paxman 'Economic' boiler being only about half the length of a Lancashire boiler of corresponding capacity, a very considerable saving is effected in the boiler setting and buildings; and in case of shipment the freightage cost may be only one-third of that for a Lancashire boiler.

Principal Dimensions of Standard Sizes of Paxman Economic Boilers with Single or Double Flues.

It is of course possible to obtain a much greater evaporation when the draught is ample, and the user is prepared to sacrifice economy to increase the evaporation.

The Cochran Boiler.

Fig. 53, p. 1481, represents one of Messrs. Cochran & Co.'s Patent Vertical Multitubular Boilers, as manufactured by them at Annan. These boilers are used very largely both ashore and afloat.

The advantage which this kind of boiler presents over other kinds for land use and export has long been recognised, and its principal merits consist in great economy of space, in not requiring any brickwork setting, in having a large amount of highly effective heating surface, in obtaining plenty of steam, and in being very economical in fuel, besides being perfectly accessible for cleaning and repairs outside and inside.

For winch boilers this type combines the advantage of the cross-tube boiler and the horizontal boiler without their disadvantage, and has been found the most suitable for large passenger, mail, and cargo steamers running to all parts of the world.

The boilers are made in a range of standard sizes, as per following Table, which gives full particulars of their standard dimensions.

Evaporation of Cochran Boilers.

Messrs. Cochran's formula for evaporation is :—

$$E = 26\ (G - 2)\left(5 + \frac{\frac{H}{G} - 13}{7{\cdot}5}\right)$$

where,

E = Evaporation in lbs. per hour ; G = Grate area in sq. ft. ; H = Heating surface in sq. ft.

The first expression of the formula represents the coal burnt per hour ; the second expression represents the water evaporated per lb. of coal.

THE COCHRAN BOILER.

FIG. 53.

The evaporations given by this formula can be obtained under favourable conditions, but the makers' practice is to recommend that about 75 per cent. of this maximum evaporation should be relied upon for continuous working.

In the Evaporation table (p. 1480) it will be noticed that there are two sets of figures, showing coal consumption and evaporation. Under 'Heavy Steaming' are given the evaporations as per formula, and under 'Easy Steaming' the evaporations are calculated at 75 per cent. of this amount.

The above prices are those in operation on January 1, 1922, and for boilers of 100 lbs. working pressure. The boilers are tested by makers to 200 lbs. hydraulic pressure. The price for 'boiler and fittings only' includes boiler with smoke-box, combustion chamber plate and lining, firedoor, manhole and cover, mudholes and doors, and one set of cast-iron firebars and plate ashpit damper. Mountings consist of steam stop valve, safety valve, feed check valve, pressure gauge and protector, blow-off cock, one set of water gauges, and two test cocks.

The plates from which all these boilers are made are of the best quality mild steel, made by the Siemens-Martin process to the requirements of the British standard specification for marine boilers, and tested at the steel works by Lloyd's Surveyor.

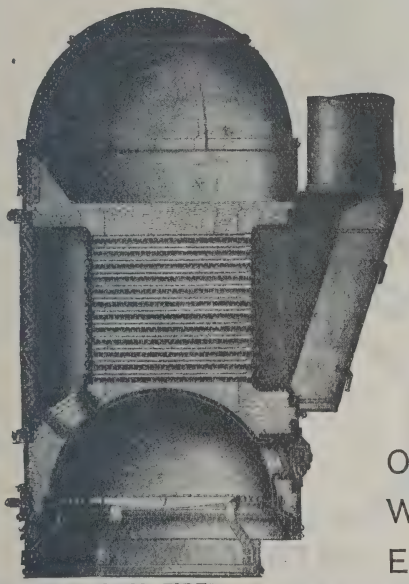
Class B boilers are provided with a Lloyd's certificate, and the specification of fittings and mountings is slightly different.

The boiler lends itself readily to firing with oil fuel, the maximum evaporations as obtained with coal fuel being easily obtained when burning oil with a slight increase in efficiency.

The self-contained character of the boilers renders them particularly applicable for the utilisation of waste heat from reheating furnaces, puddling furnaces, coke ovens, etc.

WATER-TUBE BOILERS FOR LAND SERVICE.*

THE NICLAUSSE BOILER.



This boiler is built in France by Messrs. J. & A. Niclausse of Paris, and in England by *The British Niclausse Boiler Co., Ltd.*, of Clock House, Arundel Street, Strand, London, W.C. 2.

It consists of a compact nest of large, straight, short solid drawn tubes, closed at each end and mounted at the front end in solid drawn pressed steel headers, upon the top of which is mounted a capacious steam and water drum. There is thus only a single row of headers. The heating surface of the outer tube is rendered highly efficient by the provision of an inner tube to carry the water to its back end, whereby the circulation must always be in only one, and that the correct, direction. The tubes are closed by a tapered screwed pressed steel cap at the back end, and at the front end by a tapered screwed pressed steel plug, to which is

attached the inner tube by a swivelling connection, whereby it can be readily withdrawn. Both plugs and caps can be easily removed for inspection and cleaning. It is generally sufficient to remove the front plug and withdraw the inner tube once a year for washing out by means of a hose applied to the outer end of the inner tube *in situ*.

Fig. 54 shows the arrangement of the header and evaporating tube ends.

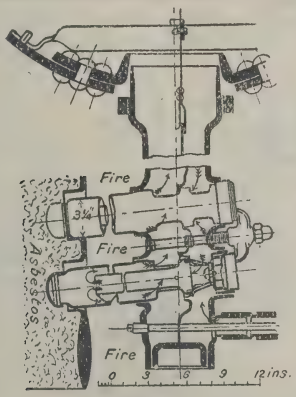

FIG. 54.

No expanding of the tubes into the headers is required, as the joints are made by coned metal-to-metal surfaces, which are formed by special machinery, positively ensuring accurate fitting and interchangeability. The same Niclausse system of jointing is adopted for the connection of the headers to the drum, and it is found to be perfect under the highest working pressures, no jointing material being required.

Owing to the foregoing special constructional features the boiler can be rapidly erected without expert services, and a special feature of the boiler is that any tube can be withdrawn and replaced within a few minutes.

Fig. 55 shows the tools used for inserting and withdrawing the tubes, which can be easily handled by one man.

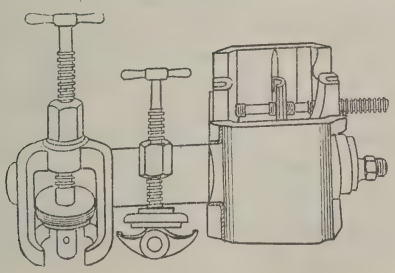

FIG. 55.

The header is divided into two compartments, of which the front communicates with the inner tube and the back with the annular space between it and the outer tube, through corresponding oblong ports cut in the outer tube.

Fig. 56 shows the system of feed distribution. This arrangement ensures that the lower tubes are always supplied with hot and purified feed water and that the deposit of impurities contained in the feed can mainly take place in the trough located for that purpose in the drum. What little escapes from the drum trough harmlessly, settles in the upper tubes (where the temperature is low) and produces only soft mud, which can easily be removed by washing out. The interior surfaces are thus always in a clean and efficient condition.

It will be seen from fig. 56 that the feed water is injected into the steam space against suitable baffles, whence it falls into a trough, which extends throughout the length of the drum, distributing the feed evenly over all the headers.

This method of injecting the feed water has the advantage of liberating contained air, with the result that the deterioration of tubes in this boiler is practically non-existent, their life being anything from 12 to 15 years.

The pressure parts, consisting of tubes, headers, and drum, are supported upon a framework of light structural steelwork, which relieves the relatively small amount of brickwork

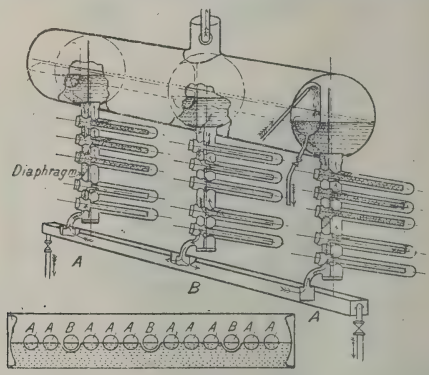

FIG. 56.

required, of all stress, whilst all the pressure parts are perfectly free to expand and contract in any direction, the tubes and headers being held only at one end.

The weight of the boiler and the amount of brickwork it requires is relatively low, the largest piece being the drum, whose diameter invariably is 1 metre, and whose length is proportionate to the number of headers employed.

A very important feature of the boiler is that the means employed for cleaning the exterior surfaces are so simple and easily applied that cleaning is usually done every day, so that

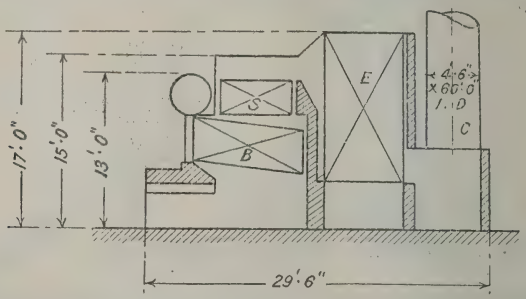

FIG. 57.

the heating surfaces are always in a clean condition, resulting in a very high average efficiency during regular work. External cleaning is done by means of a steam lance inserted through the front doors and headers, which have suitable passages provided in them for this purpose. This process of lancing can be effected within half an hour by one man, without his having to open any doors and interfere in any way with the operation of the boiler.

Another advantage of this boiler is that it gives an exceptionally high capacity per square foot of ground occupied and per cubic foot of space occupied. The depth and height remain constant,

OVER ALL OTHER TYPES OF WATER TUBE AND CYLINDRICAL BOILERS

THE SINGLE HEADER
PREMIER
SHORT STRAIGHT TUBE

NICLAUSSE

(Entirely Franco-British).

Ensures the following advantages :—

1. Larger grate area immediately under the tubes.
2. Greater capacity per sq. ft. of ground space and less height.
3. Cleaner Heating Surfaces—ever clean inside and outside.
4. Higher average efficiency in regular service.
5. Quicker change of a defective tube—in one hour.
6. Shorter annual overhauls—2 days all tubes out and in.
7. Lesser necessity for spare boiler equipments.
8. Hotter and purer feed to tubes next to grate.
9. Earlier steam at full load ($\frac{1}{2}$ hour)—lesser banking.
10. Better circulation, in the correct way *only*—no surging.
11. Freer expansion and contraction of all parts.
12. Heavier overloads without fear of tube troubles.
13. Lower maintenance and operation charges.
14. Cooler and cleaner boiler-houses.
15. Lighter deadweight in metal and brickwork—cheaper
16. Closer arrangement of Boilers—saving space. [transport.
17. Easier cleaning facilities.
18. Cheaper Steam.

WEDNESFIELD, Nr. WOLVERHAMPTON.

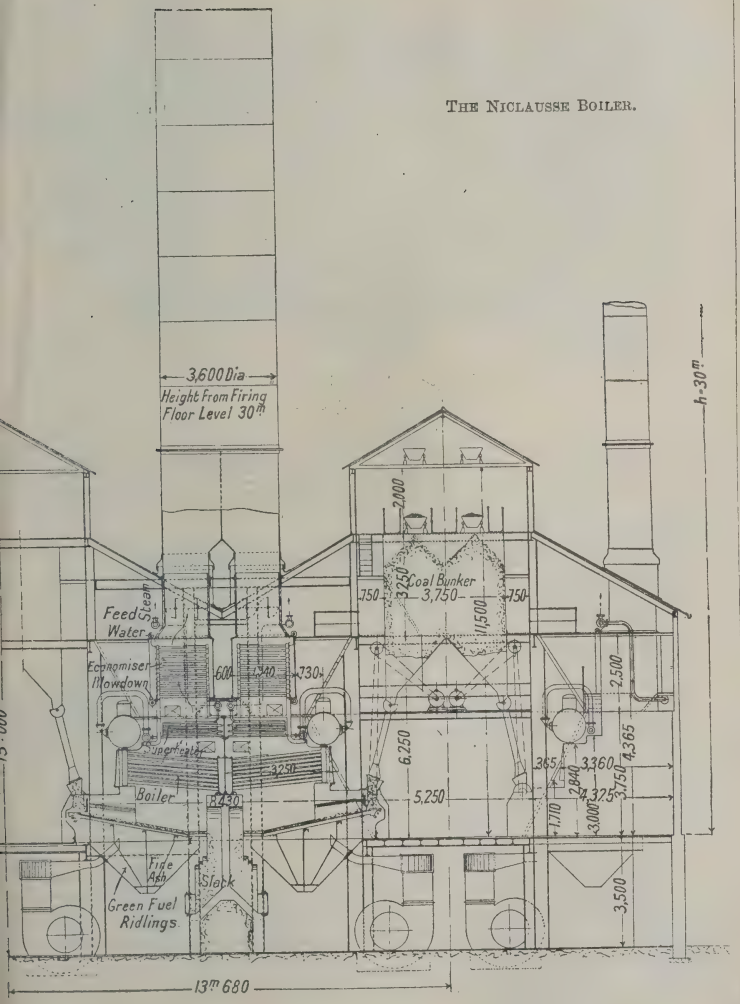

FIG. 58.

Arrangement of Niclausse Boilers, Stokers, Superheaters, and Economisers, in Power House Service.

the width only varying, according to the number of headers employed in proportion to the capacity.

The boilers may be placed back to back, since all parts can be withdrawn entirely from the front, consequently for modern power house equipments and large units the exceptionally compact arrangement shown in fig. 58 is attainable.

In cases as at Rotherham and Southend Electricity Works, where cast-iron economisers are used these can be arranged directly at the back of the boiler, as shown in fig. 58. The firm advocates, in preference to this, their integral type equipment, as at St. Pancras Electricity Works, comprising boiler with superimposed sectional superheater, and steel tube economiser, with forced draught stokers and induced draught short chimneys, as shown in fig. 59, the draught requirements being very moderate.

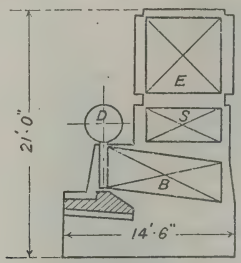

FIG. 59.

The arrangement, fig. 57, p. 1484, gives, for boiler with chain grate stoker, a normal production per square foot of ground space occupied of 95 lbs. of steam per hour from and at 212° F. For boiler, stoker, cast-iron economiser, chimney, and fan, a production of 53 lbs. can be obtained. The normal production per cubic foot of space occupied by the complete equipment is 3·5 lbs., taking overall dimensions.

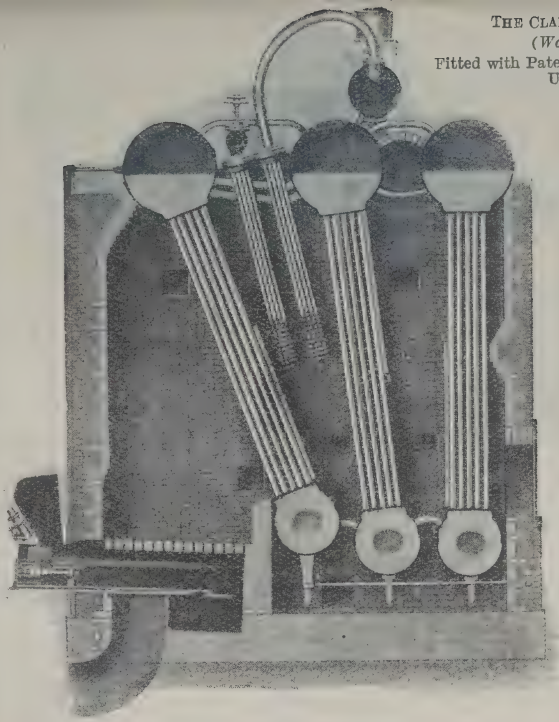
The arrangement shown in fig. 59 gives a normal production of 130 to 150 lbs. per square foot of ground space occupied, depending upon the types of stokers employed.

The firm's latest high duty marine type boiler (see page 2020) is also applicable for land service. Test performances of this boiler (showing its high efficiency) were given in detail in the 'Engineer' of March 13, 1914, and in the Journal of the Institution of Mechanical Engineers, July, 1914.

THE CLARKE-CHAPMAN BOILER.

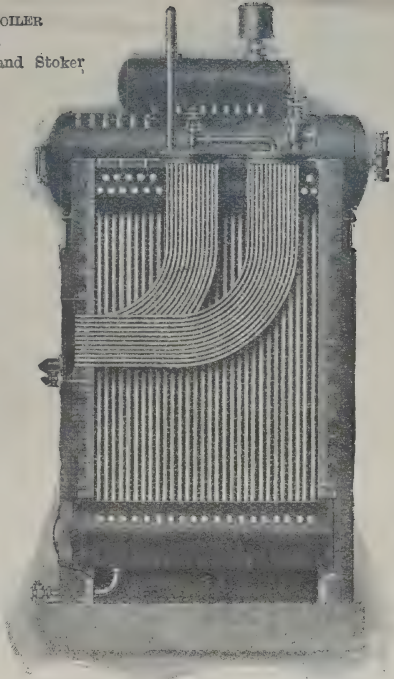
(Woodeson's Patent.)

The 'Woodeson' Patent Water-tube Boiler, as shown by fig. 60, is manufactured by Messrs. Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne, and consists of three sections, each comprising steam drum, water drum, and a number of groups of tubes expanded into same; these tubes are nearly vertical and perfectly straight, and manholes are arranged on steel drums immediately over each group through which any tube can be withdrawn.



A spacious steam dome is arranged over the steam drums to ensure a supply of dry steam and to maintain a steady water level. The bottom drums are absolutely hanging so that expansion and contraction can take place without effecting any damage to boiler.

The boiler as shown is also fitted with a Clarke-Chapman Patent Superheater between the front and centre sections.



In the design of the 'Woodeson' boiler, a special feature is the ease of access for purposes of examination or repairs, the time which has to be expended on same being practically reduced to a minimum; thus in a boiler of say 6,100 square feet of heating surface, containing 456 tubes, the only work to be done to thoroughly examine the insides of this large number of tubes for their total length is the removal of the manhole door on one end of each bottom drum and one manhole door off each of the three steam drums: thus access can be gained to every tube, and these being perfectly straight they can be thoroughly examined for the whole of their length. The removing and replacing of the manhole doors can be done by an ordinary fireman, no skilled mechanic or complicated tools being required. There is an entire absence of screwed joints in the boiler.

Each tube being nearly vertical and perfectly straight and entering the steam drum direct without intervention of any headers, ensures a perfect steam release, and so adds to the efficiency of the boiler, as there are no sharp turns to retard flow of the steam globules to the steam space. Also, deposits are not retained in the tubes, but are collected in the large mud-drums: thus over-heating and destruction of tubes are reduced to a minimum.

(Woodeson's Patent).
Fitted with Patent Superheater and Stoker
Underfeed Type.

Front Elevation.

Side Elevation.
(Showing Superheater in position.)

FIG. 60.

THE STIRLING BOILER.

This boiler (fig. 61) consists of two or more steam drums connected by banks of tubes, 3½ ins. outside diameter, to one or more mud drums, the tubes being sufficiently curved to allow them to enter the drums radially. These curves, which are all to the same radius, while materially simplifying the manufacture of the boiler, provide as their main object against any evil results that might be caused by expansion or contraction.

All the upper drums are connected by steam-circulating tubes, but the front and middle drums only are connected by water-circulating tubes.

The tubes employed are of mild steel, and are subjected to a hydraulic test-pressure of 1,000 lbs. per square inch before leaving the maker's works.

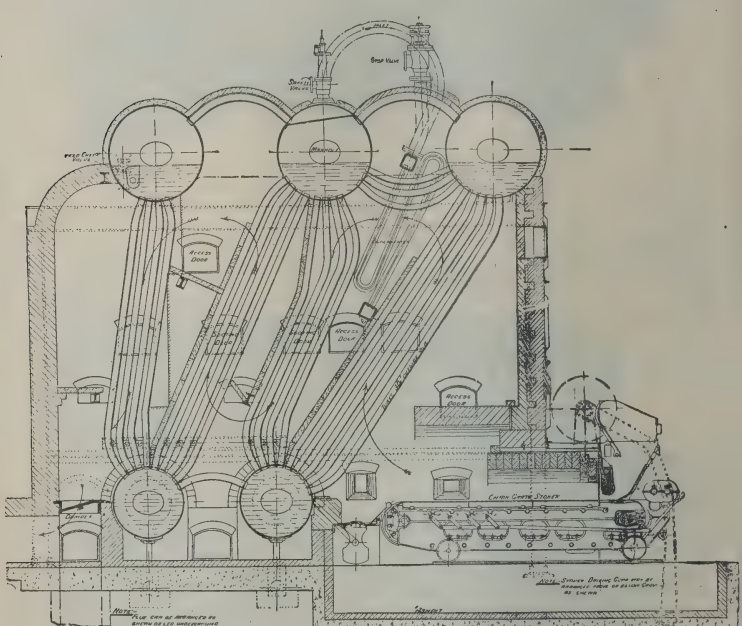

FIG. 61.

The drums are made of the best quality open-hearth boiler steel.

All portions of the boiler are circular in form, so that there can be no tendency to deformation of any part owing to internal pressure.

Each tube has a discharge outlet of its full area for the escape of the steam as generated, so obviating steam pocketing in the tubes, with its attendant risks of blistering, etc., whilst the circulation is rapid, free, and continuous.

The drums and banks of tubes are so arranged that the water in the steam drum, from which the steam supply is taken, is in a state of quiescence, ensuring an absence of priming and an unusually high dryness factor for the steam.

The feed water is introduced into the top rear steam drum, and practically throughout the whole course of its progress through the boiler is travelling in a direction opposite to that taken by the gases, thus securing a very efficient heat transfer throughout the whole surface of the boiler.

The boiler is entirely independent of the brickwork, the upper or steam drums being carried on a steel framework, while the mud drums are supported by the tubes from the upper drums and left free to allow for contraction and expansion.

* These weights do not include furnace fittings.

The overall sizes of a Stirling boiler of a given heating surface can be arranged to suit varying conditions—e.g. a boiler to evaporate 7,000 lbs. of water per hour can be built to occupy from 12 to 20 ft. in height, 7 to 15 ft. in width, and 14 to 21 ft. in length. The boiler can therefore be adapted equally well for boiler-rooms with low ceilings and ample width as for those having little width but ample height.

A marine type of boiler is supplied for land work when the space available is limited.

Taking the average of a great number of tests on the Stirling boiler extending over a period of many years, the efficiency of the boiler runs out from 75 to 78 per cent.

This type of boiler will give satisfactory results with all classes of fuel, and it is much adopted for the utilisation of waste heat, whether in the form of blast-furnace gas, waste heat from coke ovens, heating and puddling furnaces, and the like. It is also largely employed on sugar estates abroad, fired with megass in special furnaces.

THE GALLOWAY FIVE-DRUM WATER-TUBE BOILER.

This is generally similar to the 'Stirling' type boiler, and has been designed for large units and high efficiencies. The arrangement is easy to keep clean internally.

The 'Thompson' Water-Tube Boiler.

('Sinclair' Patents.)

This boiler (fig. 62) consists of either two, four, six, or eight drums, one, two, three, or four at the top for steam and water, and a corresponding number at the bottom. Each series of drums is brought into communication one with the other by a number of short tubes, whilst large, straight tubes, set nearly vertically, connect the top drums with those at the bottom. By this means the water, which is fed into the boiler from the back of the steam and water

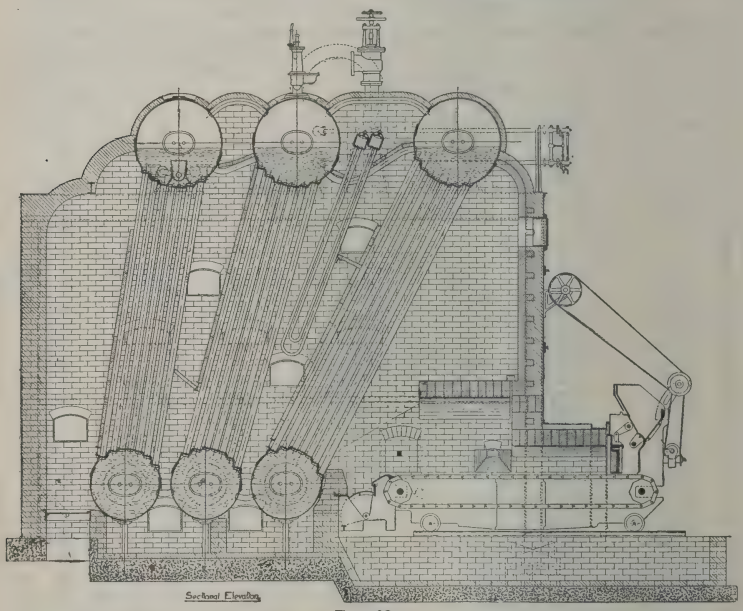

Fig. 62.

drums, passes down the back row of tubes, each of which has a discharge outlet equal to its full area, and thus affords a free, rapid, and continuous circulation which in its turn prevents the deposit of scale on the heating surface of the tubes.

The eight-drum type of boiler is known as the Integral Economiser Boiler, the back or fourth bank of tubes being the Economiser.

The drums (fig. 63), made of mild steel, are longitudinally divided into halves—that proportion which receives the tubes, being hydraulically pressed into a series of flats, forms a right-angled surface and bearing to each tube—consequently, each tube being in its own pocket, any breathing or leakage is obviated.

The following points are special features:—

1. *Tubes.*—The tubes are so arranged, as to spacing, that any one tube may be removed and replaced without in any way disturbing any others.

The tubes are all passed in and out of the boiler by way of the fire-door opening, thus saving the necessity for extra head room.

Each tube can be examined throughout its whole length by holding a lamp at one end.

2. *Drums.*—The steam and water-drums are of a large and ample capacity, so essential for the obtaining of dry steam.

Any scale that may be deposited in the boiler falls into the mud-drums at the bottom.

3. *Boiler.*—The boiler is suspended from steel girders which rest on steel columns based in cast iron; it is thus entirely independent of the brickwork, ensuring freedom for expansion in every part, and enabling the brickwork to be removed and replaced, if necessary, without in any way disturbing the boiler or its connections.

The largest size of these boilers can be cleaned and restarted in full work within the period of three days, there being only six manhole joints to be made.

* These weights do not include furnace fittings.

THE BABCOCK & WILCOX PATENT WATER-TUBE BOILER.

STANDARD LAND TYPE.

The structure of this boiler (figs. 64, 65), composed entirely of wrought steel, may be practically considered as having three distinct parts, namely:

A series of inclined water tubes placed over the furnace, in which the water, being divided into small volumes, is quickly raised to a high temperature and rises, at the front end, through vertical connecting boxes or headers (into which the tubes are expanded).

A horizontal steam and water drum, up to which the water rises from the headers, and where the steam separates from the water, the remaining body of water returning through the vertical tubes and headers at the back end into the inclined water-tubes, where it is again subjected to the action of the fire, and again passes into the steam and water drum; thus, a continuous and rapid circulation is kept up, and a uniform temperature maintained throughout the boiler.

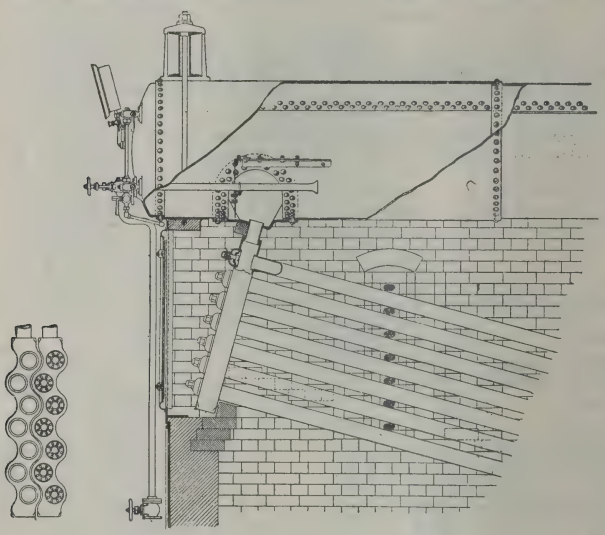

FIG. 64.—Vertical Section showing details.

A *mud-collector* is attached to the lowest point of the inclined water-tubes, into which the matter held in suspension in the water is, to a large extent, precipitated by its specific gravity.

The inclined water-tubes are of steel and the headers at each end into which they are expanded are sinuous (or staggered) and of mild steel, each complete section consisting of one zigzag row of tubes, expanded into a rear and front header. The headers are provided with handholes placed opposite the ends of each tube to permit of cleaning, and, in case of need, the removal of a tube, each handhole being provided with a cap fastened with a wrought steel bolt and clamp and a cap nut, the handhole covers being placed metal to metal. The top ends of each section are connected to the steam and water drum, not directly, but are first expanded into specially designed cross-boxes, which in turn are riveted to and extend from the underside of the drum at each end. The steam and water drum is made of the best selected mild steel double riveted for ordinary purposes; the mud drum is made of mild steel, and is provided with ample facilities for cleaning.

The entire boiler, except the furnace, is suspended by wrought iron slings, from iron girders resting on wrought iron columns, to allow the boiler to expand or contract without straining the brickwork. The boiler and furnace are enclosed in masonry lined with firebrick, the furnace being arranged below the tubes, and firebrick baffles compel the hot gases to pass upwards, then downwards, then upwards again before escaping to the chimney. These hot gases strike the tubes at right angles, thus intercepting the radiant heat from the fuel as effectively as possible; the tubes being zigzagged, the gases are thoroughly broken up as they rise, and, passing into the

F. 1493

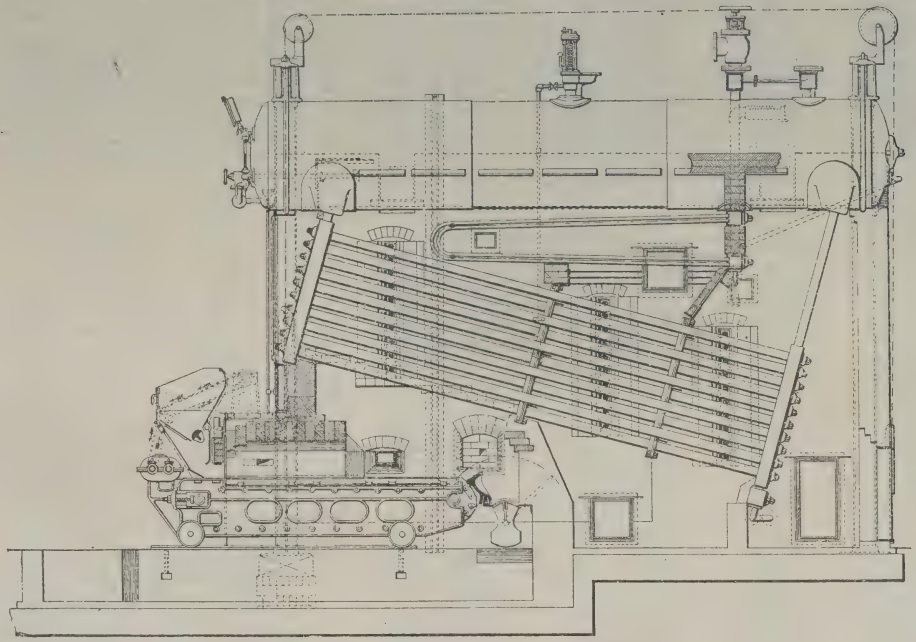

FIG. 65.—Boiler fitted with Superheater and Stoker.

combustion chamber under the drum, they expand and combine before again passing the second and third time through the tubes and on to the flue; thus complete combustion, rapid steaming, and consequent economy are secured.

The damper for regulating the draught and flow of the gases is placed in the back chamber, whilst doors for cleaning the tubes and removing soot are placed on one side of the brickwork.

A comparison of space is afforded by a new electricity works, where six Lancashire boilers, evaporating 48,000 lbs. of water per hour, are placed beside four Babcock & Wilcox boilers of the above type, evaporating 40,000 lbs. of water per hour under the same conditions. The ground space occupied by each range of boilers is in the ratio of 10 for Lancashires to 4½ for Babcock & Wilcox boilers.

CROSS-TYPE BOILER.

The general construction of this form of boiler is the same, but the drum is placed transversely, instead of longitudinally, with the tubes, and the whole boiler is constructed in pieces of comparatively light weight suitable for transport in countries where ordinary means of carriage are not available.

PORTABLE BOILER.

This form is similar to the last described, but is still further sectionalised in the drum portion, which is arranged to be riveted up on site. The boiler is also provided with an iron casing lined with firebrick, and is thus self-contained and independent of the brickwork. This type is also used for countries where transport and facilities in the matter of construction are not available.

In addition to the above types, the boilers are arranged with special furnaces for burning sawdust, lignite, rice husks, bagasse, coke breeze, refuse, coal, gas, and oil fuels.

MARINE TYPE BOILER.

In general construction this boiler (see Section XXXIII) is similar to the foregoing, but with the steam and water drum placed transversely and brought to the front. The principal difference between this boiler and those already described is the largely increased grate area, enabling the boiler to give a greatly increased evaporation per square foot of heating surface compared with the other types.

The 'C T' marine type of boiler, of large evaporative capacity, is fitted with a superheater, chain-grate stoker, and superposed economiser, for evaporating up to 120,000 lbs. of water per hour.

The Howden Boiler

This boiler (*The Howden Boiler Co.*), fig. 66, combines an evaporation from plate surfaces, as in ordinary boilers, with that from water-tubes. One boiler may consist of one, two, three, four, or more elements, all parts being made to standard gauges. By the removal of eight manhole doors, the whole of the internal working parts of the boiler, that is top and bottom drums and tubes, are at once open for examination and cleaning when necessary. All the tubes being short and straight, they can all be examined in each element in a few minutes. For outside

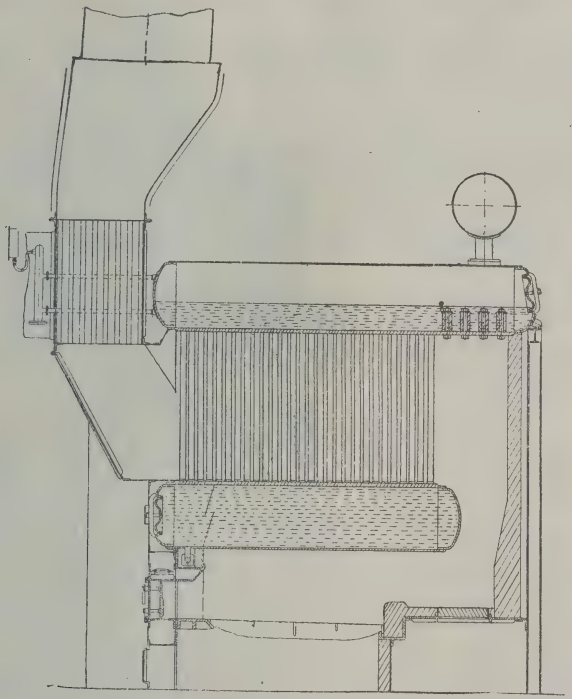

Fig. 66.

examination the side portable doors can be quickly opened or removed, also the smokebox doors, and, further, the combustion chambers are accessible by manholes from their under side, from which the back end tubes can be examined.

All the parts of the boiler when working are under an equal heat, that is, there are no parts hotter and others colder as in cylindrical multitubular boilers or ordinary water-tube boilers, and in raising steam from cold water all parts are brought under heat at same time, thus relieving the boiler from all unequal strains.

The design of the boiler gives it, all over, a rapid positive natural circulation without any piping or other adjuncts, and it is further self-cleansing internally in its water tubes, and likewise in the drums where the water is in a continued rapid circulation all over the surfaces exposed to the hot fire gases.

A No. 1 four-element boiler is capable of evaporating 20,000 lbs. of water per hour from a grate surface of 54 sq. ft., with a good bituminous Scotch steam coal, and a total heating surface of 3,125 sq. ft., under a steam pressure of 200 lbs. from a low temperature of feed water.

The 'Spencer-Hopwood' Patent Boiler.

This, a vertical boiler with inclined water-tubes (manufactured by *Messrs. Spencer-Bonecourt, Ltd., London and Hitchin, Herts.*), has the tubes spread immediately over the fire, making it extremely rapid in steam raising; 100 lbs. pressure per square inch can be obtained from cold water in the boiler in thirty-five minutes from the time of lighting the fire. A number of man-doors of the McNeil type are provided opposite both ends of the nest of tubes, giving easy access to them and also to the entire interior of the boiler for cleaning and renewal purposes.

The standard 'Spencer-Hopwood' patent boiler will evaporate from 50 to 100 per cent. more steam than a vertical cross-tube boiler of the same dimensions.

This boiler is also made in a squat pattern for use where head room is limited, and most modern railway breakdown cranes are fitted with it.

Recently a new and improved 'Spencer-Hopwood' patent boiler has been put on the market, having a much deeper nest of tubes than in the standard pattern, resulting in a higher thermal efficiency and still smaller space required for the output. In the smaller sizes this is done by arranging the major axes of the manholes in a vertical direction instead of the usual horizontal one, and using more than two, thus deepening the nest of water-tubes 33 per cent. In the larger sizes there are two or three rows of manholes which enables the nest to be deepened as much as 300 per cent. Further, by the use of more than two manholes per row of manholes, the width of the tube nest can be increased to anything desired, enabling these boilers to be made up to 8 ft. 6 ins. diameter and over, to evaporate up to 10,000 lbs. of steam from and at 212° F. per hour, so that they can be installed to do the work of a Lancashire boiler and to give as high an efficiency, without the floor space, without the brick setting, without the chimney, and without the necessity of taking hours to raise steam.

Where superheated steam is required, a superheater can be supplied for all sizes, that for the small sizes being arranged in the uptake, and that for the large sizes arranged in the centre of the deep water-tube nest.

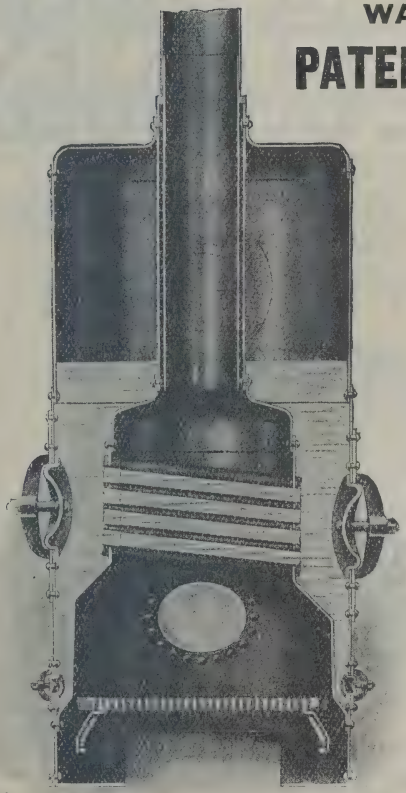
32	4,900	6,700	12 6	8 0	270	22	1,700	2,500	9 0	5 6	100

The evaporations given are based on actual tests with 5 ft. of chimney only, feed water at 212 deg. F., steam at 100 lbs. pressure per square inch, and good steam coal.

Induced draught is obtained from a steam jet included with the boiler mountings.

The new deep nest pattern will exaporate from 20 per cent. to 25 per cent. more steam than the standard pattern of the same diameter.



These boilers fired with oil evaporate 25 per cent. to 30 per cent. more than they do when fired with coal.

The Yarrow Water Tube Boiler.

This well-known boiler, which has been widely adopted in marine practice, is now being developed for land work. Several installations for land purposes have already been made, including one unit of about 11,000 square feet total heating surface, for a power station on the Tyne.

Life of Boilers.

Lancashire and Cornish boilers last about 30 years, although there are cases in which Lancashire and Galloway boilers (with dirty, but not very scaly, water) have lasted for 50 years. Water-tube boilers (subject to a good deal of re-tubing) may be taken to last 20–25 years. Marine boilers, if properly treated and taken care of, should last at least 20 years under forced draught, and 25 years under natural draught.

The life of any boiler depends, naturally, upon the degree of care with which it is handled.

BOILER FITTINGS.

SAFETY VALVES.

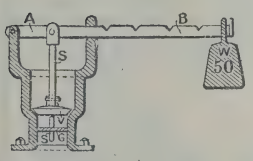

FIG. 67. B, lever; A, short arm of lever; SS, stem; V, valve; G, guide; W, weight.

To find the Weight necessary to put on a Lever, when the Area of Valve, Pressure, &c., are known.

If A = area of valve in sq. ins., P = pressure in lbs. per sq. in., l_1 = distance of valve from fulcrum, l_2 = length of lever, w_1 = weight of lever in lbs., l_3 = distance of centre of gravity of lever from fulcrum, w_2 = weight of valve and stem in lbs.

Then W, the weight required at the end of the lever,

$$= \frac{P \times A \times l_1 - w_1 \times l_3 - w_2 \times l_1}{l_2}.$$

SAFETY VALVE AREAS.

Since the steam production of a boiler is sensibly the same at all pressures, and since the density of steam increases very nearly as the pressure, and since steam escapes at an outlet at practically constant volume, it appears that safety valves, like boiler stop valves, may be reduced in size as pressure increases. Ordinary valves have a very small lift. Special valves in which the steam reaction is utilised to increase the lift will give a much greater opening. If a valve lift a height equal to a fourth of its diameter the area of opening is equal to the valve area, and no greater lift would give greater output.

It is not sufficiently well known that boilers working at a low pressure require larger safety-valves than boilers at a high pressure. Thus, for example, a boiler working at 15 lbs. by the steam gauge requires three times the area of safety valve opening that is required by a boiler at 75 lbs. This is the more important when it is remembered that in a boiler which is safe only at low pressure, an additional 15 lbs. pressure doubles the strain, whilst in the boiler at 75 lbs. a rise of 15 lbs. adds but a fifth to the stress on the plates. This point as to the safety-valves on old low-pressure boilers is too little known or recognised.

Safety-valve areas should be inversely as the absolute pressure.

In well-proportioned dead-weight safety valves it is usually expected that if a pressure of 60 lbs. per sq. in. opens the valve, a pressure of 70 lbs. will keep it sufficiently open for the escape of all the steam produced.

For the rules applicable to safety valves, see 'Standard Conditions for Marine Boilers,' p. 1416.

The former Board of Trade rules are largely followed, and as they are more detailed, bringing out many points of importance, extracts are given below, also extracts from the rules of Lloyd's and Bureau Veritas.

BOARD OF TRADE RULES FOR SAFETY VALVES.

The area per square foot of fire-grate surface of the locked-up safety valves for boilers with natural draught should not be less than that given in the table (page 1499) opposite the boiler pressure intended, but in no case should the valves be less than 2 ins. in diameter.

When ascertaining the fire-grate area, the length of the grate should be measured from the inner edge of the dead plate to the front of the bridge, and the width from side to side of the furnace on the top of the bars at the middle of their length.

[*Note.*—The table corresponds to the formula $A = \frac{37 \cdot 5}{P + 15}$, where A = safety-valve area in sq. ins. per sq. ft. of grate, and P = pressure in lbs. per sq. in.]

Where forced draught is used, the area should not be less than $\frac{A}{20} \times$ estimated coal consumption in lbs. per hour per sq. ft. of grate.

The safety valves should be fitted with lifting gear, so arranged that the two or more valves on any one boiler can at all times be eased together, without interfering with the valves on any other boiler. The lifting gear should in all cases be arranged so that it can be worked by hand either from the engine-room or stoke-hole.

Care should be taken that the safety valves have a lift equal to one-fourth their diameter; that the openings for the passage of steam to and from the valves, including the waste-steam pipe, have each an area not less than the area according to the table; and that each valve box has a drain pipe fitted at its lowest part.

In the case of lever valves, if the holes in the lever are not bushed with brass, the pins must be of brass; iron and iron working together must not be used.

Too much care cannot be devoted to seeing that there is proper lift, also that free means of escape for the waste steam are provided, as it is obvious that unless the means for escape of the waste steam are ample, the effect is the same as reducing the area of the valves or putting an extra load upon them. The valve seats should be secured by studs and nuts.

At least two valves should be fitted to each boiler.

The springs and valves must be so cased in that they cannot be tampered with.

Provision must be made to prevent the valves flying off in case of the springs breaking.

The requisite safety-valve area must be cased in and locked up in the usual manner of the Government valves.

The size of the steel of which the springs are made must be in accordance with that found by the following formula.

$$d = \sqrt[3]{\frac{L \times D}{C}}.$$

Where,

L = the load on the spring, in pounds:
D = the diameter of the spring—from centre to centre of wire—in inches.
d = the diameter, or side of square, of the wire, in inches:
C = a constant, being 8,000 for round and 11,000 for square steel.

The springs must be protected from the steam and impurities issuing from the valves.

When valves are loaded by direct springs, the compressing screws must abut against metal stops or washers, when the loads sanctioned by the surveyor are on the valves.

The springs must have a sufficient number of coils to allow a compression under the working load of at least one quarter the diameter of the valve.

Spring-loaded valves are tested under full steam and full firing for at least twenty minutes with the feed-water shut off and stop-valve closed.

When the valves are of novel design, and the accumulation of pressure exceeds 10 per cent. of the loaded pressure, the case has to be specially reported upon by the surveyor.

Lloyd's Rules and Regulations for Safety Valves.

Two safety valves to be fitted to each boiler, and loaded to the working pressure in the presence of the surveyor. In the case of boilers of greater working pressure than 60 lbs. per square inch, the safety valves may be loaded to 5 lbs. above the working pressure. If common valves are used their combined areas to be at least half a square inch to each square foot of grate surface. If improved valves are used, they are to be tested under steam in the presence of the surveyor; the accumulation in no case to exceed 10 per cent. of the working pressure.

An approved safety valve also to be fitted to the superheater.

In winch boilers one safety valve will be allowed, provided its area be not less than half a square inch per square foot of grate surface.

Each valve to be arranged so that no extra load can be added when steam is up, and to be fitted with easing gear which must lift the valve itself. All safety-valve spindles to extend through the covers and be fitted with sockets and cross handles, allowing them to be lifted and turned round in their seats, and their efficiency tested at any time.

Bureau Veritas Rules and Regulations for Safety Valves.

At least two spring safety valves of an approved design must be fitted to each main boiler. The total area of the safety valves is given by the formula

$$A = \frac{8{\cdot}7}{\sqrt[3]{(P - 18)^3}}$$

where,

A = sectional area of safety valve in sq. ins. per sq. ft. of grate surface; P = working pressure in lbs. per sq. in. No safety valve to be less in diameter than 1¼ in.

When forced draught or oil fuel is provided for, the area is to be increased in proportion to the increased evaporative power of the boilers.

Suitable arrangements and gear to be fitted in connection with the safety valves, whereby they may be lifted from the deck as well as from the stoke-hole floor.

WATER GAUGES.

The breakage of a water-gauge glass in high-pressure steam boilers is fraught with danger, especially in places where the attendants are working in confined places from which it is difficult for them to escape, and any appliance which prevents the serious consequences arising from this cause is one of the most important and desirable safety fittings that can be attached to a steam boiler.

WINN'S ASBESTOS-PACKED WATER GAUGE.

(Patent.)

In Winn's Patent 'Reliable' Asbestos-packed complete Automatic Water Gauge (fig. 68), when the glass breaks, automatic valves in both top and bottom arms instantly close, and shut off the water and steam. Both top and bottom arms can be blown through for cleaning, the

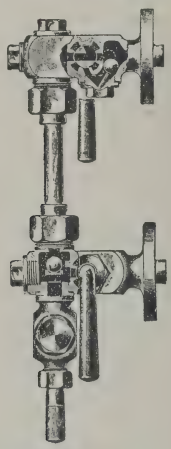

FIG. 68.

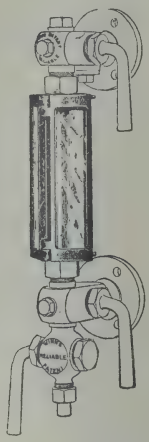

FIG. 69.

automatic valves in no way interfering with this operation; also, clearing-rods can be passed through the passages into the boiler unobstructed. The automatic valves cannot cause false water level to be shown. *(Charles Winn & Co., Ltd.)*

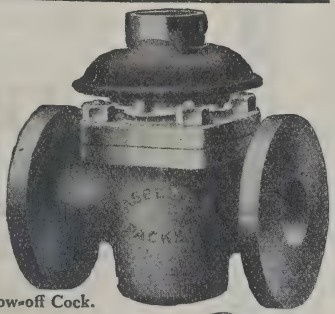
WINN'S GAUGE-GLASS PROTECTOR.

(Patent.)

Winn's Patent Reliable Gauge-glass Protector (fig. 69) is formed in halves hinged at the front, and is thus readily attached by means of thumb clips to spigots projecting from the faces of the glass gland nuts, which enables the glass nuts to be adjusted without removing the Protector. This is an important improvement, as it ensures absolute protection to the attendant at a time when the gauge-glass tube is most likely to fracture.

The plate sight glasses are easily removed for cleaning by opening the thumb clips without the use of tools. Fig. 69 shows the Two-glass Model Protector; but a four-glass model is also made specially suitable for locomotives.

Both patterns give absolute protection from personal injury by broken gauge glasses, and large numbers are in use. *(Charles Winn & Co., Ltd.)*



THE 'RELIANCE' GAUGE-GLASS PROTECTOR.

This protector *(United Brassfounders and Engineers Ltd.)*, which can easily be fitted to existing mountings, is a simple but strong and effective safeguard against accident due to bursting glasses. The plate-glass sides are made from specially toughened glass and subjected

to Admiralty tests. Special glasses with embedded wire netting are made, thus adding considerably to the strength and safety of the protector. The Reliance protector can also be fitted with an enamelled iron back plate (fig. 70) having black and white diagonal lines across same, which when looked at from front of gauge are magnified greatly up to the water level,

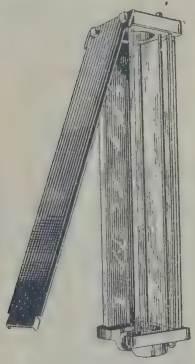

FIG. 70.

FIG. 71.

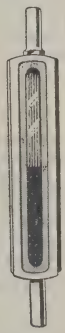

FIG. 72.

thus showing the correct level distinctly at a glance (fig. 71). These back plates are provided with a hinge-like attachment at the top, which allows the plate to swing free in the event of the glass tube bursting, and thus prevents any possibility of sudden accumulation of pressure injuring the plate-glass sides of the protector.

'REFRAX' WINDOW WATER LEVEL

This arrangement, fig. 72 (*United Brassfounders and Engineers Ltd.*), is a gauge glass and a protector combined and is self-contained. It can be fitted to any existing gauge mounting. Owing to its special construction the water appears black, while the steam space shines like silver. The water level is therefore shown at a glance and cannot be mistaken. Two types are made and stocked, suitable respectively for large and small boilers.

HULBURD'S CARTRIDGE SIGHT GLASSES.

(*Patent.*)

A neat and efficient device for protecting and rapidly removing and replacing sight glasses in water gauges and sight-feed lubricators is provided by Hulburd's Patent 'Cartridge' System (fig. 73). In Hulburd's make of gauge frames and lubricators the glasses are packed at leisure in metallic guards or sheaths, each thus forming a self-contained 'cartridge' from which the system derives its name. In the event of breakage of a glass the complete cartridge, containing the broken fragments, is easily withdrawn while under steam, and a new one readily inserted in its place. The metallic guard or cartridge case enables all splinters of glass to be removed without danger to attendants, and permits the immediate screwing up of the gland nuts without the possibility of fracture, the metallic cartridge case receiving the gland pressure and completely protecting the glass tube within it. Suitable windows are provided in the cartridge case of ample size to afford an unobstructed view of the glass tube and contents, and in the case of gauges the back is arranged as a water level indicator of special design, which shows with peculiar distinctness the height of the water column and makes it impossible to mistake an empty glass for a full one.

FIG. 73.

'WOODITE' PACKING.

The material known as 'Woodite' (*The Woodite Co.*) is of a special secret composition to resist the action of high or low pressures, whether of steam or water, and is impervious to acidulated

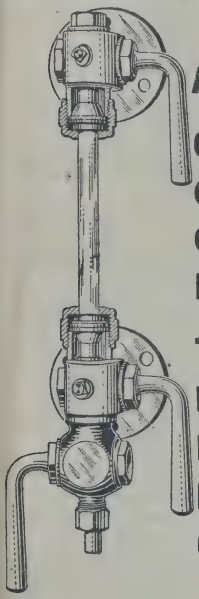
or other chemically impure fluids. 'Woodite' is made to any shape or size and of a quality of flexibility to suit the service to which it is to be applied. It has been extensively employed for conical gauge-glass rings, packing rings, pump valves, hydraulic packings, gaskets, etc., with most satisfactory results. The chief advantages of the Woodite conical gauge-glass and packing rings for steam users are their ease of application or renewal, the maintenance of a perfectly tight joint, the entire avoidance of unnecessary pressures on the glasses or rods, which causes breakages in the former and excessive friction in the latter, and the elimination of the dangers incident to steam or water passages becoming choked in the case of gauge glasses. On large slow-moving boiler feed-pumps these conical packing rings have shown excellent results and economy, working at 135 lbs. steam pressure with superheat, the piston rods being 3⅝ ins. diameter.

Ordinary valve spindles packed with these packings will always be found free to move, no matter how long the valve has been idle.

Defects in Water Gauges.

As ordinarily fitted, the gauge is usually attached directly to the boiler and provided with three taps, one connecting to the steam space, the second to the water space, and the third controlling the discharge to atmosphere. The latter should always discharge inside the boiler-house, where the effluent can be seen, and not be as it sometimes is, with a mistaken idea of cleanliness, coupled to a waste pipe, led outside, where the evidence of its action is not visible when the attendant opens the tap. It is of value to have duplicate gauges, as the cost is comparatively trifling, and one gauge serves as a check on the other. All three taps should be tested independently, that is to say, the bottom tap should be shut while the top one is opened and *vice versa*, the top one shut while the bottom is opened, so as to give a thorough 'blow through' of the steam and water connections to the boiler. Unless this is done there is no certainty of the gauge being in working order, while there is risk of the top and bottom connections becoming choked and causing a false reading. More than one serious accident has been traced to defects in the taps themselves, owing to the holes in the plugs of the taps not coinciding with the thoroughfare of the fitting, so that when the position of the handle suggests the tap is open it is in reality nearly closed. Another cause of false readings is the blocking of the passage in the glass tube through the indiarubber packing ring working over the ends of the glass, owing to the glass being cut too short and the gauge not being provided with a nipple in the bottom of the gland to protect the glass against this risk. Having regard to the serious results which may attend overheating from shortness of water, it is advisable whenever possible to supplement the water gauge with a fusible plug, and if the boiler is a large one, with a low-water safety-valve as well. (*Mechanical World.*)

Gauge Glasses.



It is important to have the fittings exactly in line with each other, and to have them large enough so as not to cause the glass to bind or to be cramped in the least. When the fittings are not in line the glass is apt to be cramped either when putting it into the sockets in the fittings or when tightening the packing nuts. Wrenches should not be used for tightening the packing nuts around the gauge glass. When a glass is packed with the proper kind of packing and the nuts have been screwed up just tight enough to prevent leakage when both the glass and the packing have been warmed, the glass may readily be turned around in the fittings with merely the thumb and forefinger.

After putting in a new glass turn on a very little steam, leaving the drip at the bottom of the glass open so that the steam will gradually fill the glass and escape through the drip-cock. The glass is thus warmed thoroughly before the water is let into it and before it is subjected to pressure. When the glass has become thoroughly hot, open the steam valve wider, then open the water valve a like amount, and continuing to open both valves alike until fully open, then slowly close the drip at the bottom. This method not only allows the fittings to be thoroughly blown out, but enables the operator to increase the pressure on a new glass and new packing more gradually. It is best to anneal all the glasses before using them. This is generally accomplished by means of a water and steam bath, the water and the glasses being heated by steam. It is cheaper in the long run to cut glasses with a gauge-glass cutter than to attempt to cut or break them off with a broken file, or by similar means, because a slight nick in the glass at the wrong place may mean the early destruction of the glass when subjected to pressure and varying temperature. Some engineers fit a thin brass or copper thimble into the upper end of the tube, as shown in fig. 74, which prevents scale and water from coming in contact with the glass when blowing out the latter, and hence it reduces the eroded and pitted appearance commonly seen at the upper end of unprotected glasses. Tubes made of aluminium may be obtained of dealers in engineers' supplies which accomplish the same result.

These tubes and thimbles, it will be seen, protect the inner surfaces of the glass only, and as the glass is liable to be crowded to one side or the other in the packing nut as well as in the fitting itself, it is a good plan to also protect the glass on the outside.

A simple means of protecting the glass on the outside is also obtained from dealers in gauge

WOODITE GAUGE GLASS RINGS.

Absolutely reliable for water and steam pressures.

Greatly prolong life of Gauge Glasses.

Overcome breakages due to excessive pressure.

Only require a few moments to instal or renew.

Do away with all digging out of old packings.

The glass is only subjected to boiler pressures.

Hindrances to free passage of water or steam avoided.

Impossible to overpack as with other packings.

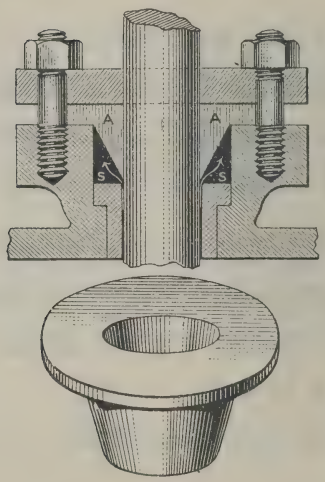
Never adhere to nor corrode the glass.

Give ideal results under all conditions.

Data required—Internal and external (bottom of thread) diameter and depth of stuffing boxes, also outside diameter of gauge glass.

Adopted by H.M. Navy, War Dept., Foreign Navies, and most of the leading Steamships and Railway Companies in all countries, as well as by Manufacturers and Steam Users generally.

THE WOODITE COMPANY,



MITCHAM COMMON,

SURREY, ENGLAND.

F. 1502

WOODITE PACKING RINGS.

AS A SUBSTITUTE.

Piston rod or valve stem packings should be tight and frictionless.

Our well-known conical packing rings fulfil both these conditions.

Wearing away of rods or spindles positively eliminated.

Easily and quickly installed or replaced.

Reduce the costs of operation to a minimum.

Scoring or scratching of rods or spindles impossible.

A slight tightening of the gland or cap nut all that is necessary.

Valve spindles packed with these rings are always free and never stick.

Every Engineer should try them to be convinced.

Do not forget that power saved is money earned.

Data required—Diameter of rod or spindle—Distance between stud bolts (if flanged), or diameter (bottom of thread) if screwed, inside diameter and depth of stuffing box.

THE WOODITE COMPANY,

MITCHAM COMMON,

SURREY, ENGLAND.

Also Woodite for Pump Cups, Hydraulic 'U' Rings, Pump Valves, Gaskets and Joints of all kinds, Sheeting, etc.

F. 1503

glasses. The arrangement consists of a rubber sleeve adapted to slide over the end of the glass, as shown in fig. 75. The glass cannot come in contact with the socket in the fitting, neither can the packing nut touch the glass when the packing is screwed up. The combination of the thimble and the latter device prevents the rapid wear of the glass at the top, and also retains the glass clear of all metallic contacts, which has been found to be very desirable where glasses are subjected to high pressure and temperature and sudden changes in the latter.

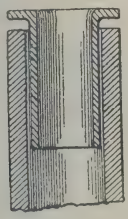


FIG 74.

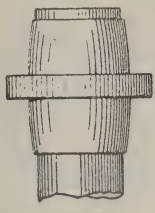

FIG. 75.

When the rubber protector is employed, separate packing rings are not needed, because the packing forms a part of the sleeve, as shown. Annealed gauge glasses protected inside and out by this or similar means will last as long under any circumstances as it is possible to make them by any means thus far made known.

If packing 'rings' are used, then in order to secure a tight joint with the least possible pressure, thus avoiding any tendency to break or to cramp the glass due to the packing, it is necessary to obtain a form of packing that will fit snugly in the space in the nut.

(*H. E. Waverly*, '*Mechanical World*.')

Superheated water acts on most varieties of glass as a violently corrosive agent, and for gauge glasses a special glass has to be used. A special gauge glass, under the name of 'Bishop's Adamant,' to resist high-pressure steam, is supplied by S. & C. Bishop & Co., St. Helens.

UNBREAKABLE WATER GAUGE.

A simple and effective form of water-level indicator which has all the advantages of the test cocks in checking the water level, but does not suffer from their disadvantages, has been patented by Messrs. Cammell Laird & Co., Ltd., and is being manufactured by Messrs. W. Crockatt & Sons, Ltd., of 64 Darnley Street, Glasgow. It consists of a perforated metal tube, and replaces the $\frac{3}{4}$-in. glass tube in an ordinary water-gauge mounting. The diameter of the holes is $\frac{1}{32}$ in. On the gauge cocks being opened, water issues from the hole below the water line in the form of a rapidly diverging white cloudy spray, well defined and readily distinguished. Steam, on the other hand, which issues from the holes above the water line, is only faintly visible and is hardly discernible. The steam jet is almost parallel and quite distinct in character from that of the water; a definite indication is therefore assured. The character of the water jet bears a distinct relation to the thickness of the wall of the tube; by reducing the thickness of the tube, the jet can be made to assume wider proportions. Good results are obtained by thinning the tube down to $\frac{1}{32}$ in. round a $\frac{1}{32}$ in. diameter hole. Much smaller holes than these, however, will give a perfectly visible jet.

PRESSURE GAUGES.

'UBEL' PRESSURE AND VACUUM GAUGES.

Pressure, vacuum and hydraulic gauges, designed on scientific principles and embodying many improvements, are manufactured and supplied by *United Brassfounders and Engineers Ltd.* (fig. 76.) The special feature of these gauges is the fitting of an improved pillar movement, by means of which the complete internal mechanism, including the Bourdon tube, is mounted entirely on an independent frame (fig. 77). This ensures absolute accuracy, as the mechanical parts are free from any strains which may be put upon the casing during fixing. This is usually a source of inaccuracy in ordinary types of gauges, where important parts are attached direct to the thin sheet metal back of the gauge, with the result that they are often twisted out of truth during fixing, and the accuracy of the mechanism thereby destroyed.

In the 'Thomas Patent Duplex Pressure Gauge' there are two Bourdon tubes (connected to two different pointers) of different length and strength, so that one is more sensitive than the other; if the two indications are identical, therefore, it is a proof that the gauge is indicating accurately. When in working order each pointer will indicate the same pressure on its respec-

tive scale, and any discrepancy between the two readings will serve as a warning to the attendant that the gauge is unreliable.

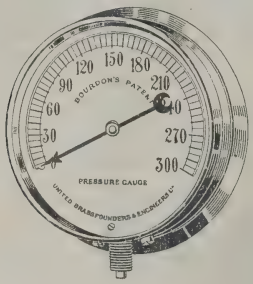

FIG. 76.

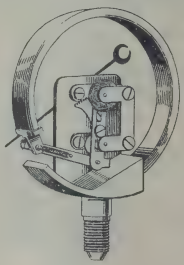

FIG. 77.

Other types of special purpose gauges are manufactured by *United Brassfounders and Engineers Ltd.* as follows:—Combined pressure and vacuum gauges, motor-car and aeroplane gauges, gas mineral water, and other miscellaneous types.

Apparatus for Testing Pressure and Vacuum Gauges.

(*Brotherhood's Patent.*)

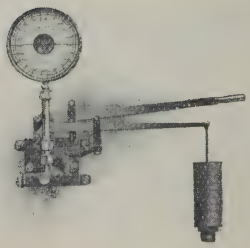

FIG. 78.

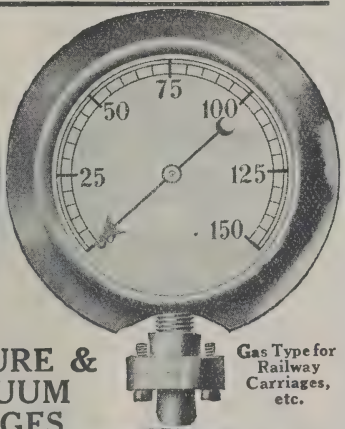
FIG. 79.

This apparatus will test the accuracy of gauges at all steps on the scale, instantaneously, independent of temperature variation, and does not rely on springs. A permanent accuracy within ½ per cent. is proved by official tests. In the pressure-gauge testing-machine a hand-operated oil pump supplies pressure below a ram which, while being entirely oil-tight under the highest pressure, will fall freely by its own weight when the pressure is released. For moderate pressures the ram lifts graduated weights direct, and for higher pressures, up to 6,000 lbs. per sq. in., weights are applied through a lever carried on hardened steel knife edges. This is shown in fig. 78.

In the vacuum-gauge testing-machine, shown in fig. 79, an oil-sealed pump exhausts the air in the space above the plunger and below the gauge. The readings being controlled by the absolute difference of pressure within and without the gauge, no correction for barometric or temperature conditions is needed. In this respect the machine possesses great advantages compared with the mercury column often employed.

The machines can be made for fixing to the wall or to stand on a shelf or table, and are enclosed in dust-proof boxes.



A certificate of the National Physical Laboratory can be supplied with each machine.

INJECTORS.

To compute the Diameter of Throat and Volume of Discharge.

d = diameter of throat in millimetres; V = volume of water required per hour in gallons; P = pressure of steam in pounds per sq. in.

$$d = \cdot 709 \sqrt{\frac{V}{\sqrt{P}}} \qquad V = 1 \cdot 985\ d^2 \sqrt{P}.$$

Example.—The pressure of steam is 200 lbs., and the volume of water required to be delivered per hour is 1,010 gallons.

Then
$$\cdot 709 \sqrt{\frac{V}{\sqrt{P}}} = \cdot 709 \times 8 \cdot 45 = 6 \text{ millimetres};$$

and
$$1 \cdot 985\ d^2 \sqrt{P} = 1 \cdot 985 \times 36 \times 14 \cdot 142 = 1{,}010 \text{ gallons.}$$

The above particulars apply to all properly proportioned live steam injectors.

The Penberthy Injector.

The 'Penberthy' Injector (fig. 80) is a perfectly automatic arrangement; by this is meant that when the injector is working and forcing water to the boiler, if the current of water be suddenly broken by any cause, such as a sudden jar or jolt in the case of a traction engine or road roller, or in the case of a marine boiler by the rolling of the vessel throwing the sea-cock out of the

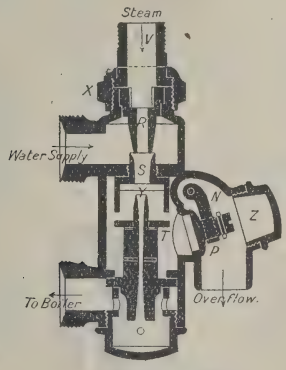

FIG. 80

R, steam jet; O, plug; N, overflow hinge; S, suction jet; V, tail pipe; P, overflow valve; Y, delivery jet; X, coupling nut; Z, overflow cap.

water for a moment, the injector will pick up the water and again establish the current to the boiler automatically, i.e. without the manipulation of a single valve or the least attention from an attendant. It is this quality which has made the 'Penberthy' so popular among marine engineers and which has led to its adoption by the great majority of the traction and threshing engine manufacturers.

The Penberthy delivers water to boiler at 160° to 212° Fahr., according to temperature and steam pressure; but 200° to 211° can always be delivered at nearly all pressures over 50 lbs. by throttling the suction valve and delivering the minimum capacity.

The injector is made in fifteen sizes, from ⅜ in. to 2½ ins., and it is also supplied in three distinct styles to suit various positions. The maximum quantity delivered is from 80 to 4,200 gallons per hour according to size, and it is applicable to boilers up to 600 h.p. Two sizes, viz. AA. to C., are especially supplied for traction, portable, and ploughing engines. It is most efficient at the pressures of 50 to 80 lbs. (when with the valve wide open it will lift 20 ft.), although it will work at a lower pressure and also up to as high as 180 lbs. under favourable conditions. It is suitable for all classes of boilers. A *low-pressure* non-lifting pattern is supplied for steam pressures below about 20 lbs.: these injectors will start at from 1 to 3 lbs. steam pressure where water is taken from a barrel or tank at, or just above, the level of the injector. With water pressure of 20 lbs. they will start at from 10 to 12 lbs. low steam, but with two globe valves in water-supply pipe the pressure can be reduced and injectors started at correspondingly lower pressures.

A special pattern (Nos. 328, 332) also is being made in ½ in., ¾ in., and 1 in. sizes, for very high pressures—namely, up to 200 lbs. No. 328 AA. is used extensively for steam wagons and tractors.

For pressures to 240 lbs., and for hot-feeds, the Auto-positive type is supplied. This type has fine working parts, and combines the features of both the positive and the automatic injector.

Over 700,000 of the Penberthy Injectors are in use.

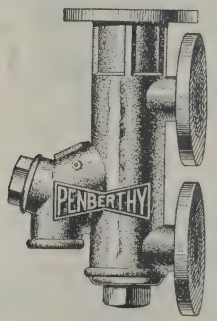

FIG. 81.

Owing to the increasing use of flange connections in this country, especially on fine works, the Penberthy Injector is now made up with flanges as shown in fig. 81. The working qualities

of the flanged injector are only slightly different from those of the screw-nipple machine, except that by the different construction of the body the high working pressure is brought up to 180 to 185 lbs. The injector with flanges is connected and operated in precisely the same manner as the injector with screw nipples. It is made in all sizes except $\frac{1}{4}$ and $\frac{3}{8}$ in.

UNITED BRASSFOUNDERS' INJECTORS (PENBERTHY TYPE).

Penberthy type automatic injectors to meet every ordinary requirement are manufactured on specialised lines by *United Brassfounders and Engineers Ltd.* The construction and action of this type of injector are well known, and are generally in accordance with the theoretical particulars given on page 1505. Particulars stating the horse-power for which various injectors are suitable, on the assumption that they are required for ordinary tube boilers, are

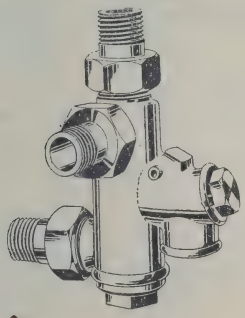

FIG. 82.

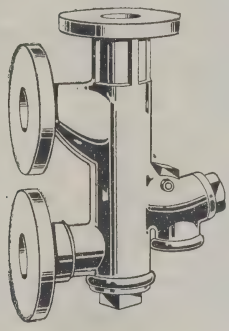

FIG. 83.

given in the table, page 1508, together with the particulars of their delivering capacity. Fig. 82 shows an external view of a standard type injector, but a large number of patterns are available, giving alternative positions of suction and delivery branches, which can be arranged to meet special requirements. A useful pattern, having flanged ends, is shown by fig. 83, the dimensions of which are given in the table, page 1508.

Other types of specialised injectors are as follows:—One-movement self-acting and re-starting injectors; 'Giffard' type injectors; 'Gresham' type injectors; 'Halls' type injectors; 'Schaffer' type re-starting injectors. A one-movement self-acting injector is also supplied, having a separate water spindle directly connected, by means of a yoke, to a main steam spindle, from which the water supply is regulated in proportion.

(*United Brassfounders and Engineers Ltd.*)

Willcox's Ejector Steam-Jet Pump or Water Raiser.

This ejector, fig. 84 (*W. H. Willcox & Co. Ltd.*), will lift water 20 ft. with any steam pressure above 25 lbs., and 25 ft. with pressure at 40 lbs. or over. On pressures above 80 lbs.,

Fig. 84.

steam must be throttled to get best results on a lift. It will also elevate 50 ft. at 60 lbs. pressure, and 65 to 75 ft. on pressures of 80 to 100 lbs., by placing the ejector within 12 to 18 ins. of water supply.

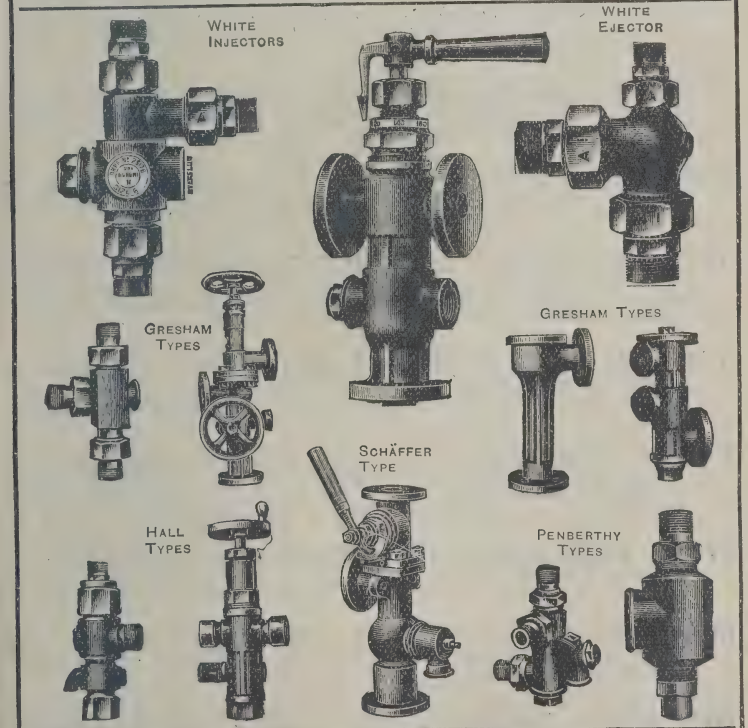
The ejectors are also suitable for exhausting air from pumps to create vacuum, and are largely used for this purpose.

Notes on Injectors.



A very frequent cause of trouble is that by one means or another the injector becomes overheated and refuses to lift its water. This may be due to steam leaking past the check valve into the body of the injector, and then passing to the suction pipe, so that the latter becomes too hot. Under these conditions it is impossible to make the injector work. Another cause of overheating is sometimes to be traced to the proximity of the fitting to the hot boiler shell, which allows heat from the latter to pass to it by conduction and radiation. In the first case the remedy is to fit a well-made check valve, combined with a plug cock, between the injector and the boiler. This should be done, even if the former is designed with a self-contained back-pressure valve. Further, the plug cock should be shut off when the injector is not in use. In the second instance, it sometimes happens that an injector is employed which is fitted with its own back-pressure valve, and it is then bolted directly to the boiler. This is very bad practice, as a single valve is not dependable in the first place, and a further point is, that the injector is much too close to the hot boiler. This is a fruitful cause of trouble. Also, should anything

go wrong with the injector, it is necessary to blow down the boiler before it can be put in order; whereas, with a combined check valve and plug cock, the latter can be closed, and the injector removed under steam.

An injector will not work satisfactorily if supplied with wet steam; therefore, in order to ensure that this is as dry as possible, it should be taken from the highest available point in the boiler.

Another defect sometimes arises through the check valve not having sufficient lift, or on account of some sort of obstruction in the delivery pipe. The effect of this is that the injector will lift the water, but on account of the greater pressure due to the obstruction against which it has to work, it will be unable to force the water into the boiler, which will consequently find an escape through the overflow instead.

In some cases the water supply to the injector is taken from a tank placed beside the boiler, on the boiler-house floor, the supply to the tank being from an external source, and controlled by a ball cock with a float attached, so that the level of the water in the supply tank is constant. This is a very satisfactory arrangement. In other instances the source of supply may be some little distance away, and connected to the injector by means of pipes. Further, if the water is taken from a well the level may vary between considerable limits. Hence, when purchasing an injector, it is of the utmost importance that the manufacturer should be given all possible data, such as the greatest static head and the length of pipe with the number of bends, so that he can obtain the total suction lift and supply an injector to suit the conditions.

Much trouble will be experienced if the feed-water is allowed to become hot. The lower the temperature the better. There are many so-called hot-water injectors, but even these will not prove very satisfactory if the temperature of the feed-water is allowed to rise too near to the maximum temperature specified by the makers. In order to prevent as much as possible any rise in temperature, it is of the greatest importance that the overflow from the injector should not be allowed to drain back into the feed-tank. An overflow pipe should be fitted that will lead this hot water clear of the feed supply. Such a pipe should not be closed, but should enter an open cup, similar to the overflow of the circulating water in a gas-engine jacket. It is then under constant observation of the man in charge, and if any irregularity occurs it is quickly detected.

Occasionally an injector will refuse to work, due to a leak in the suction pipe. If this defect is present it may be located by fixing a plug in the suction pipe and opening the steam supply to the injector, when the position of the leak will be easily detected.

Lastly, dirt and grit are a source of trouble at times. To prevent this as far as possible, a straining rose should be fitted to the suction pipe. This will not exclude all grit, and occasionally small grains of solid matter suspended in the feed-water will find their way through and lodge on the internal surface of the injector. Also if the water contains soluble salts of magnesium and calcium, it becomes heated on passing through the injector, and some of these salts are deposited, forming incrustations which may cause the injector to refuse to work, either because it has become totally choked up, or else small particles of the incrustations may break away and become lodged under the back-pressure valve or check valve and prevent its closing, when the injector will refuse through overheating.

It is always advisable to keep a spare injector in stock, and if the water contains a considerable amount of impurity, instructions should be given to change the injector at regular periods. The length of time that one should be allowed in continual service must be governed by experience with the particular conditions under consideration. In order to loosen the deposit the injector may be left to soak in diluted hydrochloric acid.

If the above very easily followed points are given attention, injectors will be found most reliable, and few complaints will be heard.

(*'Mechanical World.'*)

REDUCING VALVES.

These are very needful fittings in connection with steam appliances when steam has to be reduced from a high to a uniform low pressure. It is a common mistake to order reducing valves too large, which leads to their excessive wear. No reducing valve should be implicitly trusted; but wherever a rise in steam-reduced pressure is liable to bring about serious results a relief valve should follow the reducing valve.

Reducing valves which are too large for the amount of steam they are to pass are usually unsatisfactory; either they will open and close continually and chatter violently, or will stand in a position nearly closed and become steam-cut and leaky. It is more satisfactory to use two small valves in parallel, one set slightly heavier than the other, so that one will supply steam up to its maximum capacity before the other opens. Another way is to use one reducing valve equal to about one-half the maximum demand, and a by-pass of about the same capacity with a hand-operated valve in it, so that when the reducing valve reaches its capacity the by-pass valve may be opened wide and the reducing valve will close down and simply make up the shortage. This, of course, requires that an attendant shall observe the pressure gauge occasionally.

Hopkinson's Patent 'Absolute' Water Gauges, fig. 6440, bronze, which automatically shut off both steam and water when the glass breaks, fitted with Patent Safety Plugs and Shields
Steam Gauge:	One 10-in. or 12-in. Steam Pressure Gauge, fig. 4000, with Pillar Syphon and Tester Bend for Inspector's Gauge, fig. 4197	One Hopkinson's Steam Pressure Gauge, fig. 4000, complete with bronze control cock, fig. 4242, and bronze angle control cock on drum, fig. 6621

NOTES.—When several boilers are connected in parallel, it is most important that Hopkinson's Patent Isolating Valves, figs. 6000 and 6005, should be used.

The Steam and Feed Valve sizes are to be chosen in accordance with the evaporation and steam pressure of the boiler.

Cast-steel Junction and Feed Valves can be supplied at an extra cost if preferred, in those cases where Cast-iron Valves are specified.

Safety Valves can similarly be supplied with the parts subject to pressure in cast steel, if preferred, at an extra cost.

SECTION XXIX

PART III

SUPERHEATED STEAM—SUPERHEATERS—STEAM TRAPS—STEAM JACKETS — ECONOMISERS — WATER COOLING TOWERS — STEAM DRYERS AND PURIFIERS — HEAT ACCUMULATORS.

(Revised by T. B. Morley., D.Sc., M.I.Mech.E.)

SUPERHEATED STEAM.

When sufficient heat is added to water to just convert it all into steam, the steam is said to be dry and saturated or, for short, saturated. If more heat is added it becomes superheated. The degree of superheat is measured by the rise of temperature above that of saturated steam.

The heat required to superheat steam varies with the pressure and temperature (see Table IV., on p. 1395), but is roughly 0·55 B.Th.U. per pound of steam for each degree Fah. of superheat.

Superheating does not alter the pressure of the steam, but increases its volume in proportion (very roughly) to the absolute temperature.

Superheated steam is greater in volume than saturated steam of the same pressure; the volume of the latter is found from steam tables.

The volume of superheated steam may be determined approximately from the equation

$$V = v(1 + \cdot 0016 t_s)$$

where,

v = volume of dry saturated steam; t_s = degrees of superheat Fah. *(Goudie.)*

For the mean specific heat, heat required to superheat, and total heat of superheated steam, see Tables III, IV, V, Part I, pp. 1394, 1395.

The advantages of superheating are chiefly :—

1. Greater thermal efficiency of the engine, due to reduced condensation loss.
2. If the boiler plant is not provided with very ample heating surface the addition of a superheater increases the boiler plant efficiency apart from the engine effect.
3. As compared with saturated steam, higher steam velocities in the pipes may be used with superheated steam, and consequently the pipes may be smaller. For this reason, and also the lower coefficient of heat transmission, the percentage loss of heat in the pipe system is lower, in spite of the higher temperature.
4. Reduction in size of auxiliary plant owing to smaller weight of feed water and coal.

Degree of Superheat.

In modern practice the following are usual :—

1. General engine practice : superheat at boilers 150° F., or, say, 120° to 130° at engine Up to 650° F. total temperature, say 260° F. of superheat at 200 lbs. pressure, can be used if the engine is designed for it.

2. General turbine practice: superheat at turbine 200°-250° F., say up to 650° F. total temperature.
3. Latest turbine practice: superheat at turbine of 250° to 300° F., say up to 750° F. total temperature, at about 350 lbs. sq. in. pressure.

In general, with flat slide or Corliss valves on the high-pressure cylinder, the lower temperatures (about 550° F. total temperature) must not be exceeded.

Economy of Superheat.

Superheating reduces the steam consumption approximately at the rate of 1 per cent. for each 10° F. of superheat, but the rate is greater for the lower grades of superheat and less for higher grades.

The practical steam and fuel economy due to the use of superheated steam are about as follows, all superheats being measured at the engine stop valves:—

1. Piston and slide valve engines: 20 per cent. reduction in steam and fuel for 100° F. of superheat.
2. Drop valve and Corliss engines: 16 per cent. saving for 100° F. superheat; 21 per cent. for 150° F.
3. Uniflow engines: 12 and 17 per cent. saving at 100° and 150° F. respectively.
4. Steam turbines: 16 and 26 per cent. at 200° and 350° F. respectively.

Characteristics of Superheat.

Condensed steam is a slight lubricant. The absence of this must be met by adequate lubrication when using superheated steam. The high temperature requires a special oil of high flash-point. Pipe friction losses are reduced by superheating.

In reciprocating engines a later cut-off is required to develop the same horse-power. Hence the maximum power which can be developed is slightly reduced by superheating.

Very high superheats lead to growth and distortion of cast-iron turbine cylinders. Steel should be used at the high-pressure end.

Moderate superheat, about 50° or 100° F., is desirable for evaporating and similar heating purposes, especially with long pipe mains, but very high superheats are undesirable, as the steam should have little, if any, superheat by the time it reaches the heating surfaces of the evaporators, etc., on account of the lower efficiency of these heating surfaces with superheated steam.

Throttling slightly raises the superheat in steam; expansion, as in a turbine nozzle, very greatly reduces it.

Except for very moderate superheat, cast-iron and copper must not be used.

SUPERHEATERS.

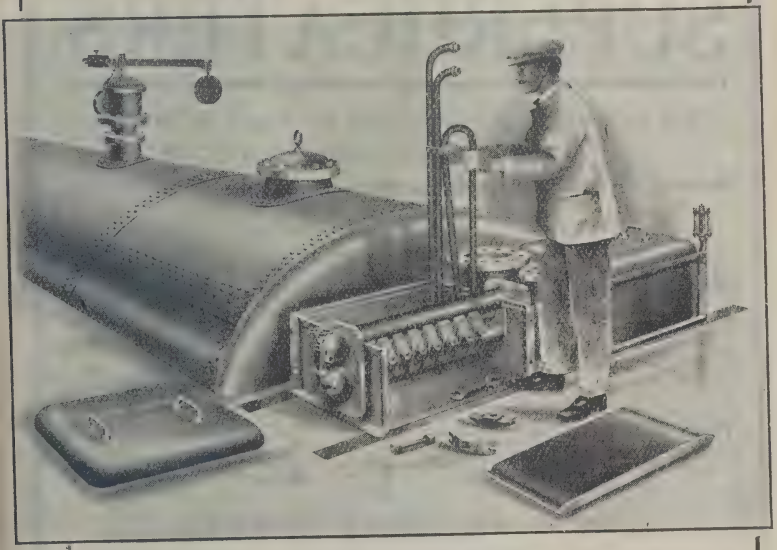
The superheat added to the steam depends upon:—

1. The heating surface per pound of steam per hour.
2. The temperature difference, gas to steam.
3. The velocity of the steam in the superheater.
4. The velocity of the hot gases past the tubes.
5. The pressure of the steam.

Factor 2 is very difficult to predetermine accurately, and hence superheaters are still mainly designed by rule-of-thumb. Modern superheaters are frequently so made that the steam velocity can be altered, thus permitting an adjustment if an incorrect estimate has been made. There are two principal methods of altering the velocity; by plugging up tubes, or removing them, and by rearranging the proportion of tubes in parallel to those in series. The first method is of practically no value.

Factors 2, 3 and 4 change with the amount of steam used, as with the load. The effect of load on factor 2 (temperature) is more marked the further the superheater is from the grate, and is very marked if in the downtake of a Lancashire boiler for instance. Factor 2 is also very much dependent on the normal rate of firing and the quality of coal used. Thus with poor coal a superheat of 100° F. at full load may fall to 30° F. at half load. If the normal rate of firing is high or the quality of coal good, the change of loading has less effect.

Heating Surface of Superheater.



(1.)

Typical values of the superheating surface as a percentage of the boiler heating surface, not counting the economiser, are:—

	Per Cent.
Lancashire boiler	28
Water-tube, B. and W. type	30
Water-tube, 3-drum type	25

Telephone 1138-9.

These values cannot be relied upon for superheats above about 200° F. For the highest values, 300°-350° F., a complete revision of the superheater boiler arrangement is necessary.

Boilers with superheaters require a smaller heating surface to give a desired efficiency.

Heating Surface of Superheater.

(2.)

The heating surface may be approximately calculated on the assumption that the heat transmission per sq. ft. of heating surface is 5 B.Th.U. per hour per degree F. of difference of mean temperatures of gas and steam.

Thus, if W = steam generated in lbs. per hour,

H = heat required to superheat 1 lb. of steam (see Table IV, p. 1395),

T = mean gas temperature,

t = mean steam temperature,

then the heating surface in sq. ft.

$$= \frac{W \times H}{(T - t) \times 5},$$

For example, let W be 6,000 lbs. per hour, the pressure 160 lbs. per sq. in., and superheat 200° F. The saturation temperature is 371° F., and final steam temperature 571° F., so that t = 471° F. H (from Table IV) = 110 B.Th.U.

Assuming a Lancashire boiler, with the superheater placed in the downtake, the value of T may be 900° F., the heating surface $= \frac{6{,}000 \times 110}{(900 - 471) \times 5} = 307$ sq. ft.

Oil for Superheated Steam.

'800 F' Occentoline.

This is a special oil for superheated steam, supplied by *Messrs. Sterns Ltd.* It has an exceptionally high flash point (650° F., the fire test being 750° F.) and is a guaranteed pure hydrocarbon, free of impurities. It is non-corrosive. It will leave no deposit, and will effectually lubricate cylinders at highest temperatures and greatest pressures.

The Gordon Patent Sectional Superheater.

This superheater (*The Gordon Superheating Company, Regent House, Kingsway, London, W.C.* 2) is constructed of mild steel, the headers being of mild steel of circular section, while the tubes are solid drawn steel of 'U' form, as shown in fig. 1.

BOOKLET UPON APPLICATION.

The Gordon Superheating Co.

REGENT HOUSE, KINGSWAY,
LONDON, W.C. 2

F. 1517

A particular feature of the superheater is the patented wedge joint shown. The one bolt illustrated tightens each pair of joints; no special tools are required, and the joint is said to remain perfectly steam-tight under all working conditions. The headers are circular in form, and are connected together by stretcher plates of ample strength at suitable distances apart to withstand the thrust of jointing up the sections.

Cover plates are fixed over the tube ends to give free access to the whole of the sections, any one of which can be removed without having to shut down the boiler or disconnect the steam pipes.

Suitable drains are arranged for on the headers to carry off water of condensation which may accumulate during the time the plant is shut down.

The standard elements employed are applicable to superheaters for Lancashire, Dry Back Marine, Water-tube, or any other form of boiler, and also to independently fired superheaters.

The McPhail & Simpson Patent Superheater.

(McPhail & Simpson, London.)

The headers and tubes of these superheaters (fig. 2) are of solid drawn wrought steel.

The simple construction, and high-class material and workmanship used in their construction, render the superheaters absolutely steam tight, and at the same time ample means are provided for getting at the tubes should they by any chance require attention. This is made possible by the provision in the headers of the patent stoppers opposite the ends of each tube, whereby easy access to the tubes is obtained for expanding, examination, etc., and any individual tube can be removed and replaced in a very short time, without disturbing the other tubes or pipe connections and without breaking a large joint.

There are no studs and no large joints used in these superheaters.

The substantial nature of the tubes entirely prevents warping.

The superheaters are adaptable to any type of boiler—Lancashire, Cornish, Babcock—and all types of water-tube boilers, both land and marine, and for independent firing.

Flooding of the superheaters, or the use of dampers, is not recommended.

The Galloway Superheater.

(Galloways, Ltd.)

This superheater (fig. 3) is made entirely from mild wrought steel. All parts are of circular cross-section and therefore very strong. There are two headers rigidly stayed together to prevent movement and vibration, and connected by seamless steel tubes. The tubes are in groups of five, each group commanded by an internal cap so as to facilitate inspection and cleaning. The headers are carried in a double-walled box resting on the brickwork and covered by a cast-iron cover, thus minimising radiation losses and protecting the superheater from weather and damage.

The joints between the superheater and the main steam piping are vertical, thus enabling the superheater to be removed for inspection without disturbing the steam pipes. If it is desired to work with the superheater removed, a slightly bent connection or cross-over pipe is inserted in its place.

The superheat usually attained is about 150° F. with moderate firing, and less at light rates of combustion or with poor coals.

The Babcock & Wilcox Standard Integral Superheater.

(Babcock & Wilcox, Ltd.)

The Babcock & Wilcox Patent Steam Superheater (fig. 4) consists of solid-drawn steel tubes bent into **U** shape, and connected at both ends with boxes or manifolds (F and H), one of which (F) receives the natural steam from the boiler through the dry pipe (N) and inlet pipes (D). The other (H) receives the superheated steam after it has traversed the superheater tubes (G), delivering it through pipes (J) and cross-box (K) to the stop valve (L) placed above the cross-box. Handholes are placed in the manifolds opposite the ends of the superheater tubes to facilitate inspection.

The flooding arrangement consists in a connection with the water space of the boiler drum; by means of the larger of two cocks (B) and connecting pipe (S) water can enter the lower manifold (H) and fill the superheater to the water level of the boiler. Any steam formed in the superheater tubes is returned into the boiler drum, through the collecting pipes (D), which, when the superheater is at work, convey saturated or natural steam into the upper manifold (F). Prior to opening the stop valve (L), when a superheater has been flooded, the water is drained away from the manifolds by the pipe (O) and the smaller cock (C). A sight glass (A) is attached to the outlet of the small cock to show when all the water has been blown out.

The superheater is placed in a position where there is practically no deteriorating condensation of the gases, and where the temperature is sufficiently high to ensure the steam receiving from 100° to 250° F. of superheat, or more if desired. It is not subject to the immediate action of the fire, as the furnace gases must first pass through the front part of the boiler, which comprises a

considerable heating surface. Assuming the boiler to be in regular work, and the firing even, no great fluctuations in temperature can take place where the superheater is fixed. It is readily accessible for examination, and for the renewal of tubes. There are no flanged joints, all the tube joints are expanded. Expansion is provided for by the tubes being free at one end, and by the manifolds not being rigidly connected with each other. Prevention against over-heating during steam raising from cold water after cleaning, etc., is ensured by the arrangement for flooding with boiling water, and using the superheater as part of the boiler-heating surface.

The Thompson Patent Sectional Superheater.

(*John Thompson (Wolverhampton) Ltd., Wolverhampton.*)

This superheater (fig. 5, p. 1520) consists of a pair of mild steel cylindrical headers connected by two groups of U or W tubes. The tubes have tapered ends machined to gauge and fitted into milled holes in the headers, making a metal-to-metal joint, and are held in position by a right- and left-hand screw stud. The advantages of this method of fixing the tubes are, perfect interchangeability and speed and ease with which any tube can be removed or replaced for any purpose, as every tube can be taken out without disturbing the headers, pipe connections, or brickwork.

The steam passes through the hot gases four times, consequently the velocity of the steam is increased and great efficiency obtained.

This superheater is adaptable to all land boilers, and is suitable for the highest pressures.

The Sugden Patent Down-Take Superheater.

(*Messrs. T. Sugden, Ltd.*, 180 *Fleet Street, London, E.C.* 4.)

This superheater (for Lancashire, Cornish, and other boilers with external flues) consists of two mild steel headers, connected by solid drawn mild steel loop tubes, and is fixed in the down-take flue at the back end of the boiler.

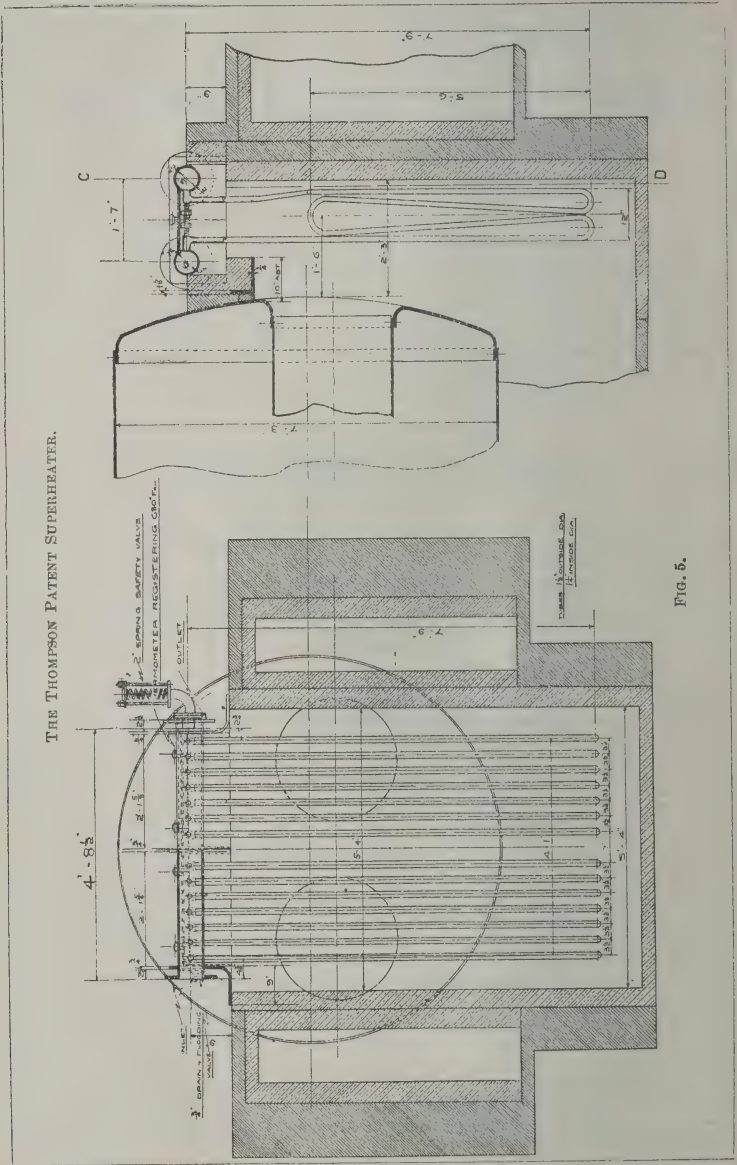
In the Single Flow Double Header Superheater, one of the headers is used as an inlet box, and is connected by piping to the main stop valve of the boiler. The saturated steam from the boiler passes forward from the inlet header through the loop tubes into the outlet header, and from thence it is supplied as superheated steam to engines or for distribution as required. Superheat temperatures up to 700° F. can be obtained.

The special features of this superheater are as follows :—

The tubes are connected to each header by expanding the tube ends, thus making a simple reliable joint free from leakage troubles. A handhole is fitted over each group of four tubes, thereby providing easy accessibility for blocking off, re-expanding, or renewing the loop tubes.

The branches for connecting to the steam pipes are pressed up out of the solid metal of each header, thereby eliminating all uncertainties which occur with welded or screwed-in branches.

Access covers are provided between the inlet and outlet boxes for examination of the down-take, and these covers also enable the condition of the U-tubes to be easily examined from the outside, and any accumulation of ashes or soot can be brushed off the superheater tubes.



The headers are supported by strong cast-iron plates and are built into the brickwork, thereby reducing radiation losses and preventing the admission of cold air to the flues.

Messrs. Sugden also supply 'Double-header Multiflow Superheaters,' and a patent 'Single-header Superheater' for restricted down-takes. This superheater takes up a width of about 6 ins., and can be placed in a down-take 1 ft. 6 ins. wide without any serious interference with the space required by an inspector for examination of the back end of the boiler.

Messrs. Sugden claim that the superheater is of the simplest and most reliable construction, and that it has stood the test of twenty years' use under all kinds of working conditions, also that the maintenance costs are exceedingly low, and in many cases 'Sugden' superheaters have been at work for 15 to 17 years without any repairs or replacements, and are still working satisfactorily in exactly the same condition as when first installed.

The superheater is supplied as a complete apparatus or is delivered in sections and built up on the site, and is arranged so that the loop tubes can be renewed without removal of the headers or any disturbance of the brickwork.

The firm are also makers of independently fired superheaters for tubular and all types of land boilers, also for marine and locomotive boilers.

F. 1521

STEAM TRAPS.

Steam traps are indispensable adjuncts to steam apparatus in which water of condensation should be drained off with regularity and certainty and without loss of steam.

A steam trap should work well and economically, and without adjustment, at all steam pressures.

'The Bradford' Steam Trap.

'The Bradford' Steam Trap (Nicholson-Lloyd Patents) embodies a new principle in this class of device. It is a float trap, but with an important difference. The float does not open or close the discharge valve. It simply releases or engages a weighted lever, which is so arranged that the outlet is instantaneously opened or instantaneously closed. There is no middle position. This effectually prevents the wire-drawing of the discharge, which cuts the valve and seat and so destroys the efficiency of those traps where the opening and closing take place gradually.

The method of operation is as follows (figs. 6 and 7). The water accumulates in the collecting chamber and gradually raises the float until the latter reaches the desired point,

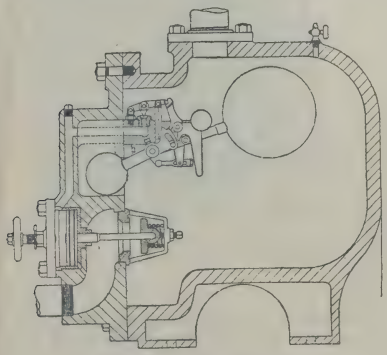

FIG. 6.—Piston-Operated Trap.

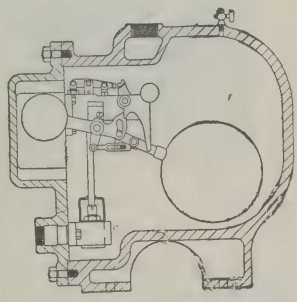

FIG. 7.—Direct-Operated Trap.

when it trips the weighted lever, which immediately opens the discharge to its fullest extent. The water is then forced out under full pressure until it reaches the bottom level, when the lever is again tripped and the discharge is at once closed. The outlet is always submerged, so that there can be no escape of steam.

The apparatus is made in two classes, viz. the piston-operated trap and the direct-operated trap. Fig. 6 represents the piston-operated trap, in which the discharge valve is operated by the steam acting on a piston working in a cylinder. By this method the maximum diameter of outlet opening is obtained without reference to the steam pressure. This is a most important feature, as in consequence of the unusually large outlet the trap will deal equally well with flooding and priming as with ordinary condensation. Fig. 7 shows the direct-operated trap, in which the action is simpler, the discharge being opened and closed directly from the trip lever, but the area of the outlet is smaller.

The traps will work at any pressure from 250 lbs. downwards, and are made in several sizes. The piston-operated traps will discharge from 10,000 to 160,000 gallons per hour when working at 100 lbs. pressure. In the direct-operated traps the discharge capacities range from 325 to 1,800 gallons per hour at 100 lbs. pressure. Both traps will force the discharge water 1 foot high for every pound of steam pressure.

An *eliminator*, which combines the above trap with a convenient form of separator, is also prepared, the manufacturers being The United States Metallic Packing Co., Ltd., of Soho Works, Allerton Road, Bradford.

The 'Ubel Fullbore' Float Type Steam Trap.

In this arrangement, fig. 11, p. 1523 (*United Brassfounders and Engineers Ltd.*), when the water in the tank 'D' rises above the lip of float 'C,' and fills the float, the pin valve 'A' is drawn down, due to the float sinking. This allows a certain amount of liquid to pass through to the outlet, and equalises the pressure on both sides of the main valve 'B.' Just before reaching the bottom, the pin in 'A' comes in contact with the bottom of 'B,' and draws 'B' off its seating, leaving the fullbore for the remainder of the liquid to escape through. Nos. 1, 2, 3, and 4 sizes have ¾ in., 1 in., 1¼ in., and 2 ins. inlets and outlets, and have discharge capacities of 800, 1,500, 3,300, and 5,600 gals. per hour: it is recommended that one-fifth of the discharge capacity be taken, in order to provide an ample margin.

Cranetilt Steam Traps.

(Crane-Bennett Ltd., London.)

These traps are made in different types, and are adaptable to every duty in connection with the trapping of steam and handling of condensation.

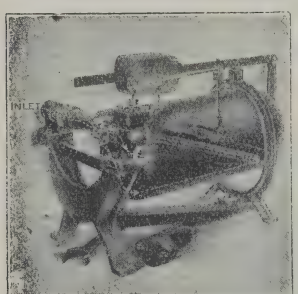

Fig. 8.

Fig. 9.

The Non-return Trap.

This type (fig. 8) will discharge against any pressure less than that at the inlet, and positively traps all the steam. The mere fact that it is seen to work is a guarantee that steam is not blowing through.

The 3-valve Lifting Trap.

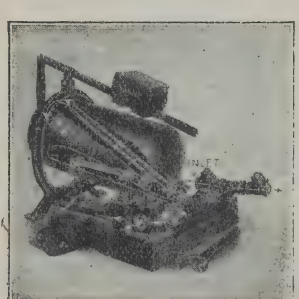

Fig. 10.

This type (fig. 9) will discharge against a pressure greater than at the inlet, and serves the double duty of a pump and receiver governor. It is thoroughly automatic and operates at a small cost; it is very simple in construction and durable; its up-keep is practically negligible. It will handle water at any temperature without danger of becoming steam-bound.

The Direct Boiler Return Trap.

This type (fig. 10) will discharge directly into boilers and has all the advantages over a pump, referred to in the case of the Lifting Trap. It will return condensation to the boilers at nearly the temperature of the steam from which it was condensed, and tests have shown temperatures as high as 300° in the water being fed to the boilers. As 10 to 11 degrees rise in feed-water temperature means 1 per cent. saving in fuel, considerable coal economy is effected.

Cranetilt traps will work with one adjustment, at any pressure up to 250 lbs. The tanks are made of malleable iron, and are subject to a 800 lbs. hydraulic test. The valves and trunnions are made of non-corrosive metals, and for superheated steam, or special duties, special metals are used.

General Notes on Steam Trap Practice.

Steam traps when cold are wide open, so that at starting all air and water are expelled from the pipes when steam commences to pass. The traps close automatically, so that there is no possible chance of water hammer and rents occurring in pipes through an accumulation of cold water suddenly receiving the impact of live steam, the cause of many accidents.

The traps should always be fixed at a point where a droop or bend in the pipe is situated, and at the lowest possible point.

In the event of the drain pipe being screwed into a cylinder or pipe, great care should be taken that the drain does not rise above the inside of the vessel or pipe, otherwise perfect drainage is not possible.

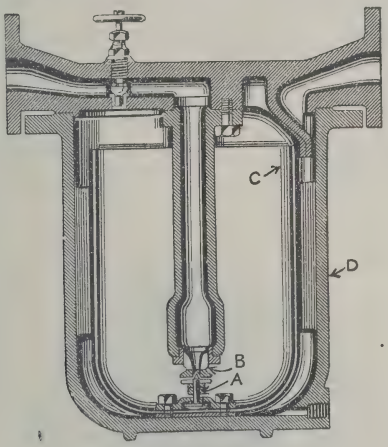

FIG. 11.

FIG. 11.—The ' Ubel Fullbore ' Float Type Steam Trap.

It will be found that if a length of pipe is fitted between traps and vessels to be drained, so as to form a reservoir for the water, it will greatly facilitate the easy working of the trap, as the discharge water is much cooler, and enables the trap to do a larger amount of work than it would do under ordinary conditions.

Every pound of steam will lift a column of water 2½ feet, so that in arranging for tanks, if 2 feet of water for every 1 lb. of steam pressure is allowed for, the allowable height for placing the tank can be ascertained. In this case a non-return valve, similar to a boiler feed check valve, should be placed on the outlet side when the trap is used for lifting water, to prevent the water returning into the pipes when main steam is shut off.

When discharging into a sealed drain it is advisable to fit a three-way cock to the outlet, so that the trap can be adjusted with the cock opened to the atmosphere. There is an additional advantage in having a three-way cock fitted, as the trap's working can be inspected at all times by simply opening the cock to the atmosphere.

By blowing the pipes through with live steam before fixing the trap, the dirt will be cleaned out, and much trouble saved in the after working of same.

The greatest precaution taken cannot always prevent grit getting into the pipes, and if same is not blown out at starting it is likely to get into the trap and become fixed in the seat or valve face. The consequence is, the trap is likely to let steam pass. Steam at high pressure cuts almost as badly as compressed air, and the longer the steam is allowed to blow through the worse the valve is cut. When this takes place the valve should be examined, and, if cut, it should be trued up in a lathe, or if badly cut it should be renewed.

STEAM JACKETS.

Steam jackets are rarely adopted to-day except for slow-running engines. There is no doubt that a well-arranged jacket leads to considerable economy when the engine is supplied with saturated steam. The economy is much less marked with superheated steam, especially as jackets are usually arranged. Having regard to the extra first cost and complication, jackets are not to be recommended with superheated steam unless the conditions are exceptional.

The usual arrangement of steam supply is defective: the steam is supplied to the jacket, and a trap fitted to drain away the condensed steam, but there is no through flow. Usually, on intermediate and low-pressure cylinders the jacket steam pressure is reduced to a few pounds above the steam chest pressure; except to relieve the cylinder barrels and liners of mechanical stress, there is no justification for such an arrangement; from the point of view of steam economy it is ridiculous and largely nullifies the value of the jackets. Wherever possible, the jacket steam should have a through flow. With saturated steam the engine steam should pass through the jackets and then through a water separator before entering the cylinders.

When jackets are used with steam superheated 100° F. or more, they are unnecessary on the high-pressure cylinder.

Reheaters, which are a form of steam jacket applied to the receivers between the cylinders, are useless with saturated steam.

Small and slow-running engines benefit most from jackets.

ECONOMISERS.

General Notes.

The standard pattern for pressures up to 250 pounds per square inch is represented by the Green and similar economisers.

For the latest turbine practice, with pressures of 350 to 450 pounds per square inch, steel pipes are used, and it is becoming usual to design the economiser as an integral portion of the

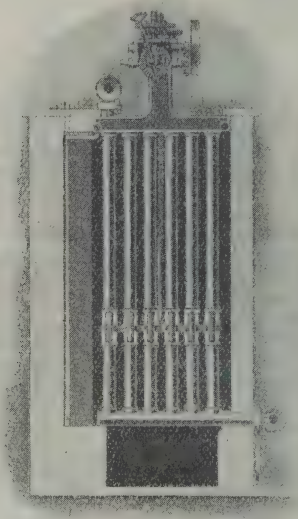

FIG. 12. The 'Green' Economiser

boiler unit. In this sense there is no economiser, but only an equivalent addition to the boiler heating surface. An alternative method is to use cast-iron pipes of moderate surface, sufficient to heat the water to about 200° F. A rotary pump then delivers the water into the boiler proper. The aim of this arrangement is cheapness and the use of standard plant.

Economiser surface can decrease almost inversely as the gas and water velocities, and in fact follows very much the same laws as for boiler and superheater surface.

When using very cold feed, below 90° or 100° F., it should be preheated to 100° F. by live or other steam before passing to the economiser, or the pipes will usually sweat and serious external corrosion take place.

The 'Green' Economiser.

The 'Green' Fuel Economiser, fig. 12 (*E. Green & Son Ltd.*), is a flue-heated feed-water heater. It consists of a series of sections or rows of cast-iron tubes 4.$\frac{3}{16}$ ins. in diameter and 9 ft. long, placed in an enlarged part of the main flue, the tubes being fitted on their external surface with slow-moving scrapers. The sections are from 4 to 12 tubes in width, and the usual number of tubes is 96 per Lancashire boiler. When of large size the economisers are divided into a series of groups of 72 or 96 tubes each. The temperature of the waste gases may be reduced from 650° F. to 350° F., and the feed-water heated to a temperature of from 225° to 300° F. It is not advisable to feed an economiser with water at a lower temperature than 100° F. When the feed-water is colder than this, a small pipe should be led from the heated feed into the entering water, thus raising the temperature by mixture. This prevents external corrosion of the tubes, and improves the action of the scrapers.

The weight of an economiser is about 1 ton for each eight tubes. Its water capacity is 6$\frac{1}{4}$ gallons per tube, and its heat-absorbing surface 10 sq. ft. per tube. The general rule is to provide 4 tubes per ton of coal per week (56 hours). Another rule is to provide 1 tube for each 3 indicated horse-power, but a more accurate standard by which to calculate the size of the economiser required for a given boiler plant, is the evaporative capacity of the boilers.

This economiser is claimed to effect a saving in coal varying from 15 per cent. to 20 per cent in ordinary practice.

The 'Hudson' Economiser.

This economiser (*The Hudson Economiser Co.*) which is also a steam condenser, is of simple construction, and, having no tubes, is claimed to cost nothing for renewal of parts.

The apparatus possesses two special features, viz.:—

1. It extracts the grease from the exhaust steam *before* the latter comes in contact with the cold feed, and thus purified steam is obtained. This is important, as it is said to be impossible to perform the operation of separating the grease from the water afterwards without incurring considerable and constant expense.

2. The *purified steam* comes into direct contact with the *cold* feed (which enters the top chamber of the machine through a patent spray), the water being boiled, a large proportion of the carbonates and other impurities are thrown down, and these are easily removed through the manhole. Thus softened water may be obtained, *absolutely free from oil*, at a temperature of from 200° to 210° F. suitable for boiler feed, and, if required, a large surplus of hot softened water for washing and various other purposes may also be obtained by condensing the whole of the exhaust steam.

In many cases this softened water (free from oil) is being used for cask-washing in breweries, also in public baths, laundries, dye works, mineral-water factories, ice-making works, etc.

By use of this economiser, *incrustation* is entirely arrested before the feed-water enters the boiler, and generally the use of a metal brush may be substituted for the costly chipping of scale from the interior of the boiler shell. In this way a large saving is effected, and the apparatus by reason of this fact alone is of great value to steam users.

A report on *economy trials* by Professor T. H. Beare, M.I.C.E., showed an economy of fuel of 18·8 per cent. by the use of the economiser.

Economiser Data.*

The present standard design of economiser has been practically the same since the first inception, and it would seem to be a very difficult matter to suggest any real improvement on the original design.

The economiser pipe is usually of a standard dimension of 9 ft. length and 4.$\frac{9}{16}$ ins. external diameter, being constructed to suit the boiler pressure and tested by hydraulic pressure to, say, 200 lbs. over working pressure. Each of these standard pipes has approximately 10 sq. ft. of heating surface, holds 6$\frac{1}{4}$ gallons of water and weighs $\frac{1}{3}$ ton. The power required to drive the scrapers is very small, being, for example, about $\frac{1}{2}$ h.p. for a set of 96 tubes. Cast iron is the most suitable material for the tubes, at any rate up to 300 lbs. steam pressure, as steel, wrought iron, copper, brass, etc., will not resist so well the corrosive action of the hot gases.

Makers recommend an installation large enough to hold one hour's supply of feed water in the pipes. Thus if a boiler is evaporating 650 gallons per hour, each tube holds 6$\frac{1}{4}$ gallons, and the number of economiser tubes would be then 104. When the evaporation is not known it is customary to allow 4 pipes for every ton of coal burnt per week of 54 hours, or one pipe for every 3 i.h.p. developed.

* Abstract from 'Exact Data on the running of Steam Boiler Plants.' (D. Brownlie, B.Sc. Hons. (Lond.), F.C.S., J. Compston, and H. W. Royse; *Engineering*, November 1, 1918.)

Out of 250 boiler plants (see page 1468) only 155 were fitted with economisers, the other 95 having no means of utilising the waste heat from the boiler flues. In these 155 plants, the exact average saving obtained was 11·4 per cent. of the coal bill. In actual practice, therefore, only about 17 per cent. of the plants fitted with economisers were saving 15 per cent. or over of the coal bill, whilst over 30 per cent. were saving less than 10 per cent., the true average for the whole 155 plants being 11·4 per cent. as stated.

The average figures from the 155 plants added together showed a beneficial rise in temperature of the feed-water of from 115 deg. F. before the economisers and 241 deg. F. after, i.e., an average rise of 126 deg. F., equivalent to 11·4 per cent. saving. The corresponding fall in the flue gas temperatures from the 155 plants were 581° F. before the economisers and 389° F. after.

The reason the average figures for the actual saving are only 11·4 per cent. is not the fault of the economiser as an appliance, but is due to the fact that the economical generation of steam on scientific lines is not understood, and economisers generally are not installed on correct lines. The economiser is an absolutely essential part of any up-to-date boiler plant, and the saving obtained should be 17½ per cent. to 20 per cent. under average conditions.

Other advantages of the economiser are the reduction of the strain on the boilers by the provision of a high-temperature feed water preventing unequal expansion and contraction, and also that there is always a large reserve of hot water at hand for any sudden demand for steam. Further, the evaporative capacity of the boilers is greatly increased.

The chimney, as a draught producer, is an unscientific and wasteful method of creating a draught, depending for its efficiency on a great waste of heat. If this waste is utilised to the full by the economiser then the draught is curtailed and it is impossible to burn the necessary amount of coal to maintain the evaporation, in spite of the assistance of the economiser. There are many boiler plants that are forced, for this reason, to open slightly the by-pass dampers and allow a portion of the hot gases to go straight up the chimney to waste, so as to maintain a draught to burn the amount of coal required to keep up steam. The mere installing of economisers on rule-of-thumb lines may therefore in some cases be of little real advantage. This difficulty is, however, of little or no importance in the case of mechanical draught.

The water delivered into the economisers should not be over, say, 5 deg. to 6 deg. hardness, when all encrustation troubles will be at an end.

Thousands of economiser pipes have been rendered useless in a few years because of corrosive action. One remedy is to ensure that the feed water does not enter the economiser at a temperature of less than 100 deg. F., by providing an automatic circulating arrangement to take continuously a small portion of the water from the hot end and mix it with water from the cold end.

THE CUMBERLAND ELECTROLYTIC PROCESS FOR PREVENTING CORROSION.

This process eliminates corrosion and prevents scale in economisers of all kinds; in those of the Green, Lowcock or Clay Cross type it is necessary to replace the usual 4-in pipes with others of 8 ins. diameter, otherwise the process cannot be installed

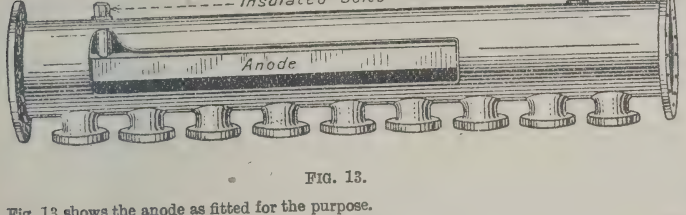

FIG. 13.

Fig. 13 shows the anode as fitted for the purpose.

WATER COOLING TOWERS.

(The Hudson Economiser Co., 110 Bishopsgate, London, E.C. 2.)

In the 'Hudson' patent Water Cooling Towers an allowance of not more than 5 per cent. of the volume of water in circulation is required to make up for loss due to evaporation and possible leakage. The water being frequently heated and 're-cooled' is considerably improved in quality; should it be of a 'hard' nature the carbonates, etc., are precipitated, and a few circuits destroy its scale-forming properties. In cases where large 'cooling reservoirs' are still in use a small 'cooling tower' may be beneficially erected to work in conjunction with them, the reservoirs being utilised to complete the 'cooling' process to the requisite temperature, and a small 'chimney tower' being used to carry all steam and vapour to a height of about 60 feet before liberating it, thus overcoming the inconvenience of having 'steaming' water spread over a large area.

In the system a perfectly free and unrestricted circulation of air in contact with the water is effected, the interior fittings being arranged so as to expose the descending water to the rising air current under the best possible conditions to effectively cool it; even in the hottest climate it is possible to reduce the temperature of the water several degrees below that of the local atmosphere.

The efficiency of the Hudson 'cooling tower' is due to its fulfilling the following conditions :— (1) A perfectly free upward circulation of air. (2) The retention of the water sufficiently long to ensure a complete cooling process. (3) A continuous breaking of the water into a fine spray. (4) The spreading of the water 'film-like' over extensive and exposed surfaces. (5) An evenly distributed 'shower-like' descent of the water from one tier of hurdles to the next. It is effective when working under adverse climatic conditions—viz. when the surrounding temperature is high and the air saturated with moisture.

An important feature of the Hudson apparatus is the great simplicity of its interior fittings. The hurdles are laid in specially prepared recesses, obviating the necessity of 'nailing' down, and whilst being perfectly secure against displacement they can be easily and quickly removed when necessary. Copper rivets are exclusively used in their construction, and there is consequently no corrosion : they are specially treated with a patent composition and are practically indestructible. The hurdles (used for the purpose of breaking up and exposing the descending water) are arranged in tiers laid at an angle of 45 degrees, and are reversed at suitable intervals, for the purpose of retarding the water in its descent. Each hurdle consists of three bars, each bar having four unequal sides. The upper surface of each bar acts as an irrigation or splash bar, causing the water to be broken up into a very fine spray, in which form it readily evaporates and gives up its heat to the rising air current. The bars are grooved at frequent intervals, and the natural tendency of the water to adhere to the wood and flow from the lower point in a thick stream is thus checked and a perfectly uniform and evenly divided shower throughout the cooler is ensured.

STEAM DRYERS AND PURIFIERS AND WATER SEPARATORS.

Dry steam plays a far more important part in the efficiency of engines and boilers than is generally recognised, the economical efficiency of an otherwise high-class plant being frequently marred by the waste, condensation, broken joints, etc., due to wet steam.

Water carried forward from the boiler by priming, although it does no work whatever, is nevertheless heated up to the same temperature as the steam itself, and therefore represents a loss in coal proportionate to its weight. All boilers prime more or less, but priming is invariably heavy in boilers that are worked to their limit, or in any way hard pushed.

An engine may be economical in steam according to diagram, and yet anything but economical if regard is had to the quantity of water contained in the steam, or to the amount of condensation in the cylinder, which the presence of water greatly increases. In the same way a boiler may appear to have a high evaporative efficiency, judged by the quantity of water it disposes of, whereas its efficiency would frequently appear in quite a different light if judged only by the amount of water it evaporated, i.e., gave off as dry steam.

Dry steam itself is not a good conductor of heat, but water is, and therefore its presence in steam pipes and cylinders should never be permitted, as by acting as a conductor between the steam and the metal it sets up active condensation and absolutely prevents economical results being obtained, even in engines of the best design.

In addition to the above considerations, there is also the fact that water in steam pipes invariably causes leaky joints and other annoyances of a nature only too well known.

HEAT ACCUMULATORS.

Where, as in the case particularly of rolling mill engines and winding engines, large quantities of steam are exhausted intermittently, this steam may be profitably utilised in exhaust steam turbines. In order to give a steady supply of steam to the turbine, the exhaust from the high pressure is first passed into a storage vessel or heat accumulator, which consists essentially of a large container in which a large mass of material is placed which can absorb the heat of the engine exhaust during its working periods and redeliver it to the turbine during the 'bridge' periods, i.e. when the reciprocating engine is not exhausting any steam.

An exhaust steam turbine working with steam at, say, 16 lbs. per sq in. abs., and a vacuum of 27·5 ins., will require, with allowance for auxiliaries, about 40 lbs. steam per K.W. hour, so that for every 1,000 lbs. exhaust steam per hour available, and deducting 16 per cent. for wetness and leakage, $\frac{1,000-160}{40} = 21$ K.W. can be obtained.

The proportions of the accumulator depend on the bridge period or time of regeneration, the range of temperature allowable, and the material used to store the heat, as well as on the steam rate. Early accumulators were made up of old boilers packed with old rails, etc., but water is a much more efficient material, for iron has a specific heat of about 0·11 and a specific gravity of about 7, so that its volumetric specific heat is only about 0·77.

The range of temperature to be allowed in the accumulator must be decided upon, and from these figures the mass of water to be employed must be calculated. If the accumulator becomes too hot it will reduce the power of the engines which feed it. If it becomes too cold this proves that the turbine is doing more work than can be supplied by the waste steam. It is considered that usually the stops to be bridged by the accumulator are 60 secs. in colliery work and 30 to 45 in rolling mills. The admission to a steam turbine is assumed to be 16·5 lbs. absolute, the range being 15 to 18 lbs., or 10° F. In some plants, pressure rises more than ½ lb. above atmosphere, and it may fall to 12 lbs. absolute or 5½ ins. of vacuum. A reflux valve is arranged in that case to prevent the vacuum getting back to the engine—an important safeguard for a winding engine.

In calculating accumulators,

$$\mathrm{WTL} = wt,$$

where,

W = lb. of steam supply per sec.; w = lb. of water in accumulator; T = time of regeneration in secs.;

L = latent heat of steam per lb.; t = range of water temperature in accumulator.

It is essential that the steam should mix with the water, or this will be locally heated only. Shallow dishes of water piled in tiers with narrow spaces for steam admission between them have been used, or the water may be kept in continuous circulation by a pump which delivers it in a shower through an upper steam space.

In the Rateau-Morison type of steam accumulator, great attention has been paid to efficient circulation. This has been attained by means of a number of vertical open-ended cylinders, each containing a nozzle with upturned star-shaped opening. This is placed 9 ins. below water-level, and sets up a powerful up-flow through the cylinder, which draws from the base of the accumulator and discharges the heated water at the surface.

As many as 30 such circulators are hung on curved branch pipes from each side of the exhaust main which runs along the crown of the accumulator boiler. Below the main is a third row. The accumulator is a plain cylinder laid horizontally with about 6 ft. of water depth. Circulation is so rapid that a difference of only 2° F. occurs between top and bottom of the water. The circulation cylinders have their discharge openings all turned to one end of the accumulator, and all oil is then drifted that way and collected behind two vertical plates and blown off periodically.

Accumulators are made of old Lancashire boiler shells, or built up of cast iron segments or may be of ferro-concrete.

An increase of vacuum from 26 to 28½ ins. will reduce the steam consumption of a turbine by 25 per cent. With this vacuum the condensate will be about 80° F., and if there is any spare steam it should be applied to feed heating. In this case by heating the feed to 200° an economy of 12 per cent. is secured.

THE PAXMAN Positive Valve Gear engines are suitable for boiler pressures up to 200 lb. per square inch, with a total steam temperature up to 600 degrees Fahr.

The economy of the steam consumption of these engines is remarkable, it being possible to obtain one-horse power for every $9\frac{1}{2}$ to $10\frac{1}{2}$ lb. of superheated steam.

With an installation comprising our 'Economic' type of boiler and Positive Valve Gear engine combined, we are able to guarantee consumptions of 1·1 to 1·2 lb. of coal per I.H.P. per hour under suitable conditions.

PART IV

ENGINE TYPES FOR VARIOUS DUTIES—WEIGHTS OF ENGINES.

(Revised by T B. Morley, D.Sc., M.I.Mech.E.)

ENGINE TYPES FOR VARIOUS DUTIES.

Each type of engine has a field, not sharply defined, in which it shows to best advantage.

Elaborate and expensive types are least desirable when coal is very cheap, the working hours few, labour unskilled, or the working conditions very rough.

Non-condensing engines consume from 20 to 50 per cent. more steam and coal than condensing engines.

Unless floor space is limited or very high speeds are desired, a horizontal engine is generally more satisfactory than a vertical. It is cheaper to instal and more accessible for running and overhauling.

Steam turbines are relatively uneconomical in very small units. In the neighbourhood of 1,000 to 1,500 horse-power they surpass the best reciprocating engines, and for very large units—unless for some special purpose, as driving a reversing rolling-mill—are without serious rival. To show to advantage a turbine must be run condensing, with a good vacuum.

Where economy is at all important the ordinary simple (single-expansion) engine is at a marked disadvantage; which, however, is least with steam superheated 120° or 150°F. For most purposes the compound is the standard type, although the uniflow (a special form of single-expansion engine) is widely adopted. Triple and quadruple expansion engines are more economical than compound, but are more costly and complex. They are therefore chiefly employed on ships, for towns pumping, flour mills, and other situations where coal consumption is specially important. Their superiority over the compound engine is reduced if the steam is superheated.

The class of engine is frequently designated by the valve gear. Thus the plain slide valve gives the cheapest engine and also, other things being equal, the least economical.

The piston valve is really a circular slide valve, and gives an engine of similar characteristics. For the highest economy and class of engine Corliss or drop valves are desirable. The Corliss valve is really a circular slide valve of small diameter which rotates to and fro through a small angle in its valve chamber. The drop valve may be of the double-beat seating type or of the double-beat piston type. As a rule Corliss and drop valves are operated by a trip valve gear or other form of valve mechanism enabling the cut-off to be automatically varied to suit the load. Slide and piston valves, on the other hand, are not so suitable for cut-off governing and are not usually so arranged, but rely on throttling the steam to meet changes of load. High-speed engines almost invariably have piston or slide valves, because trip and other cut-off gears are unsuitable at high speeds of revolution.

Cut-off, or expansion, governing gives the best economy for variable loads, except at very light loads, when throttling is superior. The difference is least with highly superheated steam, which tends to equalise the steam consumptions at different loads (measured per horse-power, of course).

The superior economy of Corliss and drop valve engines is often believed to be due to the superior qualities of trip valve gears. Actually this is a very minor factor. The chief gain arises from the fact that the inlet and exhaust ports and valves are usually quite separate.

The following list shows the engine types adopted for various duties in first-class engineering practice :—

Duty.	*Type of Engine.*
Agriculture, occasional service	Simple, slide or piston, N.C.
„ regular service	Compound, slide or uniflow, N.C.
Cement works	Compound, Corliss or drop, uniflow, S.
Electric generating, small	Compound, high-speed vertical, Corliss, or drop, S.
„ „ medium	Compound, Corliss or drop; uniflow; or turbine, S.
„ „ large	Turbine, S.
Factories, cotton mills, etc.	Compound, Corliss or drop, uniflow, S.
Flour mills	Compound or triple, Corliss or drop, uniflow, S.
Paper mills	Compound, Corliss or drop; uniflow, also with steam extraction, S.
Portable	Same as agriculture.
Pumping, centrifugal	Compound, usually high-speed vertical, also uniflow if at moderate speed, S.
„ hydraulic and town water	Triple three-crank vertical, slow-speed, Corliss or drop, S.
„ well pumps	Compound or triple, Corliss or drop, S.
Rolling mills, not reversing	Horizontal compound, Corliss or drop, uniflow, S.
„ „ reversing	Two- or three-crank, piston valves, simple or tandem compound, often N.C., S.
Winding	Two-crank simple or compound (tandem usually), N.C., S.

Note.—N.C. indicates non-condensing. S. indicates superheated steam.

Engine Types, General.

As coal increases in price the general tendency must be towards the more efficient engines. Thus, for agricultural, portable, and other 'occasional' engines, superheated steam is highly desirable. Condensation is often difficult to arrange, and this makes the merit of the uniflow engine less pronounced. Compounding does not add very much to the cost and justifies itself where the total hours worked in the year reaches a reasonable figure.

For factory working, a high-class compound or uniflow engine is essential and the steam should be superheated 100 to 150° F.; similarly for electric generation, other than occasional or intermittent use.

For large electric generating sets the steam turbine alone need be considered, and should use high pressure and high superheat.

For rolling mills and winding engines a fairly high degree of superheat, 100 to 150° F., is essential. If non-condensing the exhaust steam should be utilised in a low-pressure turbine. If this is not convenient condensation should be employed, although it is not yet usual. In that case compounding should be adopted. Compounding is probably almost always justified for winders for deep shafts.

The Uniflow Engine.

The special characteristic of the uniflow engine is that the steam is exhausted through a central ring of ports; the piston has a length about 90 per cent. of the stroke, and uncovers the exhaust ports at about 90 per cent. of the working stroke (see fig. 1). The steam enters by inlet valves, usually of the double-beat seating type, placed at the cylinder ends, and, as it leaves at the middle, the inlet ends are never cooled by exhaust steam rushing over their surfaces, nor are the exhaust ports exposed to live steam. The clearance volume is 2 to 3 per cent. of the stroke volume, and compression normally begins when the piston covers the exhaust ports—i.e. at about 10 per cent. of the compression stroke.

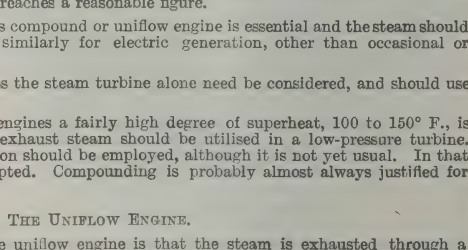

Fig. 1.

The high compression serves to heat not only the clearance surface, but the piston face, and condensation during admission is reduced to a minimum. Cyclic temperature changes in the cylinder walls are reduced, and the temperature falls gradually from the ends to the exhaust belt.

The entire expansion takes place in one cylinder, hence early cut-off is necessary.

The number of expansions is usually about 10; that is, about 10 per cent. cut off. This is not quite so high a figure as a typical compound engine, but owing to the absence of receiver losses and reduced initial condensation, a better economy by 5 to 10 per cent. is obtained with the uniflow, if condensing.

The full steam pipe pressure comes on the large piston, and the load on the line of parts is high in proportion to the M.E.P. This makes for weight and cost, but higher unit stresses, if based on steam pressure only, are permissible if due advantage is taken of the heavy reciprocating parts and high rotational speed to give a high inertia loading. The turning is then equal to a good tandem compound engine, but is inferior at low rotational speeds.

Owing to the high compression ratio, if the vacuum falls below normal, the pressure at the end of compression would become excessive unless an efficient preventive device ('compression release gear') is provided.

The Galloway Uniflow Engine.

(Galloways, Ltd., Manchester.)

The steam valves are double-seated drop valves, and are placed in the cylinder covers, which form steam jackets for the valves and cylinder ends. In boring the cylinder, allowance is made for the higher temperature, and consequent greater expansion, at the ends when working. The cylinder is provided with an inspection door, by removing which the piston rings and cylinder bore may be inspected.

The novel features of the engine described are the patent shockless high-speed valve gear and the automatic compression release gear. In this valve gear (fig. 2) oil under pressure is

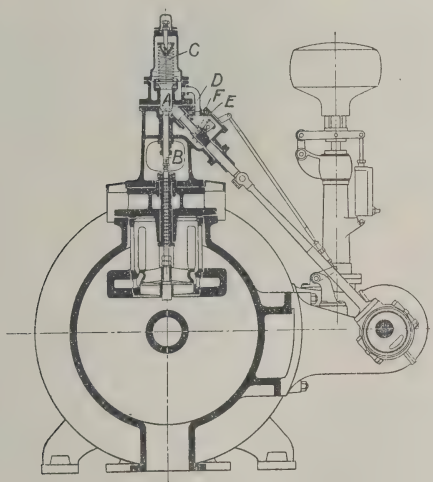

Fig 2.—Cross Section of Cylinder.

applied below the plunger A connected to the valve spindle B and lifts the valve. An eccentric on the lay shaft operates the ram D of an oil pump in the valve bonnet. The ram is hollow, and has a ring of slots or ports E, which at certain parts of the travel may be covered by a sleeve F, the position of which is controlled by the governor. On the upstroke of the pump oil is forced into the chamber below the plunger, thus raising the plunger and the steam valve. At a point determined by the position of the governor, the ports in the hollow ram are overrun by the sleeve and the oil escapes. The valve is then free to close under the combined

action of a spring and dashpot. The valve gear is silent, compact, and takes little power to operate it.

The automatic compression release gear is shown in Fig. 3. Two supplementary exhaust valves G, H, are arranged on the side of the cylinder. They are normally kept closed by springs J, K. On the engine lay-shaft is a sleeve L carrying two cams of tapering form, which are capable of longitudinal movement. Their axial position is made to correspond automatically with the vacuum by means of the spring-controlled piston O of a small cylinder P at the end of the lay-shaft, one end of this cylinder being in communication with the condenser. The

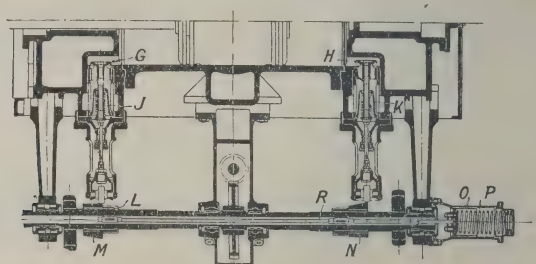

FIG. 3.—Arrangement of the Automatic Exhaust Gear.

piston operates the cams by the rod R. At normal vacuum the small end of each cam is just clear of the roller on the valve stem, and the valves are not opened. If the pressure in the condenser rises the cams move axially, so that each exhaust valve is opened during part of the compression stroke, the amount and duration of the opening depending on the cam position, and hence on the vacuum. This engine starts without vacuum, as it drives its own air pump, and the compression release gear gives full relief of compression until a vacuum is established, and then permits the compression to increase until at normal vacuum full compression is reached. Fig. 4 shows the action of this gear.

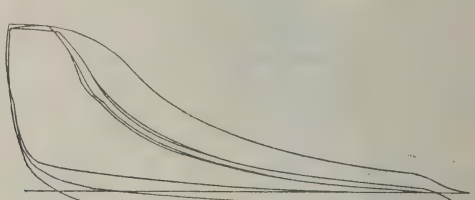

FIG. 4.—Indicator Diagrams, showing Operation of Compression Release Gear.

THE PAXMAN POSITIVE VALVE GEAR ENGINE.

The Paxman type of engine is chiefly noticeable for its simple positive valve gear, its high rotational speed, massive construction, and silent running, its sensitive inertia governor, frictionless metallic packing, and also for its low steam consumption, a result of under 10 lbs. per i.h.p. hour being obtainable under favourable working conditions.

With the Paxman valve gear, fig. 5, no dash-pot is used. The valve is raised by the cam lever A, acting upon the roller B, this lever being moved by the eccentric, and the whole movement is accomplished without noise or hammering. The roller B is always kept in close contact with the cam or lever A during the travel of the valve, by means of the spring shown in the

bonnet. The cam does not move clear of the roller until after the valve is seated, and consequently, even when the engine is running at the highest speeds, the gear is entirely silent. The friction to which the valve is exposed is practically nil.

There is no tripping movement with the valve gear, but the valve is lowered gently on to its seat by means of the cam (the profile of which is so shaped as to allow this to be done rapidly) and when the valve is seated, and not until then, the cam moves clear of the roller. The system renders quite permissible the employment of such high piston speeds and revolutions (even in the case of very large engines) as could not be possible with trip-gear.

The valves are free to lift easily in the case of any abnormal pressure arising within the cylinder, and they thus act as relief valves, avoiding all danger of water shock.

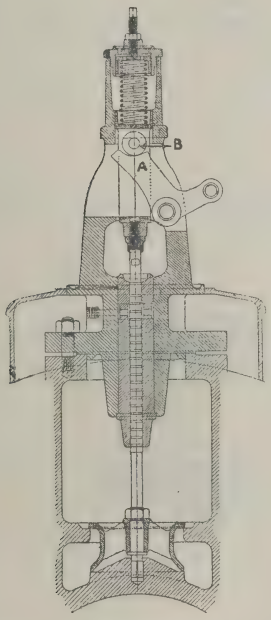

FIG. 5

The valve spindles are grooved and work in cast-iron sleeves; by means of the Paxman system of draining, no stuffing boxes are required, which reduces the friction to a minimum, and allows the governor to be extremely sensitive while having great stability.

The governor is of the inertia type, and is placed on the side shaft; it is directly connected to the two high-pressure steam eccentrics, which eccentrics are movable on a slide block keyed to the shaft: thus the governor can alter the eccentricity, and consequently the cut-off. It regulates within an exceptionally short period, and the momentary change of speed due to the load being thrown on or off is only slightly in excess of the permanent change. Fig. 6 shows graphically the very slight alteration in speed occasioned by throwing the load suddenly off or on the engine, the resultant change of speed being hardly perceptible. The action of the Paxman governor is immediate, and it combines extreme sensibility with a perfect stability comparable with the best turbines.

Fig. 7 shows the piston-rod packing of the Paxman effective type. By eliminating springs, friction is reduced to a minimum, and as the packing is free from wear, perfect steam

tightness is assured. The packing consists of a series of cast-iron rings which fit over the rod, and are held in cast-iron boxes which allow them to oscillate sideways, thus avoiding friction between rod and rings. There is no gland bush, the steam having direct access to the packing, but it returns to the cylinder during the period of expansion, instead of leaking through the packing. The rings form a series of chambers which are efficiently drained, any steam escaping

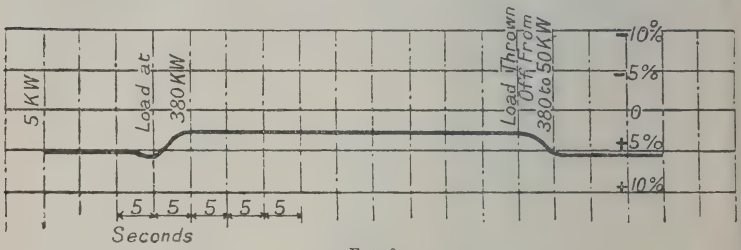

FIG. 6.

from the front chamber entering the second chamber, and there expanding. A small part of it may escape to the third chamber and undergo further expansion, and so on, but the last ring will never show the slightest leakage.

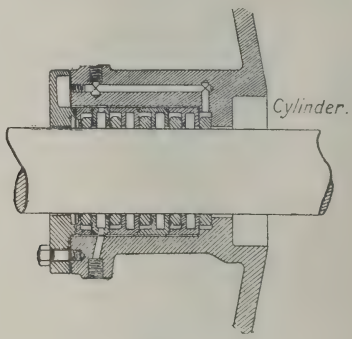

FIG. 7.

Paxman engines are made of the single-cylinder coupled compound, or tandem compound horizontal types, and for any steam pressure up to 190 lbs. at the engine stop valve.

ROBEY DROP-VALVE REVERSING AND OVERWINDING GEAR.

(Patent.)

The distinguishing feature of this gear, fig. 8, page 1535, is its simplicity combined with absolute efficiency.

Both steam and exhaust valves are actuated by the one eccentric marked A. This is effected by the rod B actuating the rocking lever C, which is supported on a fixed bearing D, giving an up-and-down motion to the steam actuating lever E, and the exhaust lever F; the latter, by means of the bell crank lever G, opening the exhaust valve at the proper moment.

The steam admission rod E by means of the well-known Robey trip-motion opens the steam valve. The rods E and F have a constant movement, and the reversing is done by varying the

position of the rod B. This is effected by moving the eccentric A (the strap and connections are omitted in the figure). This eccentric is mounted on a square block H, which is driven from a fixed plate on the layshaft.

By means of the sliding sleeve on the layshaft, and two bell crank levers, the eccentric A can be moved to the position indicated by the dotted lines, and the engine will then run in the opposite

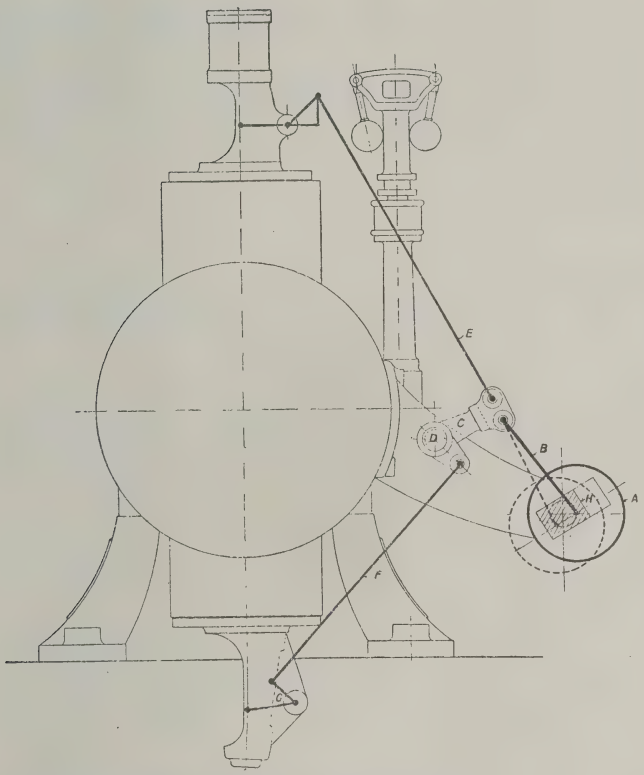

FIG. 8.—Robey Drop-Valve Reversing Gear.

direction. The sliding sleeve is connected by a simple fork connection to the reversing lever and the power necessary to move this eccentric A is very small indeed, and the lever can be worked by hand in engines up to the largest sizes.

Each end of the cylinder has an exactly similar arrangement of the gear, and the same sliding sleeve actuates both eccentrics.

When it is desired to have the gear under the control of the governor, and not by hand alone, it is necessary to have a small auxiliary eccentric on the layshaft, which is keyed on in a fixed

position, and does not vary with the direction of running of the engine. This auxiliary eccentric, in conjunction with the governor, regulates the exact cut-off in accordance with the speed of the engine.

When the governor is in the lowest position, the cut-off is at the maximum, and the driver has therefore only to turn full steam on at the commencement of the wind, as the governor will cut off the steam when maximum speed is obtained. The connection of the governor to the gear is automatically thrown out of action when the engine is reversed, thus enabling the driver to put full steam against the engine.

The steam admission valves are of the well-known Robey type, and there is no liability whatever for the valve to hold up. As a measure of precaution, however, an arrangement is fitted which closes the valve positively if it should by any means not fall, but this has never been known to come into action.

Indicator diagrams show that the lead at all points is practically constant.

In the patent overwinding gear the steam is shut off immediately at the cylinder instead of at the throttle; this renders the system particularly effective.

The overwinding gear is absolutely part of the valve gear, and has not to be driven by an independent chain or gearing of any description.

The Robey High-Speed Vertical Engine.

(Open Type.)

Figs. 9, 10 show the latest type of high-speed vertical engine with open front. It is fitted with the Robey improved crankshaft throttle governor driven direct from the crankshaft without either gearing or belt, thus ensuring absolute reliability. The flywheel can be supplied either suitable for belt driving or of the disc type suitable for direct coupling.

Specification.

Cylinder is made of the best cold-blast iron, free from all defects, fitted with bright covers secured by studs and nuts. All stuffing boxes have gunmetal neck bushes and gunmetal glands. Cylinder drain cocks are fitted with copper-pipe connections.

Governor is of the crankshaft throttle type, dispensing with either belts or gearing for actuating governor. The speed of the engine can be varied while running by means of the adjusting arrangement fitted on the governor.

Piston is of cast iron fitted with expanding rings.

Piston Rod is of steel, coned at top end, fastened to end of piston by nut and pin, and forged solid with crosshead.

Crosshead is of forged steel, fitted with cast-iron slipper, with ample bearing surface and suitable means of adjustment.

The gudgeon pin is of case-hardened tough mild steel ground up true.

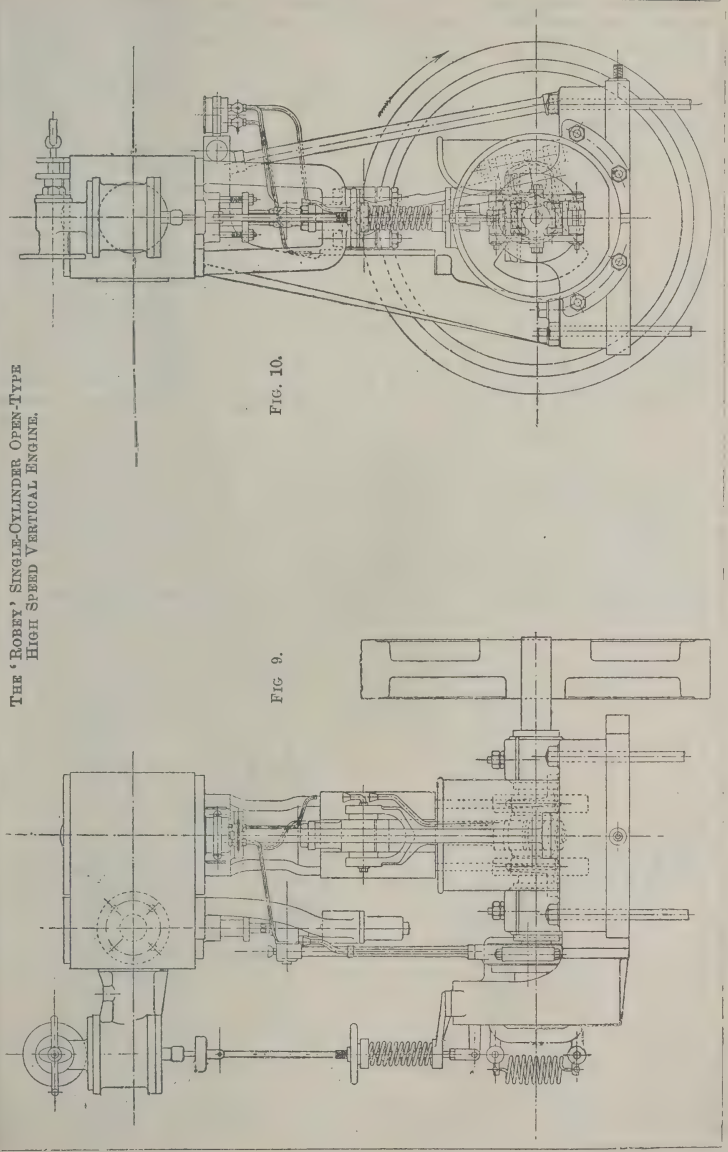
Connecting Rod is of best mild steel finished bright all over, fitted with marine large end, and small end provided with adjustment. The top is fork ended and with gudgeon pin shrunk in.

Valve Rod is of best mild steel with case-hardened eye adjustable by a small cotter.

Crankshaft is of steel turned all over and of the balanced slab type.

Standard is of special design with open front, securely attached to baseplate and cylinder, and has a removable polished pillar in front.

Crosshead Guide is tooled out perfectly true, and well fitted with oiling arrangements.



Base Plate and Bearings.—The cast-iron base plate has two adjustable bearings, fitted metal to metal, resting in bored-out carriages formed in base plate and secured by cast-iron caps, with brass and glass needle or drop-feed lubricators.

Flywheel is provided of a heavy pattern, accurately balanced, and turned on face for driving belt, or of the disc pattern with facing for direct coupling to dynamo as required.

Oiling Arrangements.—A special oil reservoir is provided at the top of engine standard with connecting pipes to all working parts.

The crank chamber is formed to collect the oil after use, which may be drawn off by means of a small cock provided at the bottom of the engine bedplate. Suitable splash plates are provided.

Extended Bedplate.—This can be made of suitable design to suit any make of dynamo.

THE GALLOWAY DROP PISTON VALVE ENGINE.

(*Patent.*)

The special features of this engine (*Galloways Ltd.*) lie in the steam valves, fig. 11, which are of the drop piston type working in a slotted seat, which in turn is carried by a short vertical cylinder standing in the inlet valve of the steam chest. This short cylinder is surrounded on all sides by steam at one temperature and pressure, and remains truly circular under all conditions however much the steam temperature and pressure may vary. This preserves the circularity of the valve liner and therefore its steam-tightness.

The piston valve itself is of the double-beat type fitted with 'Duplex' spring rings. The duplex rings are so arranged that they cannot fall out of the body of the valve in case of breakage.

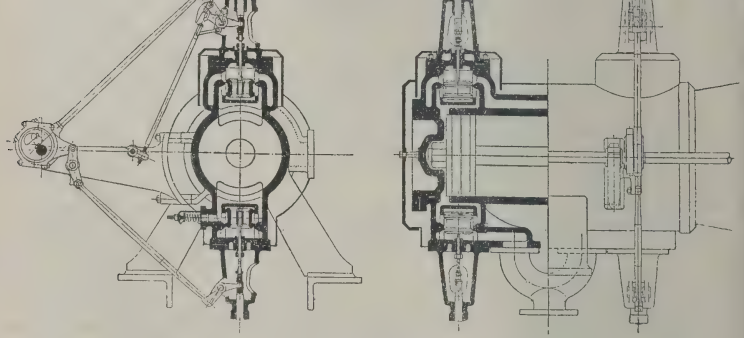

FIG. 11.—Sections through Cylinder, showing Drop Piston Valves.

There being two rings, one inside the other, bedded against each other over their whole circumference, the ring cannot be collapsed by the application of sudden pressure, as when the ring passes over a steam port. On test, the steam leakage in a 14-inch steam valve of this type proved to be a fraction of 1 per cent.

The Galloway Reversing Rolling Mill Engine.

In connection with the reversing rolling mill engines Messrs. Galloways fit a patent single lever expansion control gear. By the employment of one handling lever, both the throttle valve and the cut-off are suitably varied in a predetermined manner. This is so arranged that during the mean rolling period the engine works with variable cut-off and full steam pressure in the cylinders, thus securing maximum economy. When starting up, the gear partially closes the throttle and gives late cut-off so as to produce an even steady turning at a slow speed. When the handling lever is brought to mid gear at the completion of a pass, the control valves are forcibly closed so that no steam leakage can take place. By means of this valve gear the steam consumption is claimed to have been reduced to one-half, or less, of that normally required, whilst the output of the rolling mill is increased, as the single lever expansion control gear gives very rapid action on the part of the engine.

Forced Lubrication.*

Forced lubrication as a continuous or arterial system of conveying oil under pressure to all the working parts of an ordinary reciprocating engine was patented in 1890 (No. 7397) and introduced by Messrs. Belliss & Morcom Ltd. of Birmingham in their self-lubricating engine (*vide* sectional illustration, fig. 12, which shows their original design of compound engine 'O' type). The constant supply of oil under pressure prevents the working surfaces coming together, the film of oil taking an appreciable time to squeeze out, which is sufficient in a double-acting engine running at a high speed to last until the stress is reversed and the film on the other brass comes into operation; the bearing surfaces are thus prevented from coming into actual contact. In this system the engine is enclosed, and oil drawn from a reservoir in the bedplate by a pump is fed to circumferential grooves in each of the main bearings. The crankshaft is drilled, so that oil drawn from the circumferential grooves in the main bearings is conducted to similar circumferential grooves in the crankpins and thence to the crosshead pins and guides. The valve motion is lubricated in the same way, also the working joints in the governor. The oil escaping from the journals returns to the oil-well in the bed for re-use. The pump, which is of the oscillating type without loose valves or packings, is operated from the eccentric and draws its supply through a gauze strainer. The pressure of oil generally used may be anything between 10 and 25 lbs. per sq. inch.

The Belliss and Morcom 'O' Type High-Speed Engine.

The special feature of this engine, fig. 12, is the arrangement of the slide valves, requiring one eccentric and rod only. The low-pressure valve is superimposed above the high-pressure, working in the same valve chamber, the high-pressure valve taking steam on the inside and exhausting direct to the low-pressure, which cuts off on the outside edge. The cranks are necessarily set opposite to each other, the steam being admitted simultaneously to the top of one cylinder and the bottom of the other, by which arrangement the reciprocating parts are to a great extent balanced, the stress on the bearings much reduced, and a high speed of revolution made possible. A variation of speed not exceeding 3 per cent. between full and no load can be guaranteed. The governor gear is arranged so that the speed of the engine is capable of being adjusted whilst running.

A modification of this design of engine, more recently introduced, is the 'V' type (see fig. 13, page 1540).

Back Pressure and Extraction Engines.

Increasing attention is now being paid to the saving of fuel, which is rendered possible by the combination of power supply and heating services, the heating being effected by using exhaust steam or steam taken from the engine at an intermediate pressure. Factories using steam for heating in their own industrial processes offer special opportunities in this direction, though schemes have also been successfully carried out in which the heating of adjoining offices and houses has been effected in addition to the heating required in the factory processes.

For example, in a factory requiring 200 i.h.p. for driving machinery, and 3,200 lbs. of steam per hour at about 5 lbs. per sq. in. gauge pressure for heating purposes, the methods of independent and combined supply may be compared as follows. In the independent method an economical condensing engine would be used, taking, say, 11 lbs. steam per i.h.p. hour, or $11 \times 200 = 2,200$ lbs. steam per hour. The total steam is thus $2,200 + 3,400 = 5,600$ lbs. per hour.

In the combined system, a back pressure engine would be used, exhausting at the pressure required for the heating steam. It would require, say, 18 lbs. steam per i.h.p. hour, or 3,600 lbs, per hour. Allowing 10 per cent. for loss by condensation, 3,240 lbs. exhaust steam per hour are available for heating. Thus the steam to be generated for all purposes is 3,600 lbs., as

NOTE.—The Power given in Columns 2 and 3 is the Brake Horse-Power; the Indicated Horse-Power will be correspondingly higher.

against 5,600 lbs. in the former case, and even though the whole of this steam has to be generated at high pressure and (preferably) superheated, the fuel consumption at the boiler is reduced in nearly the same proportion. The saving in fuel is thus $\frac{5,600 - 3,600}{5,600} \times 100 = 35{\cdot}6$ per cent. nearly.

In the 'intermediate steam extraction' system, which is adapted for fluctuating power and heating requirements, a compound engine is used, the heating steam is taken from the receiver between the cylinders, and only a part of the steam used in the h.p. cylinder passes to the l.p. cylinder, and thence to the condenser. By means of a pressure regulator, the intermediate pressure is allowed to vary only between fixed limits. With an increased demand for heating steam, the pressure falls slightly, the pressure regulator makes the l.p. cut-off take place earlier, and, if the load on the engine remains unchanged, the speed governor makes the h.p. cut-off correspondingly later; thus more steam passes through the h.p. cylinder and less through the l.p. Provision is usually made for supplementing the 'extraction' steam, when necessary, by steam taken directly through a reducing valve from the live steam main; this additional supply is also controlled automatically. The l.p. cylinder may with advantage be of the uniflow type.

By means of such systems the large proportion of heat carried away and lost in the condensing water of even highly economical power plants is greatly reduced; cases are on record in which the heat utilised as work in the engine, together with heat made available for heating purposes, amounts to 77 per cent. of the heat in the steam delivered by the boiler.

STEAM TURBINES.*

FLOW OF STEAM—NOZZLES—BLADE EFFICIENCY—LOSSES—PACKINGS—ROTORS—MATERIALS—TEST DATA—TURBINE TYPES—REDUCTION GEARS.

(Contributed by H. L. Guy, Wh. Exh., A.M.Inst.C.E., A.M.I.Mech.E.)

In this section the following symbols have been used in the indicated significance, except where otherwise stated :—

c = absolute velocity in ft. per sec.
g = constant of gravitation = 32·2 ft. per sec.^{2}
H.h. = heat drop in B.Th.U.
N = speed in r.p.m.
P = pressure in lbs. per sq. ft.
p = pressure in lbs. per sq. in.
t = temperature °F.
T = absolute temperature °F = (460 + t)
U = peripheral velocity in ft. per sec.
v = specific volume in cubic ft. per lb.
W = weight of steam in lbs. per sec.
w = relative velocity in ft. per sec.
λ = ratio of the specific heats of a gas.
ω = angular velocity in radians per sec.
J = Joule's Equivalent = 778 ft. lbs. per B.Th.U.

FLOW OF STEAM.

When steam flows through a simple orifice from a chamber (denoted by suffix 1) into a space (denoted by suffix 2) the velocity with which discharge takes place is always dependent on the steam conditions existing before the orifice, and sometimes dependent upon those existing on the discharge side.

If the pressure, P_1, in the chamber is maintained constant, while that beyond the orifice is gradually reduced from an initial value equal to P_1, the velocity and quantity of discharge gradually increase and depend on the pressure drop over the orifice, until a critical value is reached corresponding to a definite value of the ratio $\frac{P_2}{P_1}$.

Dr. Zeuner† has shown theoretically, and the result is borne out by experiment, that the critical drop is reached when

$$\frac{P_2}{P_1} = \left(\frac{2}{\lambda+1}\right)^{\frac{\lambda}{\lambda-1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

For saturated steam $\lambda = 1{\cdot}135$, and $\frac{P_2}{P_1} = 0{\cdot}577$.

For superheated steam $\lambda = 1{\cdot}3$, and $\frac{P_2}{P_1} = 0{\cdot}546$.

---

* See also Marine Steam Turbines, Section XXXIII.
† *Technical Thermodynamics*, Dr. Zeuner.

After this *Critical Pressure Drop* has been reached, the quantity and velocity of discharge remain constant for smaller values of P_2, the discharge being accompanied by strong acoustic vibrations.

Dr. de Laval was able to obtain—and used in his turbine—much higher velocities than the critical velocity, by adding a conically divergent nozzle to the orifice. In this way the vibrations are eliminated, and although the velocity of exit from the nozzle may be considerably greater than the critical velocity, the velocity at the minimum section or throat of the nozzle and the weight of steam discharged remain unchanged from the values which would exist in a simple orifice.

From this it will be apparent that there is a discontinuity in the phenomena accompanying discharge of steam through an orifice or nozzle, and that the equations existing between the various terms entering into the formulæ of steam flow must be considered in two groups.

(a) *When the Pressure Drop is less than the Critical Drop.*

i.e., when $P_2 > 0{\cdot}577\ P_1$, for saturated steam; $P_2 > 0{\cdot}546\ P_1$, for superheated steam.

The theoretical velocity c_1 with which discharge takes place, can be calculated from the formula due to Wantzel and St. Venant,

$$c_1 = \sqrt{2g \frac{\lambda}{\lambda - 1} (P_1 v_1 - P_2 v_2)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The actual velocity of discharge c_2 is less than c_1, on account of the friction and eddy losses in the orifice, and is given by

$$c_2 = \phi\, c_1,$$

$$\text{Where } \phi = \text{velocity coefficient} = \frac{\text{Actual velocity of discharge}}{\text{Theoretical velocity of discharge}}$$

The value of ϕ for various cases is given in Table II., page 1550.

The weight of steam discharged per second is given by the relation

$$W = k\, S \frac{c_2}{v_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where v_2 = specific volume of the steam in the lower state, in cubic ft. per lb.
S = the sectional area in sq. ft. of the smallest section or throat of the orifice.
k = coefficient of discharge (see Table II.).

The expansion takes place with very great rapidity and for purposes of calculation it may be assumed to be adiabatic without serious error. The validity of this assumption has been questioned, but Dr. A. Loschge* has proved its approximate correctness by obtaining equal discharge through duplicate nozzles made of metal and of porcelain, and it need only be added that formulæ deduced from this basis agree very closely with experimental results.

For adiabatic expansion—

$$P_1 V_1^{\lambda} = P_2 V_2^{\lambda} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

from which, by combination with (2) and (3), we get

$$W = k S \sqrt{2g \frac{\lambda}{\lambda - 1} \frac{P_1}{v_1} \left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{\lambda}} - \left(\frac{P_2}{P_1}\right)^{\frac{\lambda+1}{\lambda}} \right]} \quad . \quad . \quad . \quad . \quad (5)$$

Alternative Method.

The following method of dealing with such problems, due to Dr. Zeuner, is often more simply manipulated than that already given, especially when used in conjunction with the Mollier or other entropy diagram.

If

H_1 = total heat of 1 lb. of the steam in the higher condition in B.Th.U.;
H_2 = total heat of 1 lb. of steam in the lower condition in B.Th.U.;
h_a = the heat drop available for adiabatic expansion = $H_1 - H_2$.

---

* *Engineering*, October 17, 1913.

Then

$$c_1 = \sqrt{2g \cdot J \cdot h_a} \quad . \quad . \quad . \quad (6), \quad \text{and } c_2 = \phi \cdot c_1.$$

W can be calculated as before from (3); h_a can either be measured directly off a Mollier diagram or calculated from steam tables in the following manner :—

If $t°$ = degrees of superheat; L_1 = latent heat corresponding to P_1; T_1 = absolute temperature corresponding to P_1; h_1 = sensible heat corresponding to P_1; X_1 = dryness fraction of the steam in the higher state; T_2 = absolute temperature corresponding to P_2; h_2 = sensible heat corresponding to P_2; X_2 = dryness fraction of the steam in lower state; ϕ_1 = entropy of the liquid in the higher state; ϕ_2 = entropy of the liquid in the lower state.

Then

$$X_2 = \frac{T_2}{L_2}\left[\frac{X_1 L_1}{T_1} + C_p \log_e\left(\frac{T_1 + t}{T_1}\right) + \phi_1 - \phi_2\right],$$

and

$$h_a = X_1 L_1 + C_p \cdot t \cdot + h_1 - X_2 L_2 - h_2.$$

In these formulæ the mean value of the specific heat of superheated steam at constant pressure C_p for the range of the superheat should be taken.

Nozzles which are designed for a smaller pressure drop than the critical are wholly convergent and must be sized according to the methods given in this section.

Simple orifices, the nozzles of Rateau or Zoelly turbines, and both the rotating and stationary blades of Parsons turbines, fall into this class.

(b) When the Pressure Drop is Greater than the Critical Drop.

i.e., when $P_2 < 0{\cdot}577P_1$, for saturated steam; $P_2 < 0{\cdot}546P_1$, for superheated steam.

In this case let the suffix m denote the conditions in the minimum section on 'throat' of the nozzle.

Then whatever the total pressure difference over the nozzle, that from P_1 to the throat pressure is always equal to the critical value, and the nozzle must be convergent to the throat.

By combining (1) with (2) and (4), the velocity in the throat is obtained.

$$c = \sqrt{g\lambda \cdot P\,v} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

if $\phi = 1{\cdot}0$.

(7) is identical with the expression for the velocity of sound in the conditions present in the throat, so that the velocity in the throat, or the critical velocity, is equal to sound velocity.

By substituting from (1) and (4) in (5)—

$$W = k S_m \sqrt{2g \frac{\lambda}{\lambda + 1}\left(\frac{P_1}{v_1}\right)\left(\frac{2}{\lambda + 1}\right)^{\frac{2}{\lambda - 1}}} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

from which the discharge per second can be obtained, S_m being the area at the throat in square feet.

The nozzle from the throat to the mouth must be divergent, the area at the mouth being calculated from the relation

$$S_2 = S_m \cdot \frac{v_2}{v_m} \cdot \frac{c_m}{c_2} = S \left[\left(\frac{2}{\lambda + 1}\right)^{\frac{1}{\lambda + 1}} \left(\frac{P_1}{P_2}\right)^{\frac{1}{\lambda}} \sqrt{\frac{\frac{\lambda - 1}{\lambda + 1}}{1 - \left(\frac{P_2}{P_1}\right)^{\frac{\lambda - 1}{\lambda}}}}\right] \quad . \quad . \quad (9)$$

Expressions involving λ are strictly applicable only when the expansion takes place wholly in either the superheated or the saturated region, the corresponding value of λ being introduced.

The following expressions will be found to give approximately the same results as (9).

For Superheated Steam.

If $P_1 = (1{\cdot}732 \text{ to } 20)\ P_2$ $\quad S_2 = S\left(0{\cdot}7175 + 0{\cdot}163\,\frac{P_1}{P_2}\right)$

$P_1 = (20 \text{ to } 100)\ P_2$ $\quad S_2 = S_m\left(1{\cdot}5 + 0{\cdot}125\,\frac{P_1}{P_2}\right)$

For Saturated Steam.

If $P_1 = (1{\cdot}832 \text{ to } 25)\ P_2$ $\quad S_2 = S_m\left(0{\cdot}777 + 0{\cdot}1216\,\frac{P_1}{P_2}\right)$

$P_1 = (25 \text{ to } 100)\ P_2$ $\quad S_2 = S_m\left(1{\cdot}875 + 0{\cdot}0812\,\frac{P_1}{P_2}\right)$

Introducing the numerical value of λ (1·135 for saturated steam and 1·3 for superheated steam), and with $g = 32{\cdot}2$, formula (7) becomes—

For Saturated Steam. $\quad c'' = 70{\cdot}2\ \phi\ \sqrt{p_1 v_1}$

For Superheated Steam. $\quad c_m = 72{\cdot}38\ \phi\ \sqrt{p_1 v_1}$

In the same way formula (8) would produce two expressions for the discharge depending on the condition of the steam as regards superheat. Recent researches by Loschge* and Bendemann have however shown that the numerical coefficient of the formula for nozzles having a convergent entrance is the same both for saturated and superheated steam, and that this value is 2 per cent. higher than is obtained by inserting $\lambda = 1{\cdot}135$.

This is in accordance with the previously known fact that for saturated steam the discharge from such a nozzle exceeds the theoretical amount.

Just prior to the publication of these researches Mr. H. M. Martin* propounded the ingenious theory that with steam initially saturated an unstable condition exists in the throat, cooling taking place below the saturation temperature without condensation. The decrease in specific volume which results from this 'Under-Cooling' would account for the measured excess in discharge over that calculated on the assumption of adiabatic expansion.

Prof. Stodola has suggested that this under-cooled steam obeys the same law of expansion as superheated steam, so that the experimental fact that the discharge both for saturated and superheated steam is given by one formula is rational and in line with theory.

The formula for discharge deduced from Loschge's experiments is :—

$$W = 44{\cdot}11\ k\ S_m \sqrt{\frac{p_1}{v}}.$$

Table I., giving the critical velocity and the discharge per square inch of throat area, has been calculated on the assumption that $\phi = 1{\cdot}0$ and $k = 1{\cdot}0$; the necessary correction for other values will be obvious.

The following simple formulæ, the first due to Napier and the second to Rankine, are often useful where an error of a few per cents. is admissible.

For Dry Saturated Steam.

$P_1 > \frac{5}{3} P_2$, $W = \frac{s \cdot p_1}{70}$; $\qquad P_1 < \frac{5}{3} P_2$, $W = 0{\cdot}029\ s\ \sqrt{p_2(p_1 - p_2)}$

where s = area of orifice in square inches.

Design of Nozzles.

The values of ϕ and k as determined by experiment are given in Table II. for orifices and nozzles of various kinds.

The coefficient of discharge k depends amongst other things upon the friction loss, the coefficient of contraction, and usually for a pressure drop below the critical, upon the ratio $\frac{P_2}{P_1}$.

Professor Rateau found that for nozzle C the value of k was slightly greater than unity when P_2 is less than $0{\cdot}5P_1$.

In reference to nozzles G and H, which are of the types used in impulse turbines, it should be mentioned that although the value $k = 1{\cdot}0$ has been inserted in Table II., Dr. Christlein found that the actual discharge exceeds the theoretical by a few per cent. This effect had already been observed by Mr. Rosenhain for nozzles of form F having well-rounded entrances, and he concluded from his experiments that a loss in efficiency results, and was, therefore, led to recommend that the entrance should be only slightly rounded.

These facts are confirmed by Dr. A. Loschge's researches and explained by Mr. H. M. Martin's theory, which is referred to in the preceding paragraph.

The value of ϕ for nozzle G cannot be very satisfactorily determined from Dr. Christlein's experiments; for a given value of c_1, ϕ appears to increase with the pressure and to decrease with the superheat before the nozzle.

Unfortunately, the results of Mr. Rosenhain's experiments, like those of Messrs. Siberly and Kemble, are vitiated by the fact that the wetness of the steam during the experiments was not measured.

Nozzles of type B are useful for approximate measurements of the amount of steam flowing through a pipe line. It is only necessary to put a thick plate having a cylindrical hole in it between two of the pipe flanges. If the pressure is observed before the plate (P_1) and also in the cylindrical hole (P_2) by means of a hole drilled from the rim through the centre thickness of the plate, the flow can be calculated from formula (5).

Of course, the hole in the plate should be of such a diameter that the ratio $\frac{P_2}{P_1}$ is not less than 0·6.

Several steam meters operate on this principle.

The nozzles of turbines are usually of rectangular cross-section, and the steam in passing through them turns through an angle of about 70°, as indicated in figs. G and H, page 1551. It is important to bear this in mind when employing data relating to ϕ and k deduced from straight nozzles of circular cross-section—the type usually favoured by experimentalists.

For a given ratio of expansion the length of the nozzle depends on the angle of divergence. If this angle is too great the steam does not completely fill the cone, which results in considerable loss. If the angle is too small the length of the nozzles becomes very great, and many experiments indicate that the friction loss depends on the length. An angle of divergence of 10° is very common.

The experiments of Mr. Rosenhain, and more recently of Messrs. Siberly and Kemble, show that there is no appreciable difference in efficiency for angles varying from 9° to 20°.

If the ratio $\frac{S_2}{S_m}$ is less than that theoretically required, expansion is completed beyond the nozzle. Rateau's experiments demonstrate that when this *under-expansion* is small, little loss results. On the other hand, if $\frac{S_2}{S_m}$ is greater than that theoretically required, the steam is expanded in the nozzle below the condition into which it discharges. Such *over-expansion* results in steam shock with great loss of efficiency.

When the divergent nozzles of a turbine are correctly designed for the normal load, over-expansion takes place at overloads, and under-expansion at partial loads, with nozzle cut-out governing.

The entrance of divergent nozzles should be smoothly rounded off, with a radius about equal to the throat diameter; larger radii are unnecessary and should be avoided.

Since the efficiency of a nozzle depends upon the smoothness of the surfaces with which the steam is in contact, the material of which it is constructed should be capable of withstanding erosion and oxidisation—nickel steel or a bronze highly polished is usually employed for the divergent nozzles of De Laval and Curtis turbines where high steam velocities are encountered, while cast in mild steel plates have given quite satisfactory results with the large nozzle areas and moderate velocities used in the convergent nozzles of Rateau and Zoelly turbines.

Turbine Efficiency.

The 'Overall Efficiency' of a turbine is obtained by comparing the work actually done per lb. of steam, with that which would be performed by an ideal engine working on the Rankine cycle and having the same initial and final steam conditions as the turbine.

This latter amount of work is equal to the mechanical value of the change in total heat contents (h_a B.Th.U.) which takes place during adiabatic expansion from the steam conditions before the governor valve, to those obtaining in the turbine exhaust.

h_a is referred to as the 'adiabatic heat drop' or the 'available heat drop,' and its value for the steam conditions usual in practice is given in Table III.

If

d = steam consumption in lbs. per S.H.P. hour; N = overall efficiency of the turbine, then

$$N_T = \frac{2,545}{d.h_a} \times 100 \text{ in per cent.}$$

If

d_1 = steam consumption in lbs. per K.W. hour; N_G = generator efficiency in per cent., then

$$N_T = \frac{3,414}{N_{G1}.d_1.h_a} \times 100 \text{ in per cent.}$$

The total steam consumption of the turbine is given by

$$W = \frac{d\ (\text{S.H.P.})}{3,600} \text{ lbs. per sec., or, } W = \frac{d_1\ (\text{K.W.})}{3,600} \text{ lbs. per sec.}$$

While the efficiency calculated with h_a as already defined is the true index of the performance of a turbine when running, it is sometimes the practice—and it is one which has a special value to turbine designers—to calculate the efficiency by taking the heat drop h'_a as that available between the conditions existing after the governor valve, that is, before the nozzles, and the exhaust of the turbine.

This is equivalent to eliminating the consideration of the pressure drop through the governor valve, which is rightly regarded as not being an inherent loss to any given turbine.

Suppose, for example, that two turbines are sold as 1,000 k.w. units to operate with certain steam conditions, and that one is actually capable of developing a load of 1,100 k.w., while the second can only pull a load of 950 k.w.

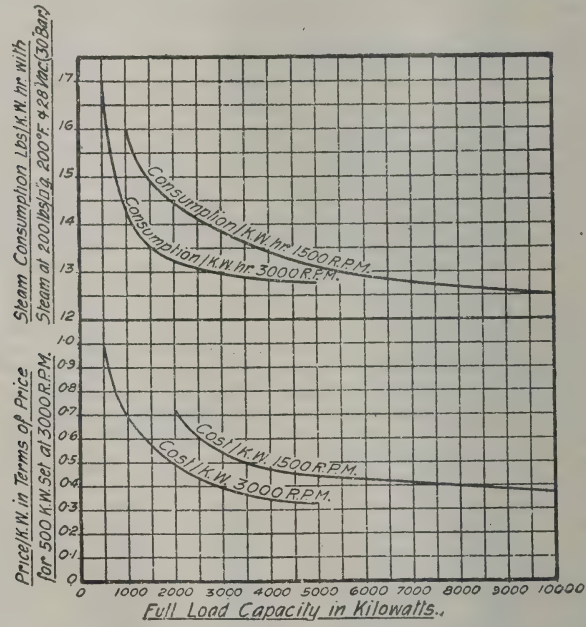

FIG. 1.—Effect of Speed on Steam Consumption and Cost of Turbo-alternators.

If these two turbines are tested on a load of 1,000 k.w., the latter will show the better steam consumption, because with the former the steam will be throttled at the governor to the greater extent. Of course, the first machine is in every way the better from the customer's point of view, providing the excess of power is not too great to be carried by the generator.

The steam consumption which can be expected from turbo-generators using steam at 200 lbs. per square inch, 200° F., and exhausting into a vacuum of 28 ins., is shown by fig. 1* for 1,500 and 3,000 r.p.m. The former speed is the highest which can be used for 25-cycle generators, while the latter can be used for either 25 or 50 cycles. These curves illustrate the effect of speed on efficiency, and cost of turbo-generator plant; thus at 3,000 k.w. the steam consumption of the 3,000 r.p.m. set is 6·15 per cent. better than at 1,500 r.p.m., while the cost per k.w. is 27·8 per cent. lower.

The steam consumption which can be obtained for other steam conditions can be approximately obtained by means of the correction curves shown in fig. 2, which are based on those given in Mr. Baumann's paper.†

The following is a summary of the results of a twenty-four hour test on a typical industrial installation consisting of the following :—

Turbine.—2,000 k.w., 3,000 r.p.m., British Westinghouse Rateau Impulse type.

Steam Conditions.—160 lbs. per sq. in. g., 160° F. supht., 28-in. vacuum.

Generator.—50-cycle, 3-phase, 6,600 volts.

Condensing Plant.—Le Blanc Multiple jet type, to condense 28,700 lbs. of steam per hour, when supplied with 2,200 g.p.m. of water at 75° F., pumps engine driven.

Cooling Tower.—Balcke type, reduced 143,000 gals. water per hour from 98° F. to 75° F., with air temp. of 60° F., humidity 75 per cent., area at base of tower 2,220 sq. ft. Height of tower, 80 ft.

Boiler.—Stirling type, 33,000 lbs. per hour capacity, 8,900 sq. ft. heating surface, drop link stokers, 96 sq. ft. grate area, no economiser.

Feed Heater.—Holden and Brooke type, into which the condenser pump engine and Weir feed pumps exhaust.

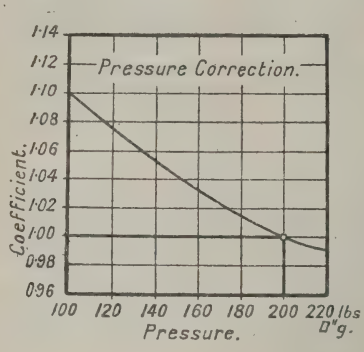
Date of test, March 15 and 16, 1916.

SUMMARY OF RESULTS. (Duration of test, 24 hours.)

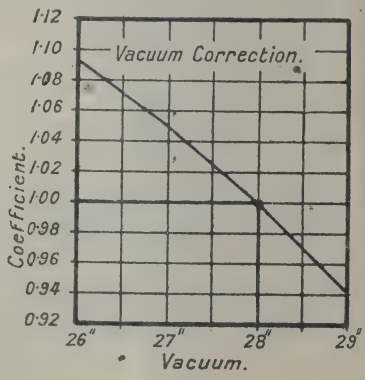
BOILER HOUSE.	
Total weight of coal burnt	76,776 lbs.
" " ash	3,304 "
" " ash, divided total weight of coal	4·3 %
Average calorific value of coal (lower value)	13,724 B.Th.U./lb.
" moisture in coal	2·391 %
" ash by sample	4·36 %
Total feed water metered	641,000 lbs.
" town " "	471,000 "
" " " divide total feed water = make up water for all purposes	73·5 %
Average feed water temperature after heaters	158° F.
" flue temperature	486° F.
" CO_2	8·82 %
Efficiency of boilers	69·83 %

CONDENSING PLANT.	
Average injection water temperature	68° F.
" extraction	87·5° F.
Water ratio	50 to 1
" injection quantity (average)	2,230 G.p.m.
Average vacuum temperature	99·6° F.
" " efficiency	96·16 %
" difference in vacuum temperature and extraction water temperature	12·1° F.

ENGINE ROOM.	
Average steam pressure before stop valve	157 lbs./sq. in. g.
" steam temperature before stop valve	510° F.
" vacuum (30-in. barometer)	28·1 ins.hg.
Total k.w.'s metered	36,570
Load factor	76·4 %



COOLING TOWER.	
Temperature of air near tower	40° F.
Inlet temperature of water at top of tower	91·75° F.
Temperature of water in sump	70° F.
Drop in temperature of water through tower	21·75° F.
Velocity of air at top of trays	188 ft. per min.
Wet-bulb thermometer over top of trays	77·5° F.
Dry-bulb thermometer over top of trays	78·8° F.
Humidity top of trays	93·4 %
Wet-bulb temperature near tower	37·96° F.
Dry " " " "	39·43° F.
Relative humidity near tower	88·26 %
Cooling water over tower	2,200 G.p.m.
Barometer	29·68 ins.
Water taken up per cubic ft. air passing through tower	7·26 grains



RESULTS.	
Coal per k.w. hour	2·1 lbs.
Steam per lb. of coal	8·35 "
Feed water metered for all purposes per k.w. hour	17·52

STEAM CONSUMPTION CORRECTIONS FOR TURBINES DESIGNED FOR VARIOUS CONDITIONS.

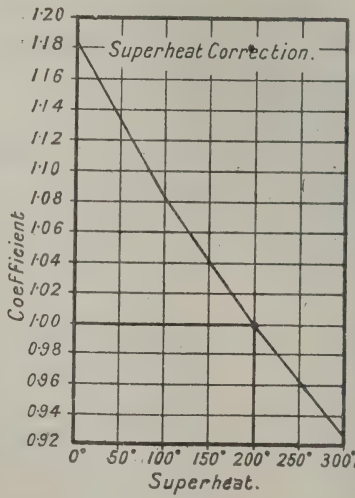

FIG. 2.

STANDARD STEAM CONDITIONS:

200 lbs. per sq. in. g.

200° F.

28 in. Vac.

For other steam conditions, multiply the consumptions obtained from fig. 1 (page 1554) by the coefficients obtained from the curves.

IMPULSE TURBINES.

A pure impulse turbine is one in which the available heat energy of the steam is completely converted into kinetic energy in stationary nozzles.

The steam jet thus produced performs mechanical work by impinging on a rotating row of blades or successive rows of rotating and guide-blades placed immediately before the nozzles.

An impulse turbine in which the whole pressure drop available is utilised in a single set of nozzles is said to consist of one *pressure stage.* If the pressure drop is subdivided between two, three, or more successive sets of nozzles, it consists of two, three, or more pressure stages.

When the kinetic energy of the steam jet is utilised in one row of rotating blades, the turbine is said to have one *velocity stage* per pressure stage. If after the first row of rotating blades, a guide blade is placed to reverse the direction of steam so as to impinge on a second row of rotating blades, the turbine is said to have two ' velocity stages,' and so on.

Since a minimum nozzle height will be fixed by practical considerations (not less than $\frac{1}{4}$ in. even in the smallest turbines), the arc over which the nozzles will extend depends upon the total nozzle mouth area required. In the high-pressure stages this may be, and in fact generally is, less than the mean circumference of the blades. Such a turbine is said to be working with partial admission, and the arc over which the nozzles extend is termed the ' arc of admission.'

This arrangement lends itself especially well to conveniently and efficiently dealing with overloads, it being only necessary to increase the ' arc of admission ' by admitting steam to additional sets of nozzles.

In the same way it is possible to divide the total number of nozzles into blocks controlled by separate cutout valves. Thus one block of nozzles can be designed to give all loads from 0 to $\frac{1}{2}$ full load, while these together with a second block give $\frac{1}{2}$ to $\frac{3}{4}$ and so on.

By this means the loss of pressure through throttling at the governor valve is reduced to a minimum, and substantial economies can be effected on partial loads. The nozzle cutout valves may be operated automatically or by hand. Nozzle cutout governing is not possible with reaction turbines.

(a) Single Pressure Stage Turbine with a Single Velocity Stage.

The nozzles of all impulse turbines can be designed by the methods already indicated, while the work done and the efficiency can be obtained by drawing the triangles of velocity a_1 and a'_2 (see fig. 3). All velocities are in feet per second.

Let

W = total weight of steam through nozzles in lbs. per sec.; c_1 = absolute velocity leaving nozzles; U = peripheral velocity at mean diameter of blades; w_1 = relative velocity at entry

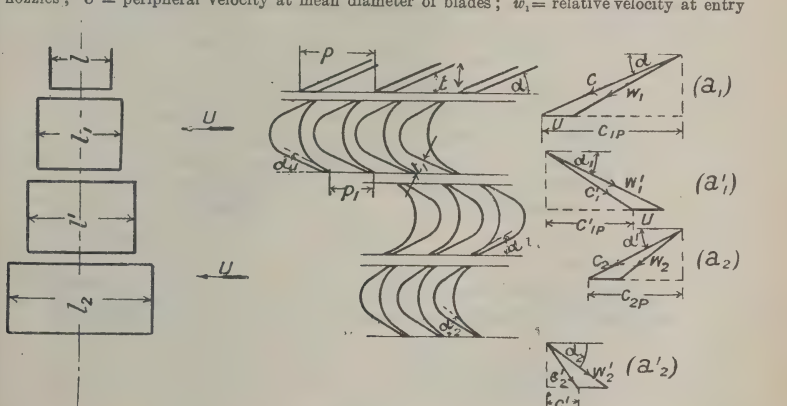

FIG. 3.

to moving blades; w_1' = relative velocity at exit from moving blades; c_1 = absolute velocity leaving the moving blade; c_{1P} $c_1'_P$ = the peripheral components of c_1 and c_1', respectively.

Then

$$w_1' = \psi_1' w ,$$

where $(1 - \psi_1')$ is the loss of velocity due to friction in the blade (see fig. 7, page 1561), ψ is called the *velocity coefficient* for the blades.

The total work done, or
The indicated work $\Big\} = \frac{W\,U}{g}\,(c_{1P} + c_{1'P})$ ft. lbs. per sec.

The blading efficiency $\eta_B = \frac{\text{(total work in ft. lbs. per sec.)}}{W.\,J.\,g.\,h_a}$

If

l = the required nozzle height; l_1 = the required blade height;

then

$$l_1 = l \cdot \frac{c_1}{w_2} \cdot \frac{t}{t_1} \cdot \frac{p_1}{p}$$

The de Laval turbine, which is of this type, is made in sizes from 5 to 500 h.p., running at 30,000 r.p.m. in the smallest size, and 10,000 r.p.m. in the largest outputs.

The peripheral speeds are as high as 1,300 ft. per second, and the steam velocity at exit from the nozzles as high as 4,000 ft. per second.

It can be shown that the efficiency varies with $\frac{U}{C_o}$ where C_o is the velocity theoretically obtained if $\phi = 1{\cdot}0$.

For a maximum efficiency, $\frac{U}{C_o}$ should be about equal to 0·5 (see fig. 5, page 1560, which gives the results obtained experimentally by Dr. O. Lasche).

(b) Single Pressure Stage. Two Velocity Stages.

In this case the work done in the first row of blades is obtained in exactly the same way as in case (*a*).

The guide-blade returns the steam jet towards the direction of U, the steam leaving it with an absolute velocity $c_2 = \psi_2 c_1'$.

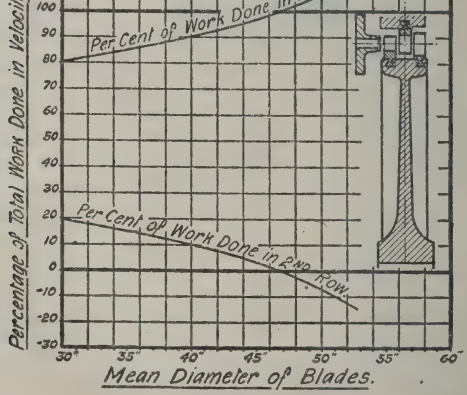
The relative velocity of exit from the second rotating blade is $w_2' = \psi_2' w_2$, knowing which, the velocity triangles a_2, a_2' can be drawn. In a_2 and a_2' the same symbols are employed as in a_1 and a_1', a suffix 2 denoting the guide-blade, while a dash denotes the second moving blade.

The total work per second is now

$$= \frac{W\,.\,U}{g}\Big\{(c_{1p} + c_{1'p}) + (c_{2p} + c_{2'})\Big\} \text{ ft. lbs. per sec.}$$

Work done in 1st and 2nd Rows of Velocity Wheels. 3,000 R.P.M.

Initial conditions :—200 lbs. per sq. in. g., 200° F. supf.; steam pressure in casing = 34 lbs. per sq. in. g.; temperature in casing = 410° F.



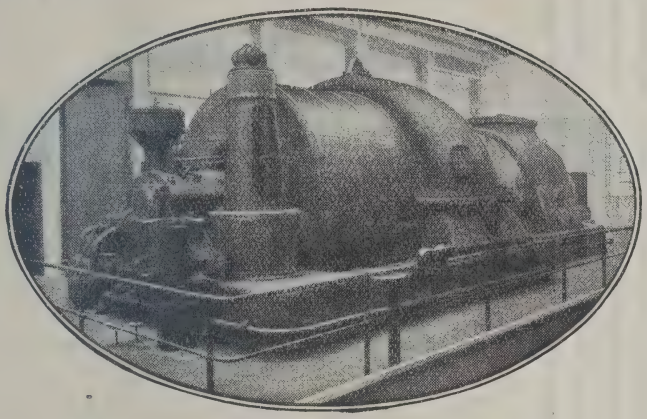


Fig. 4.

Turbo-Generator Sets

The following advantages are claimed for our Turbo-Generator Sets :—

High Efficiency at full and partial loads. . . . .

Compactness and readiness of access. . . . . .

Precise and sensitive governing. . . . . .

F. 1559

and

$$\eta_B = \frac{\text{(Total work in ft. lbs. per sec.)}}{W \,.\, J \,.\, g \,.\, h_a}$$

The height of the guide-blade $l^1 = l \,.\, \frac{c_1}{c_a} \,.\, \frac{t}{t^1} \,.\, \frac{p^1}{p}$

The height of the second rotating blade $l_2 = l \,.\, \frac{c_1}{w_2{}^1} \,.\, \frac{t}{t_2} \,.\, \frac{p_2}{p}$

As the mean peripheral velocity of the blades increases the proportion of the work done in the first row increases. This effect is illustrated in fig. 4, from which it will be seen that for the condition stated the second row does no positive work if the mean diameter of the blades exceeds 47½ ins.; it can therefore be dropped with advantage. For this reason two-row wheels are rarely used in modern high-speed machines.

(c) Single Pressure Stage. More than two Velocity Stages.

The solution of this case can be obtained from (*b*) in exactly the same way as (*b*) was obtained from (*a*).

Single-wheel Curtis stages belong to classes (*b*) and (*c*) and are very much employed for small high-speed turbines, where efficiency is not the first consideration.

The peripheral speeds for Curtis wheels are as high as 600 ft. per second, and the steam velocity 2,500 ft. per second.

For a maximum efficiency $\frac{U}{C_o}$ should be about 0·23 for two rows of moving blades, and 0·15 for three rows (see fig. 5, page 1560).

(d) Multi-Pressure Stage Turbine with Single Velocity Stages.

In order that reasonable efficiencies may be reached with practicable peripheral speeds, it becomes necessary to limit the heat drop utilised in each set of nozzles to some value considerably less than the total available between the conditions before the turbine stop valve and those present in the exhaust.

Up to a certain point, which is rarely reached in the conditions of actual design, the efficiency of each stage increases with the value of the ratio $\frac{U}{C_o}$ (see fig. 5, page 1560).

When the value of $\frac{U}{C_o}$ is known, which corresponds to the desired turbine efficiency, the value of C_o and hence of h_a the heat drop to be utilised per stage can be calculated, since U will be fixed by mechanical considerations.

Then for an equal distribution of energy over the pressure stages,

if H_a = the total heat drop available for the whole turbine,

$$\text{The required number of stages } n = e \,.\, \frac{H}{h_a}$$

where *e* is the '*reheat factor*' which depends on the amount of friction and eddy losses, the number of stages, the stage efficiency, etc., and varies between 1·03 and 1·07.

It is usually the practice to give the first stage a larger heat drop than the remainder, thus reducing the total number of wheels required, and having the considerable advantage of reducing the maximum temperature and pressure to which the turbine casing is subjected.

Having apportioned the heat drops, the steam conditions at each stage can be found—most conveniently by the Mollier diagram—and each stage can be designed as indicated under case (*a*).

The Rateau and Zoelly turbines are of this type.

In practice U varies from 350–600 ft. and the steam velocities from 800–1,600 ft. per second.

(e) Multi-Pressure Stage Turbines with Multiple Velocity Stages.

In precisely the same way as has been explained under (*d*), two- or three-row velocity wheels may be employed in the individual pressure stages.

The heat drop which can be advantageously used per pressure stage is then greater than in the case where a single row of blades is used, and thus the required number of pressure stages is reduced, but the efficiency is somewhat decreased, as may be deduced from fig. 5, page 1560.

The general design of each stage is similar to that of case (*b*).

The Curtis turbine is of this type.

(f) Combination Impulse Turbines.

It has recently become the practice to construct pressure-compounded impulse turbines of type (*d*) with a Curtis wheel having two rows of blades in the first stage. By this means a large heat drop can be employed in the first stage with reasonable efficiency and with the consequent advantages already mentioned.

The Curtis-Rateau and Curtis-Zoelly turbines are of this type.

Diagram showing the best efficiencies obtained in Dr. O. Lasche's experiments on Impulse Wheels. The efficiencies have been corrected for disc friction.

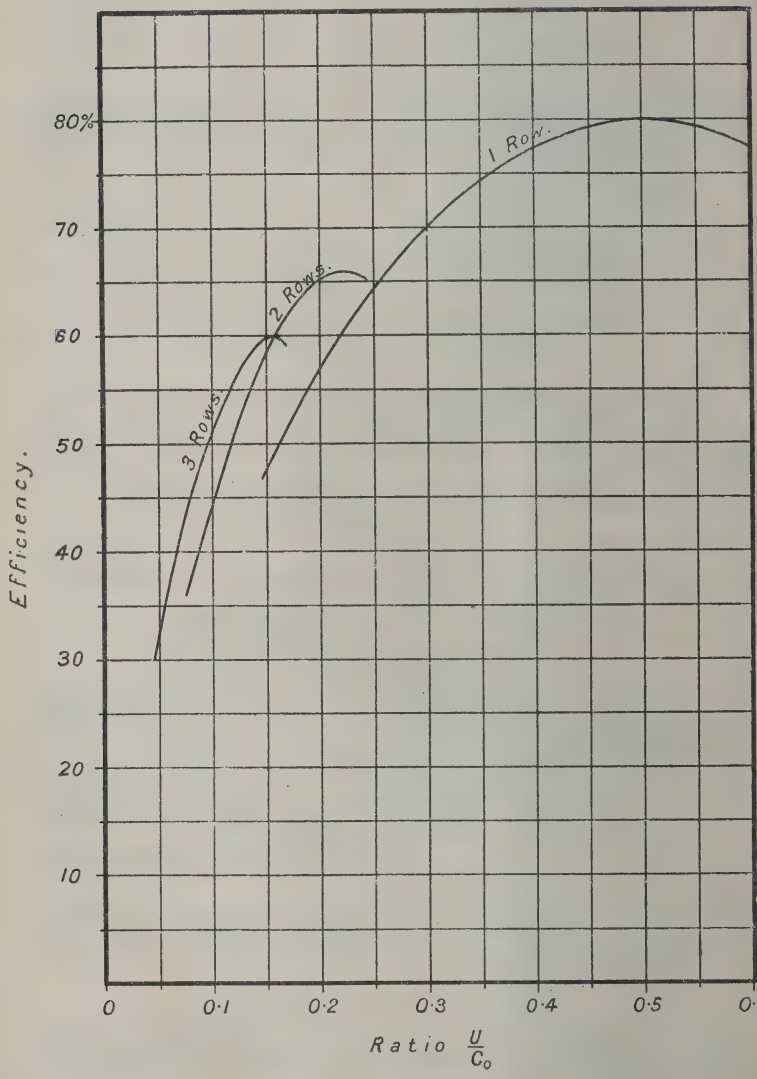

FIG. 5.

CARRY-OVER ENERGY.

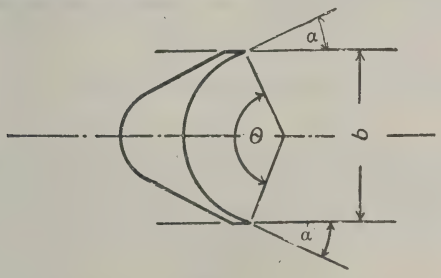
In pressure-compounded impulse turbines, the kinetic energy of the steam leaving the last blade of any pressure stage—except the last—is not entirely lost; part of it at least being recovered in the succeeding stage.

The total energy available in the succeeding stage is then greater than the adiabatic heat drop by an amount equal to $\frac{a c^2}{2g}$, where c is the absolute velocity of exit from the velocity blades and a is a constant.

For full admission, Prof. Rateau has suggested the value $a = \frac{2}{3}$, while for partial admission the value $a = \frac{1}{2}$ may be taken.

THE VALUE OF ψ, THE VELOCITY COEFFICIENT FOR BLADES.

The value of ψ has been the subject of researches by Prof. Rateau* and Dr. N. Briling.†



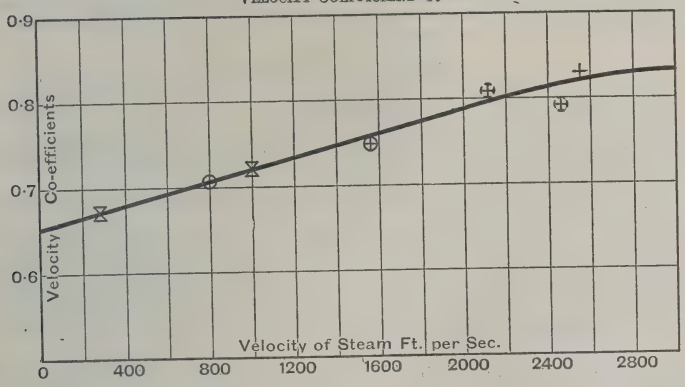


FIG. 6.

⊕ *Rateau. (Engineering 10/12/09.) Mean Values.*

⊕ *Values deduced from Rateau's experiments on Bucket Reaction; Congrès International de Mécanique Appliquée 1900.*

⧖ *Briling's Experiments with 20 m/m Buckets (Engineering 29/4/10).*

\+ *Stodola "Steam Turbines" deduced from Delaporte's Test of a de Laval Steam Turbine.*

FIG. 7.

* *Engineering*, December 10, 1909. † *Z. Ver. Deutsch. Ing.*, January 1906.

Prof. Rateau found that ψ was a characteristic of each type of blade depending on their size and spacing and slightly increasing with velocity.

Dr. Briling, whose experiments covered a wider field, found that ψ increased with velocity, decreased with the width of the bucket, and appeared to be principally dependent upon the angle through which the steam was diverted in the blade.

Briling deduced the following formula from his experiments :

$$\psi = \psi_o - 0{\cdot}000432\,\theta^{\frac{4}{3}}$$

where θ = total angle in degrees through which steam is turned in the blade (see fig. 6).

ψ_o = 0·90–0·97 for blades with rounded inlet edges.
= 0·95–0·99 for blades with sharp edges.

Mr. H. M. Martin* has given a useful diagram combining Rateau and Briling's results with others deduced from various tests, which is reproduced in fig. 7; from this the following expression can be deduced.

$$\psi = 0{\cdot}65 + \frac{w}{15{,}000}$$

w being the velocity of the steam relatively to the blade in ft. per sec.

PITCH OF IMPULSE BLADES.

The best value of the pitch p has been determined experimentally by Dr. Briling † as being connected with the blade angle $\alpha°$—which he takes as being the same at the inlet and outlet—and the blade width by the following relation.

$$p = \frac{r}{2 \sin \alpha°}$$

$$r = \frac{b}{2 \cos \alpha°}$$

Briling is of the opinion that 30° is the most suitable angle for impulse blading.

In practice, the blade angle varies from 20° to 50°, the largest angles being used at the exhaust end of a turbine when it becomes difficult to provide sufficient area. The pitch varies from 0·5 to 0·75 of the blade width.

REACTION TURBINES.

In a reaction turbine the available heat energy of the steam is converted into kinetic energy, both in the stationary and the moving blades.

In the most usual case—*considering a stage as consisting of a fixed blade and the following moving blade*—one-half of the available heat drop per stage is utilised in the fixed blade and the remainder in the moving blade. The turbine is then said to have a half degree of reaction.

Thus, both the fixed and moving blades perform the function of a nozzle in precisely the same way, and are identical in form and thermodynamic purpose.

Since there is a heat drop in the moving blades, there must also be a pressure drop across them. This is a characteristic of the reaction turbine as compared with the impulse turbine.

A second characteristic lies in the fact that the arc of admission to the first stage of a reaction turbine must extend around the complete circumference. For this reason nozzle cutout governing is not possible, and overloads can only be dealt with by admitting steam at some intermediate point in the expansion with a consequent loss in efficiency. The point usually chosen is immediately before the I.P. expansion.

The steam enters the moving blades with a relative velocity approximately in an axial direction, and leaves them at a higher velocity in a direction inclined to the plane of rotation, the blades being impelled forward by the reaction of the leaving steam.

Reaction Blading with Half Degree of Reaction.

In this case since the outlet angles of the fixed and moving blades are the same, and the heat drop utilised in both is the same, the velocity triangles at inlet to and exit from the moving blade are identical (see fig. 8).

* *Steam Turbines—their Theory and Construction*, H. M. Martin.
† *Z. Ver. Deutsch. Ing.*, January 1906.

Hence

$$c_1 = w_1' \; ; \; c_1' = w_1.$$

If h = heat drop in any stage (one fixed and one moving blade) and with the remaining symbols as were used when considering impulse turbines—

$$c_1 = \frac{1}{2\,U\cos\alpha}\,(25{,}050\,\zeta\,h + U^2)$$

Where $(1 - \zeta)$ is the energy loss in the conversion of heat to velocity.

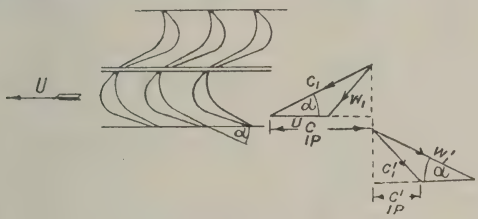

FIG. 8.

Capt. Riall Sankey has given 0·8 as the value of ζ, whereas the statement of Sir Chas. Parsons that the blading efficiency in the low-pressure end of the turbines of the 'Mauretania' reached the value of 85 per cent., shows that ζ may be as high as 0·86 under those conditions, while the efficiencies reported to have been obtained with the Ljungström turbine of quite small capacities could only be reached if ζ was as much as 0·85.

U and α being known, the velocity triangles can be drawn.

The work done per stage

$$= W\,\frac{(c_1^2 - c_1'^2)}{2g}, \text{ or, } = W\,\frac{(2k\cos\alpha - 1)}{g}v^2, \text{ where } k = \frac{c_1}{U}.$$

The blading efficiency

$$\eta_B = \frac{c_1^2 - (c_1'^2)}{2g\,J\,.\,h}, \text{ or, } = U^2\,\frac{(2k\cos\alpha - 1)}{J\,.\,g\,h}.$$

The required blade length can be obtained from the relation

$$\pi\,.\,D_m\,.\,l\,.\,q = \frac{W\,.\,v_2}{W_1'},$$

Where D_m = mean diameter of annulus in feet; l = radial length of annulus in feet = (blade height) + (tip clearance); v_2 = the specific volume after the moving blade in cubic feet per lb.; q = annulus area factor.

At any stage the 'annulus area factor' is the ratio of the available area of the channels at exit from the blades in a direction at right angles to α, to the area of the annulus between the drum and the casing at that stage.

The properties of Parsons blading, with the exception of q and α, were published by M. Lelong,* and will be found in Table IV.

As in the case of impulse blading, the blading efficiency varies with $\frac{U}{c_1}$ and reaches a maximum when $\frac{U}{c_1} = 0{\cdot}9$. Such a high value is not practicable in ordinary working conditions, nor is it necessary for the realisation of high efficiency, because the curve connecting $\frac{U}{c_1}$ and η_B is very flat in the region of its maximum.

Fig. 9, which gives this relation for $\zeta = 0{\cdot}8$, is due to Stodola.†

The efficiency for changes of ζ within the limits actually to be met with can be obtained by increasing the efficiency as obtained from fig. 9 by the same percentage as ζ exceeds 0·8.

In electrical work $\frac{U}{c_1}$ varies from 0·4 to 0·6.

The peripheral velocity of forged steel drums may be as high as 400 ft. per second, and even higher speeds are possible with solid drums, or drums made from special steels of high ultimate strength.

For Double Wing Blades α 60°; q = 0·85 in.

EFFICIENCY OF REACTION BLADING FOR $\zeta = 0{\cdot}8$.

FIG. 9.

The velocity of the steam c_1 varies from 500 to 800 ft. per second.

In marine work $\frac{U}{c_1}$ varies from 0·3 to 0·45, and for the high-pressure stages the peripheral velocity varies from 80 to 120 ft. per second.

REACTION TURBINE DESIGN.

The blades of Parsons turbines are not usually increased in height from row to row, but are arranged in groups having the same height and the same mean diameter. The angles of the blades of any one group are usually the same, but in some cases they are gradually increased so as to obtain the correct progression of areas for constant steam velocity relatively to the blade.

The blades of such turbines for land purposes are generally placed on three-drum diameters of increasing size, referred to as the H.P., I.P. and L.P. expansions.

The relative distribution of heat drop between the different expansions and their relative geometric properties are given in the following table :—

Expansion.	H.P.	I.P.	L.P.	H.P.	I.P.	L.P.
Adiabatic heat drop used . .	1	1	2	1	1	1
Number of groups of blades .	1	1	2	1	1	1
Mean diameter of annulus . .	1	$\sqrt{2}$	2	1	$\sqrt{2}$	2
No. of rows of blades per group .	1	$\frac{1}{2}$	$\frac{1}{4}$	1	$\frac{1}{2}$	$\frac{1}{4}$
No. of rows of blades per expansion	1	$\frac{1}{2}$	$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{4}$

The first of these arrangements is that most commonly adopted.

In electrical work there are from two to three groups of blades in the H.P. expansion.

In any given turbine and for groups of blades with the blade angle the same, the ratio $\frac{D^2l}{v}$

should be constant, where D = mean diameter of the blades, l = their length, and v = the mean specific volume of the steam in the group.

The last group on the L.P. expansion is often made the same height as the preceding group, semi-wing blades being used in place of ordinary blades. In some cases it is necessary to use semi-wing blades in earlier stages, when wing or double-wing blades would be used in the last group.

In order to reduce the unsupported length between bearings, and to enable the tip clearance to be kept small, it is becoming the practice in turbines of 5,000 kw. and over to use two cylinders. The first cylinder contains the H.P. expansion only and can be made of cast steel, very fine clearances being possible by eliminating the danger due to the growth of cast iron.

c_1, for any particular stage, can be calculated from the formula already given when the heat drop h is known.

The blading efficiency throughout the turbine can be found from fig. 9 when the ratio $\frac{U}{c_1}$ is known.

For groups of blades having the same angles and height:

if

n = number of blades in the group considered; R = ratio of expansion over the group; H_a = adiabatic heat drop for the group.

Then the heat drop used in the first stage

$$h_1 = \frac{(1+e)H_a}{\left[0{\cdot}07 + \left(\frac{R^2-1}{R^{\frac{2}{N}}-1}\right)\right]}$$

The heat drops for the other stages of the groups form with h_1 a geometric progression having $R^{\frac{2}{N}}$ as a common ratio.

In most cases it will be sufficient to calculate the first and last stages of any one group.

Considerable changes can be made in the output of a Parsons turbine by twisting the blades of the first few rows so as to increase or diminish the openings at exit. Such adjustments are sometimes necessary on the test plate, and alterations up to 20 per cent. on output can sometimes be effected in this way.

Disc Drum Type.

Just as in the development of the pure impulse turbine combinations of the simple types have been evolved so the disc drum type has been introduced into the sphere of the reaction turbine.

In this case the high pressure and less-efficient part of the reaction turbine is replaced by a Curtis wheel having as a rule two rows of blades. This design possesses the advantages already mentioned in connection with combination impulse turbines, and in addition it results in a considerably shorter and stiffer rotor than in the pure Parsons machine.

TURBINE LOSSES.

Diaphragm Gland Loss.

The diaphragms of a pressure-compounded impulse turbine must obviously be provided with a clearance between themselves and the shaft, thus providing a leakage area through which steam can pass.

The diaphragm gland is usually made either as a labyrinth packing or as a closely fitting white metal bush.

Although the clearances may originally be very small they are greatly increased by whipping of the shaft, or even by the static deflection.

The percentage leakage can be estimated as being equal to the ratio of the clearance area to the nozzle area in any diaphragm.

In order to reduce this loss, some designers employ carbon packings held together by garter springs in the diaphragms.

The diaphragm clearance is usually from $\frac{10}{1000}$ ins. to $\frac{30}{1000}$ ins. radially.

LABYRINTH PACKINGS.

The glands at the cylinder ends are usually of the labyrinth packing type.

In impulse turbines the labyrinth is invariably of the radial clearance type, while in Parsons turbines the packing at the thrust block end is of the axial clearance type, the other being of the radial clearance type.

Mr. H. M. Martin* has deduced the following formulæ:

$$\text{Weight of leakage steam} = 68 \cdot A \sqrt{\frac{p_o\left(1-\frac{1}{r}\right)}{v_o(N + log_e r)}} \text{ lbs. per sec.,}$$

where,

p_o = pressure before the gland in lbs. per sq. in.; v_o = specific volume of steam in cub. ft. per lb.

* *Steam Turbines—their Theory and Construction*, H. M. Martin.

r = ratio of expansion through gland; N = number of labyrinths; A = sectional area of leakage path in sq. ft.

If the velocity with which the steam flows out of the last labyrinth is greater than sound velocity, this formula should be amended, but the correction is small, and as it is in the nature of a reduction in the weight of the leakage steam, it can safely be neglected where N is greater than 8, which is the usual case in practice.

N varies between wide limits and may be from 8 in the case of low-pressure glands of impulse turbines to 30 for the high-pressure glands of Parsons turbines.

The clearance usually allowed varies from $\frac{10}{1000}$ in. to $\frac{80}{1000}$ in., but this may increase in actual working in the same manner as the diaphragm clearances.

In order to reduce the loss of turbine efficiency due to gland loss which might otherwise be considerable, the high-pressure packing is usually connected at one or two points in its length to some intermediate stage in the turbine.

The leakage over each of these sections can be calculated by the formulæ already given, r now being the ratio of expansion over any section, and $p_0 . v_0$ the conditions before that section.

Except in those cases where a water gland is used, the gland at the exhaust end is sealed by steam at a higher pressure than atmospheric, taken from a stage in the turbine, and in order to ensure that air is not leaking into the exhaust, the pressure is adjusted until a small quantity of steam is seen escaping into the engine-room.

The cylinder glands of the A.E.G., Zoelly, and Curtis turbines are of the carbon type, for which a considerable reduction in leakage is claimed.

The advantages of these are questionable since they cannot be renewed or adjusted without opening the turbine, and in some designs it is even necessary to strip the rotor.

The carbon rings which are in segments are kept together and caused to bear on the shaft by grater springs. This type of gland requires frequent inspection and renewal.

Dummy Loss.

In the majority of single-flow Parsons turbines the axial thrust on the blades and drum is balanced by dummy pistons. A labyrinth packing is formed on the periphery of the dummy pistons to reduce the leakage of steam which would otherwise take place across the dummy piston to the exhaust to which they are connected on one side.

The loss of steam through the dummy clearances can be calculated in precisely the same way as the loss through a labyrinth packing, and in many designs is of considerable magnitude.

The double-flow type of turbine was in the first instance introduced to eliminate this loss by obviating the necessity of balance pistons.

Disc Friction.

A considerable amount of work may be absorbed in rotating the discs of impulse turbines in the dense steam present in the first stages of a pressure-compounded (disc) turbine.

Professor Stodola* has given the following formula for the disc friction loss:

$$\text{B.H.P.} = \frac{6.1}{10^8} D^2 U^3 \gamma,$$

where,

D = mean diameter of blades in feet; U = mean peripheral velocity feet per sec.; γ = density of steam in lbs. per cubic ft.

The experiments upon which this formula is based were performed either in air, superheated steam, or in steam whose exact condition as regards wetness was unknown.

Professor Lewicki has demonstrated that the combined work of disc friction and windage falls off with superheat, some of his experiments showing a reduction of 10 per cent. in the work done for an increase of superheat of 100° C. As the total loss due to disc friction is usually of the order of a few per cent. of the output of the turbine, the reduction with superheat is of little importance.

On the other hand, it seems probable that the disc friction would increase rapidly with the wetness of the steam, but there are at present no data for estimating this increase. For these reasons, the disc friction loss for any given turbine cannot be calculated with certainty.

Windage.

In addition to the disc friction, loss results from the fanning action of the blades as they rotate.

The laws governing this action cannot be regarded as established, the range of experiments has been limited, and results by the same experimenters are discordant. Professor Stodola* gives the following formula:—

$$\text{B.H.P.} = \frac{4 \cdot 6}{10^7} . D . l^{1.5} . U^3 . \gamma . ,$$

where,

l = blade length in inches; D = mean diameter of blades in ft.; U = mean peripheral velocity in ft. per sec.; γ = density of steam in lbs. per cubic ft.

* *Die Dampfturbinen*, 4th Ed., Prof. A. Stodola.

Mr. W. Kerr has recently carried out some careful tests on this subject, and by comparing his own results with those of Prof. Stodola and Dr. Lasche, suggests that for wheels carrying two rows of blades the work calculated by the above formula must be multiplied by 1·23, for three rows by 1·8, and for four rows by 2·9.*

When mixed pressure turbines are working with low-pressure steam the high-pressure end is rotating idly in an atmosphere of steam, and with disc turbines the work done in disc friction and windage is not negligible. With reaction turbines a windage loss alone is present, and this is mainly due to the fanning action of reaction blading. Sir C. A. Parsons has stated that in the case of a reverse element of a marine turbine rotating in a vacuum the loss is of the order of 1 per cent., so that the loss due to the rotation of the high-pressure element of a mixed-pressure Parsons turbine rotating in steam twelve times as dense as a 28-in. vacuum may be considerable.

Water Glands.

An interesting feature in the development of turbine design consists in the introduction of the water gland.

In this type, an air-seal is produced by a paddle-wheel acting as a centrifugal pump. The pressure difference over the gland is balanced by the centrifugal head produced in the water as it is whirled around covering areas of different internal radii on the two faces of the paddle.

The ribs on the sides of the paddle should be $\frac{1}{4}$ in. deep.

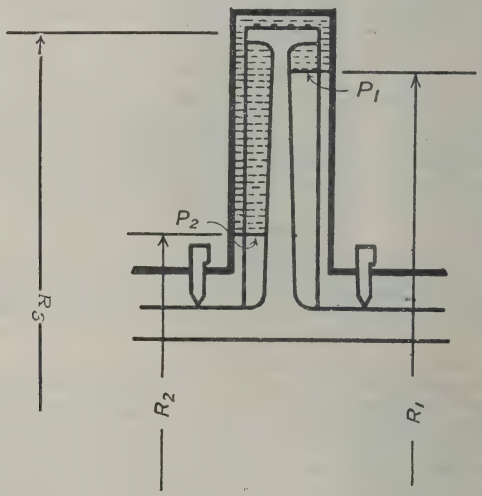

FIG. 10.

If P_1 (fig. 10) = the pressure on the high-pressure side in lbs. per square ft.; P_2 = the pressure on the low-pressure side in lbs. per square ft.; R_1 = inner radius in ft. of the whirling water on the H.P. face; R_2 = inner radius in ft. of the whirling water on the L.P. face; p = density of water = 62·3; ω = angular velocity of paddle in radians per second. Then

$$P_2 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_1^2 - R_2^2) \text{ and } P_3 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_2^2 - R_1^2)$$

The value of A varies from 0·9 to 1·10″.

Although the water gland when first introduced gave rise to troubles, it has proved successful when used in conjunction with a labyrinth packing, for the purpose of preventing air leaking into the turbine casing.

* *Engineering*, August 22, 1913.

Since a sufficient centrifugal head to form a seal is not developed until the turbine is running at some speed near the normal, it is necessary to steam-seal the glands as the turbine is started up.

The gland must be supplied with a constant stream of water to make up the loss which takes place by evaporation on the vacuum side of the seal. The water is admitted at the periphery of the gland, and should be supplied from a head of about 15 ft. This will, of course, be equal to $(P_3 - P_1)$.

A water gland cannot be used to seal against steam at a pressure above atmospheric, because the water boils and the seal is destroyed.

Tip Clearance Loss.

As has already been pointed out, there is always a difference of pressure over both the fixed and rotating blades of a reaction turbine.

In consequence of this pressure drop there must always be a leakage of steam over the blades through the clearance which must be provided at their tips. The magnitude of the tip clearance is determined by the experience of the designer with his particular type of machine; it depends on the diameter of the drum, its flexibility, the maximum temperature to which the blades may be subjected, the possibility of distortion of the casing, and the exigencies of meeting stringent guarantees.

The amount of clearance varies with different makers, from about $\frac{15}{1000}$ in. to $\frac{80}{1000}$ in., but no definite rules can be laid down.

The smallest clearances are to be found at the high-pressure end, for it is there that the loss in stage efficiency is most serious and may amount to over 50 per cent. with the small blade heights often necessary.

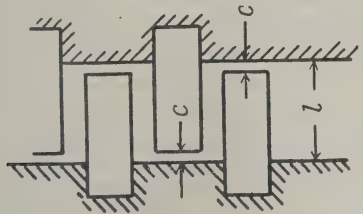

FIG. 11.

Mr. Alexander Jude* has conducted some interesting experiments on this subject, and the following formula is a slight modification of the result he deduces.

$$\text{The ratio } \frac{\text{leakage steam}}{\text{total steam}} = \frac{\lambda c}{q l}$$

Where l (fig. 11) = radial length of the annulus; c = tip clearance; q = annular area factor; λ = ratio of actual steam flow through the clearance to that which would blow straight through if there were no distortion or friction.

From his experiments on standard ½-in. Parsons blades, Mr. Jude has deduced the following values of λ:—

Clearance	0·01	0·02	0·03	0·04	0·05	0·06	0·07 in.
λ	0·42	0·66	0·81	0·9	0·95	0·98	1·0 ,,

According to Sir C. A. Parsons the loss of stage efficiency from tip clearance leakage is about twice as great as the ratio of the leakage steam to the total steam.

As in the case of the other losses which depend upon the value of fine clearances, it is probable that the tip clearance loss increases with the life of a turbine; and in particular, this effect will arise where very small tip clearances were originally adopted to enable high efficiencies to be obtained on the test-plate.

Bearings.

l = the length of a bearing in inches; d = diameter of journal in inches; p = pressure on bearing per square inch projected area; N = speed of turbine in R.P.M.; μ = coefficient of friction; v = peripheral speed of journal in feet per second.

Then the work done in overcoming the bearing friction is

$$\text{Friction work} = \frac{\mu \pi l d^2 p \text{N}}{720} \text{ ft. lbs. per sec.}$$

The heat equivalent of this work must be carried away from each bearing if they are to remain at a constant temperature.

* *The Theory of the Steam Turbine*, A. Jude.

According to Lasche's experiments, if $t°$ F. is the final steady temperature of the bearing, the coefficient of friction is given by the following relation :—

$$\mu \cdot p \cdot (t° - 32°) = 51{\cdot}2.$$

For turbine bearings $t°$ should be from 120° F. to 150° F.

Assuming a temperature of 140° F., which is about an average value, these expressions can be reduced to:

$$\text{Work done in friction} = 3{\cdot}75 \left(\frac{l}{10}\right) \left(\frac{d^2}{100}\right) \left(\frac{N}{1{,}000}\right) \text{b.h.p.}$$

With average bearings bedded in the normal way, it is found that the work done exceeds the amount just given, being usually about twice as great.

One of the striking features of the recent developments in steam turbines has been the successive increases in the specific loadings and rubbing speeds on bearings.

This rating up of bearings has been accompanied by uniform success in all cases where the natural requirements of good lubrication have been safeguarded.

The oil supplied to the bearing has two functions to perform : it must sustain the oil film, and it must flush the bearing copiously to carry away the heat generated in shearing the oil film.

The quantity of oil required by the latter consideration is by far the greater of the two; the necessary amount of oil can readily be estimated from the relation that for ordinary turbine oils—

1·0 b.h.p. in oil friction raises 1·0 gallons of oil per minute by 10° F.

In the average case the temperature of the oil passing through the bearings is such that its temperature rise in passing through the bearing is from 20° to 40° F.; therefore, for 40° F. rise in temperature the oil quantity which should be supplied to a bearing is given by oil which should be supplied $= 2 \times \frac{3{\cdot}75ld^2N}{40 \times 10^3}$ gals. per min., or, approximately, $= \frac{2ld^2N}{10^5}$ gals. per min.

This represents the minimum quantity required, and may be increased up to double this amount with advantage.

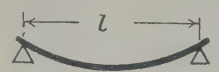
The lengths of turbine bearings vary from $l = 2{\cdot}5d$. to $l = d$, the former value being usual for lightly loaded slow-speed bearings of older design, and the latter being approached with modern high-speed high-rated bearings.

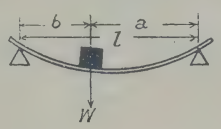
At the present state of the art it is impossible to state the upper limits for permissible loading and rubbing velocity. Bearings are now quite common with loadings up to 110 lbs. per sq. in. and with rubbing velocities up to 130 ft. per sec.

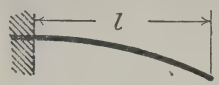
According to modern ideas and practice, the old rules of the form pv = constant are quite unsound—in fact, when p is increased, v can and should be increased.

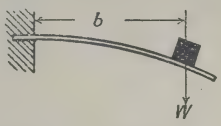
After leaving the bearings the oil is passed through an oil cooler, where it is cooled to some temperature usually below 110° F., although, of course, the actual temperature depends upon that of the cooling water available.

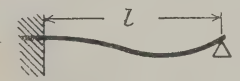
Turbine bearings give remarkably little trouble, providing the oil is kept clean, and there is no tendency to emulsify.

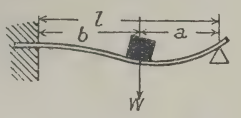


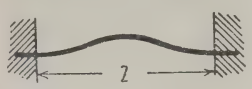


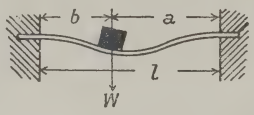












There are a large number of suitable oils available for turbine work, but in all cases care should be taken to see that any oil used readily separates out completely when subject to an emulsification test.

In very small turbines the bearings are sometimes ring-lubricated, and in such cases the peripheral speed should not exceed 40 ft. per sec.; at higher speeds the oil tends to be thrown to the outside of the ring by centrifugal force.

Even in very small turbines there is now a tendency to fit a forced lubrication system provided with an oil cooler.

Lubricating System.

In all cases except where ring lubrication is employed for small turbines, an oil pump is provided to maintain a pressure of about 10 lbs. per sq. in. in the lubricating system. It should be emphasised that the actual oil pressure is of secondary importance, the prime object being to flush the bearings with a copious flood of oil, and that for this purpose 2 lbs. per sq. in. may be sufficient in a properly designed system. The oil on leaving the pump passes through a cooler of sufficient capacity to maintain the temperature of the oil leaving the bearings at about 60–68°F. above that of the inlet cooling water, bearing temperatures of 150° F. being quite permissible. The main oil pump is usually driven by gearing from the turbine shaft, and the normal pressure is reached when the turbine motor is running at about one-third the normal speed. A hand pump is usually provided to supply oil under pressure during starting up or shutting down, when the speed of the set is less than one-third the normal. An oil strainer should be placed on the suction side of the pumps to prevent grit being circulated. Two to three gallons of oil should be taken out of the tank daily and carefully filtered, the level of the tank

Note Units employed.

being kept constant by making up with freshly filtered oil, or when necessary, new oil. Once in each twelve months the oil tank and all accessible portions of the lubricating system should be emptied and cleaned ; the tank should then be filled sufficiently with paraffin oil to enable the whole system to be flushed by operating the hand pump. The paraffin oil dissolves any gummy matter which may have deposited from the lubricating oil and thoroughly flushes away all dirt to the oil tank ; the paraffin can then be removed and new or freshly filtered oil put in. These simple precautions will result in a real economy in oil consumption and a freedom from troubles and maintenance charges which will amply repay the trouble involved.

See also 'Lubrication' (page 910).

Critical Speeds of Turbine Shafts.

At the critical speed of a loaded shaft, a small disturbance sets up vibrations which may reach a dangerous magnitude. For a uniform shaft, when the obliquity of the loading masses may be neglected, the critical speed coincides with the natural frequency of transverse vibration.

Although turbines have been run for considerable periods at their critical speeds without failure, this is a very dangerous proceeding and should be carefully avoided. It follows, therefore, that the critical speed should always be estimated, and should be at least 30 per cent. removed from the running speed.

This particularly applies to turbines of the disc type, and the calculation can be made with some degree of certainty. In drum turbines, the calculation is much more difficult, but in such cases as usually arise the critical speed is much above the running speed.

Table V. gives the formula for calculating the critical speeds of shafts of uniform diameter in certain standard cases.

Dunkerley has evolved theoretically, and demonstrated experimentally, a law from which can be determined the critical speed of a loaded system which corresponds to any combination of the standard cases.

By means of Table V. in conjunction with Dunkerley's formula, the first critical speeds of sensibly uniform shafts can be approximately calculated for any combination of loading, and any method of fixing the shaft at the bearings.

Thus if a rotor consists of a uniform shaft loaded with weights $W_2 W_3$ etc. as external loads,

n_1 = the critical speed of the shaft without the external loads.
n_2, n_3, etc. = the critical speed of a massless shaft loaded with weights $W_2 W_3$ etc.

Then the critical speed N of the system is given by

$$\frac{1}{N^2} = \frac{1}{n_1^2} + \frac{1}{n_2^2} + \frac{1}{n_3^2} + \ldots\ldots$$

In those cases of rotors having shafts stepped in diameter, as is usually the case in practice, the method already given is only a rough approximation, owing to the difficulty of judging the diameter of the equivalent uniform shaft.

Such cases may be dealt with by obtaining the maximum static deflection y of the shaft under various loads, by the graphical methods due to Mohr.

Then if

N = critical speed in R.P.M.
$N^2 y = C$, where C is constant.

For impulse turbine shafts supported in bearings which do not fix the direction of the shaft Mr. K. Baumann* has found that the value of C varies from 10·5 to 10·6.

See also pages 924, 927.

MATERIALS FOR TURBINE CONSTRUCTION.

The use of such high peripheral speeds as are common in turbine practice introduced a new consideration into machine design ; because, unlike the conditions existing in reciprocating engine parts, the stresses in the various members are in the main due to centrifugal forces resulting from their own rotation. The stresses in a given turbine will, therefore, be proportional to the square of the numbers of revolutions per minute, and to the density of the material.

With an increase in the possible speed of rotation of a given turbine, the efficiency will in general be improved, since the average ratio $\frac{U}{C_a}$ in the various stages will be increased, or a greater heat drop can be utilised with the original efficiency.

On the other hand, the available heat drop per stage might be increased, so that the required number of stages for a given efficiency can be correspondingly reduced, or with the same number of stages the mean diameter of the blades can be reduced inversely as the revolutions per minute, both of which alternatives would result in a cheaper turbine.

Hence, it will be seen that in turbine work it is eminently desirable to use the highest possible peripheral speeds, the limit of which will be determined by the ultimate strength of the material employed.

* *Recent Developments in Steam Turbine Practice*, Inst.E.E., April 1912.

British Electrical and Allied Manufacturers Association's Specifications for Turbine Forgings, Etc.

The following particulars have been extracted from the Association's specifications for forgings for turbine discs, shafts, and general forgings for use on land turbines.

The following table gives the minimum physical properties acceptable for each of four grades of materials:—

Grade *	I.			II.			III.			IV.		
	L.	T.	R.	L.	T.	R.	L.	T	R.	L.	T.	R.
Minimum ult. tensile tons per sq. in.	30	30	30	35	35	35	40	40	40	48	48	48
Yield point	15	15	15	17½	17½	17½	20	20	20	30	30	30
Minimum elongation per cent.	30	23	20	25	20	18	22	18	16	17	14	12
Minimum reduction in area, per cent.	45	40	38	40	35	32	35	32	30	40	35	30
Bending Angle	180°	160°	150°	180°	150°	135°	180°	150°	120°	180°	130°	100°
Test radius	⅛″	⅛″	⅛″	¼″	¼″	¼″	¾″	¾″	¾″	¾″	¾″	¾″

* L.=Longitudinal. T.=Tangential. R.=Radial.

Grades Nos. I, II, and III are for carbon steels, whereas grade IV applies to an alloy steel. A margin of 3 per cent. below the reductions in area given in the above table is allowed to the steel maker providing this is compensated by a corresponding increase of 3 per cent. on the elongation.

Bend Tests.

A cold bend test is made upon test pieces having a rectangular section of ⅜ in. by ¾ in. These test pieces shall be machined and the edges rounded to a radius of ⅛nd. The test pieces shall be bent over the thinner section, and the bending shall be done by pressure or by blows. The test pieces must withstand being bent around the radii and through the angles given in the table without fracture.

Additional Test before Rejection.

If either tensile or bending test fail to fulfil the test requirements, and the inspector agrees that the test piece does not clearly represent the quality of the material, two duplicate specimens may, if the maker wishes, be tested, and if the results from both are satisfactory the quality of the material shall be judged therefrom, and not from the original test which failed. If, however, either of the duplicate tests fail the material represented will not be approved, and the manufacturer shall have the option of retreating and again presenting for test.

Table VI. gives the physical properties of steels used for steam turbine blading, the data for which have been supplied by the courtesy of Messrs. Thomas Firth & Sons, of Sheffield.

The blades of Parsons turbines are commonly of brass, the usual mixture being alloy of 63 per cent. copper to 37 per cent. zinc, having an ultimate strength of 20 tons per sq. in., an elastic limit of 12 tons per sq. in., and an elongation of 40–50 per cent.

The blades of impulse turbines are usually made of 5 per cent. nickel steel, although bronze blades are sometimes called for.

The physical properties of a bronze are greatly dependent on the treatment to which it may have been subjected, cold working having the effect of raising the ultimate strength and reducing the ductility.

Such an increase in the ultimate strength is to a large extent artificial, the material returning to its virgin state under the influence of high temperature or vibration.

The importance of this effect will be emphasised by the figures published by M. Breuil† and reproduced in Table VII. respecting the effect of temperature on some materials used for blading.

† *Engineering*, July 5, 1912.

TABLE VI.—PHYSICAL PROPERTIES OF STEELS USED IN STEAM TURBINE CONSTRUCTION.

Nature of Material.	Yield Point, Tons per sq. in.	Ultimate Strength, Tons per sq. in.	Elongation on 2-in. Gauge Points.	Purpose for which Material is Employed.	Remarks.
			Per Cent.		
5 per cent. nickel steel sheets	—	40	17	Turbine blades and shrouding strips supplied mild in sheets for stamping and bending	—
5 per cent. nickel steel sheets	—	35–42	20–24	Turbine blades and shrouding strips	Higher carbon content than above
5 per cent. nickel steel bars	30–35	40–45	25	To be drawn into blade sections	—

TABLE VII.—MATERIALS FOR TURBINES.

Nature of Material.	Elastic Limit, Tons per Sq. In.	Ultimate Strength, Tons per Sq. In.	Elongation.	Temperature.
			Per Cent.	
70 per cent. copper, 28 per cent. pure zinc	34·9	36·2	11	Ordinary
	34·3	36·2	8·5	100° C.
	32·7	34·3	11	200°
	22·2	24·1	30	300°
	7·6	12·7	75	400°
85 per cent. copper, 15 per cent. manganese	38·7	41·3	10·2	Ordinary
	36·8	40·0	10·5	100° C.
	37·5	41·0	11·0	200°
	33·0	36·8	21·0	300°
	21·0	24·1	68·0	400°

From this it follows that before figures relating to the strengths of alloys can be accepted as working data, the effect of temperature and the previous history of the specimens fractured in the test should be known.

Phosphor bronze has been largely employed for impulse turbine blading when conditions were such that abnormal corrosion was expected, and gives satisfactory results with dry steam where the steam velocities are moderate and the stresses induced in the blades relatively small. The following represent the average properties of this material as given by Mr. W. B. Parker.*

Maximum tensile stress	Not under 24 tons per sq. in.
Elastic limit	„ 12 „ „
Elongation on 2 ins.	13 per cent.
Modulus of elasticity	16,000,000 to 17,800,000 lbs. per sq. in. within a stress range of 0 to 10 tons per sq. in.

The average composition is as follows :—

Tin	From 3 to 5 per cent.
Copper	From 94·9 to 96·9 per cent.
Phosphorus	Not less than ·1 per cent.

* *Steam Turbine Blading*, Institute of Metals, September, 1915.

Copper nickel alloys are now being used for the manufacture of turbine blading, the best known being Monel metal, which has the following properties when in the form of turbine blading :—*

Maximum tensile stress	38·7 to 39 tons per sq. in.
Elastic limit	14 to 16 „ „
Elongation on 4 ins.	32 to 33 per cent.
Reduction in area	66·75 to 70·7 per cent.
Modulus of elasticity	22,500,000 lbs. per sq. in. over a stress range of 1 to 15 tons per sq. in.

The composition is as follows :—

Silicon	0·14 per cent.
Lead	Trace.
Copper	27 per cent.
Iron	3·85 „
Manganese	1·87 „
Nickel	67·1 „
Carbon	Nil.

Monel metal may contain both graphitic and combined carbon totalling up to ·5 per cent.

TURBINE TEST CORRECTIONS FOR STEAM CONDITIONS.

While it is rarely possible to make tests upon a turbine under the exact steam conditions for which it has been designed, the performance which may be expected under the designed conditions can be estimated from the steam consumption actually obtained during the test.

The usual practice consists in correcting the test consumption for the difference between the steam superheat, pressure, and vacuum during the test, and that which is specified for the turbine.

These 'corrections' are arranged as coefficients by which the observed consumptions must be multiplied, and are determined for any steam conditions from consideration of the changes in available heat-drop and turbine efficiency which takes place with any change in that condition.

A very complete list of these corrections has been published by Mr. K. Baumann† and the values he gives are incorporated in this section.

Superheat Correction.

Where the superheat is different from that specified, the following corrections should be made, both for high-pressure or low-pressure turbines.

Between :—

0–100° F. superheat 1 per cent. improvement of steam consumption for every 10° F. superheat.

100–200° F. superheat 1 per cent. improvement of steam consumption for every 12° F. superheat.

200–300° F. superheat 1 per cent. improvement of steam consumption for every 14° F. superheat.

Correction for Initial Wetness of Steam.

For each 1 per cent. wetness the steam consumption, if measured as condensed water, will be 2 per cent. too high.

Pressure Correction.

The correction which is to be made for the pressure depends upon whether the change in pressure is before the stop valve or before the nozzles.

Thus, if in the case of a high-pressure turbine working on a constant generator load the pressure before the stop valve is raised, say 10 lbs. per sq. in., the governor valve closes slightly, but the pressure before the nozzle will be very little altered, the only result being that the steam is throttled to a greater extent than formerly.

---

* *Steam Turbine Blading*, Institute of Metals, September, 1915.

† *Recent Developments in Steam Turbine Practice*, Inst.E.E., April 1912.

The effect of such an increase of pressure will be that the steam consumption will be improved by the small amount corresponding to the superheat due to the additional throttling.

In such cases the steam consumption will be improved by 0·5 per cent. for every 10 per cent. increase of pressure.

When, on the other hand, the pressure before the nozzles is increased, the correction is of quite different magnitude and is:

For high-pressure turbines, an improvement of 1½ per cent. in steam consumption for 10 per cent. increase in pressure.

For low-pressure turbines, an improvement of 4 per cent. in steam consumption for 10 per cent. increase in pressure.

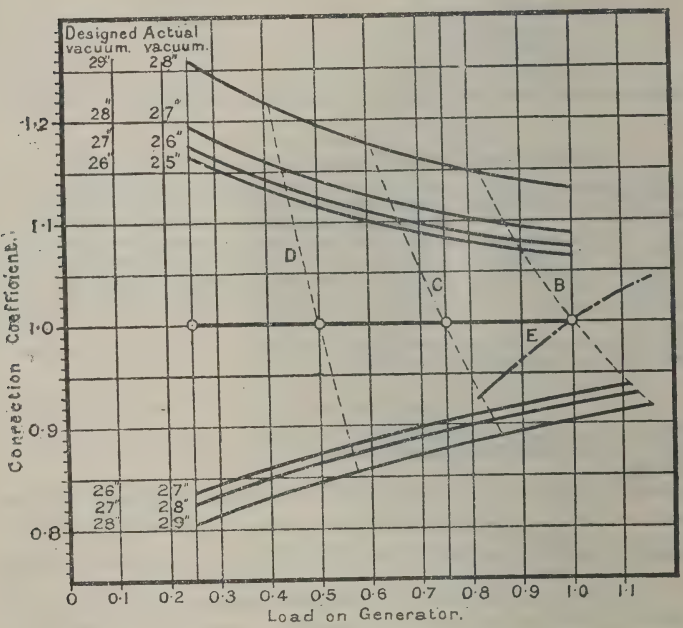

FIG. 12.—Vacuum Correction for Low-pressure Turbines.

Vacuum Correction.

In any test, the correction for vacuum is usually of greater magnitude than that for pressure or superheat. Although every care has been exercised in estimating these corrections, it is obviously desirable that the total correction should be as small as possible, and if only for this reason every effort should be made to obtain during a test a vacuum as little different as practicable from that for which the turbine was designed.

Table VIII. gives the correction for vacuum which should be employed for various designed conditions with high-pressure turbines or mixed-pressure turbines, working with high-pressure steam.

TABLE VIII.—VACUUM CORRECTION FOR HIGH-PRESSURE AND MIXED-PRESSURE TURBINES.

Partial loads are expressed as fractions of the full load for which turbine is designed.

The correction is to be made when the turbine is run on a vacuum other than that for which it was designed.

		29	13·5	9·9	11·3	13·3	16·8			28—29

The Theoretical Correction is given for 150° F. Superheat.

The actual correction given for various loads can be used for any superheat between saturation and 300° F.

It should be noted that at any load and for the same designed steam conditions and actual vacuum, the correction in the case of a mixed-pressure turbine (M.P.) is greater than for a high-pressure turbine (H.P.).

Thus, for example, the correction for an M.P. turbine at full load and working with high-pressure steam is the same as for a H.P. turbine on half load. The assumption underlying this is that the M.P. turbine is designed to give the same output on H.P. as on L.P. steam, and that, therefore, the conditions in the nozzles and blading of the L.P. end of the M.P. turbine are the same as that of a H.P. turbine designed for twice that output. Changes in vacuum only affect the conditions in the last few stages of a turbine, and these in a M.P. turbine on H.P. steam are operating under the same conditions as those of a H.P. turbine at half load.

Vacuum correction for low-pressure turbines or for mixed-pressure turbines working with low-pressure steam are still larger than those already considered.

In fig. 12 a coefficient will be found for various loads on the generator which is the ratio :—

$$\frac{\text{Steam consumptions for 1 in. } \begin{matrix}\text{above}\\ \text{or}\\ \text{below}\end{matrix} \text{ the designed vacuum.)}}{\text{(Steam consumption for the designed vacuum.)}}.$$

While the corrections as given above can be applied to the generality of cases, special conditions may arise where corrections must be separately considered.

Thus, it is possible to obtain little or no benefit by increasing the vacuum with a turbine designed for a certain load at a certain vacuum and modified to operate on a considerably higher load and a higher vacuum; in such a case the velocity in the exhaust would be exceedingly high, and may even approximate to sound velocity.

In back pressure turbines, or the high pressure end of reducing turbines, all corrections will be considerably larger than those given above, and these require separate consideration in each case.

It cannot be too strongly emphasised that every endeavour should be made to arrange the test conditions in such a way that all corrections are as small as possible.

TYPES OF TURBINES.

Turbines may be classified according to the steam conditions under which they operate. It should be noted that the energy available in adiabatic expansion of steam from 180 lbs. per sq. in. g. and 100° F. superheat to 28 ins. vacuum, is about twice that available if the expansion is carried down to atmospheric pressure only. Hence the addition of condensing plant approximately doubles the amount of work which can be done per lb. of coal, without necessitating any increase in boiler capacity.

High-Pressure Turbines.

High-pressure turbines take their steam directly from the boilers, and expansion takes place in the turbine down to the pressure in the condenser. This may be regarded as the fundamental class of turbine. The steam conditions are usually 200–150 lbs. per sq. in. g. pressure, 0°–200° F. superheat, and 27½ ins. to 28½ ins. vacuum (30 ins. Barm.). Of course, the range of possible conditions is greater than these: for instance, in collieries and steel works, steam pressures of 100–50 lbs. per sq. in. are to be met with, while steam temperatures of 700° F. will probably be adopted in the near future.

Low-Pressure Turbines.

Low-pressure turbines take their steam at about atmospheric pressure, the source almost invariably being the exhaust from non-condensing reciprocating engines. The initial steam pressure is usually from 20–15 lbs. per sq. in. abs., and should in all cases be above atmospheric pressure in order to eliminate the risk of air leakage into the steam pipe line. Low-pressure turbines require no governor gear if connected either mechanically or electrically to the reciprocating engine from which they obtain their steam. In the event of the engine being shut down the turbine is supplied with steam from the boilers through a reducing valve.

Back-Pressure Turbines.

Back-pressure turbines take their steam directly from the boilers and exhaust at or above atmospheric pressure. Such turbines may be used in case where the exhaust steam is required for heating purposes, and the back pressure usually ranges from 1–20 lbs. per sq. in. g.

In certain cases the back pressure may be as high as 40 lbs. per sq. in. g.

Back-pressure turbines are used to a considerable extent to drive the auxiliaries, their exhaust steam being utilised for feed heating; by this means the losses in the turbine are recovered in the feed heater, and an overall efficiency for back-pressure turbine and feed heater of over 90 per cent is obtained.

Mixed-Pressure Turbines.

When L.P. steam is utilised in an L.P. turbine it is obviously desirable that the turbine set may be operated at will independently of the reciprocating engines from which it obtains its steam, so that in the event of the engine being shut down the turbine may operate with reasonable economy. This becomes possible by the addition of what is really a B.P. exhausting into the L.P. turbine, and having a common casing and spindle. This combination forms a mixed-pressure turbine, which can operate not only on either H.P. or L.P. steam, but if sufficient L.P. steam is not available to carry the load, the deficit is automatically supplied by admitting H.P. steam to the H.P. end of the turbine.

The governor gear is automatic and adjusts itself so that all the L.P. steam available is used in preference to H.P. steam.

In mixed-pressure turbines the governor gear is of special importance, as for successful working in parallel with other alternators the changes from L.P. steam to H.P. steam must be effected without any appreciable change in speed or load of turbo-alternator.

Reducing Turbines.

With a B.P. turbine the amount of steam available for heating purposes, and the work done by the turbine, are directly connected. In most installations it is desirable to be able to vary these quantities independently of each other, and to meet this demand 'Reducing' turbines were introduced.

An R.P. turbine consists of a B.P. turbine to which an L.P. turbine is added. The B.P. turbine is designed for the maximum amount of steam required by the heaters it supplies.

As the demand for heating steam decreases, an automatic governor gear by-passes the supply to the L.P. end of the turbine, and at the same time the supply of steam to the H.P. end is decreased.

In this way the load the generator can carry is independent of the amount of heating steam required.

The governor gear should be operated in such a way that the pressure of the heating steam remains constant.

An increasing demand for this type of machine has arisen in recent years as a result of the extremely economical results which can be obtained in those manufacturing works requiring both electrical power and heating steam.

In order to obtain the best result the pressure at which steam is taken from the turbine for

heating purposes should be as low as possible in view of the requirements of the heating process. The effect of back pressure on the consumption of heating steam can be seen from

POWER OBTAINED FROM HEATING STEAM.

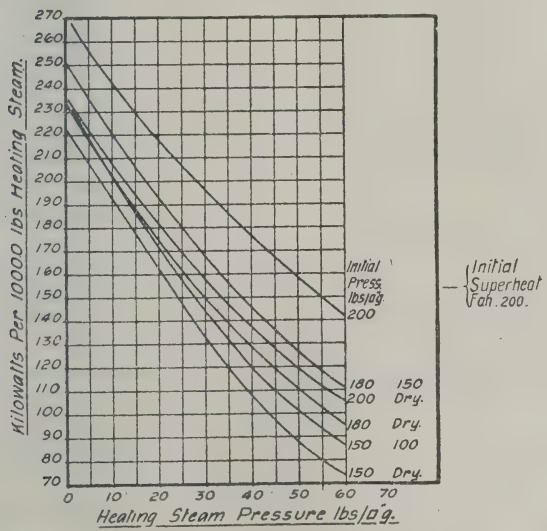

FIG. 13.

the following table, while the variation in the power which can be obtained from back pressure on reducing turbines is shown in fig. 13 for various steam conditions.

PERCENTAGE CHANGE IN STEAM CONSUMPTION OR WORK CAPACITY OF HEATING STEAM FOR A CHANGE IN HEATING STEAM PRESSURE OF 5 LBS. SQ. IN. G.

BRITISH ENGINEERING STANDARDS SPECIFICATION FOR STEAM TURBINES FOR ELECTRICAL PLANT.*

No. 132–1920 (Abstract).

RATING.

The rating of the steam turbine shall be the rated output of the generator to which it is coupled. (The British Engineering Standards Committee have laid down that the rating of the generator shall be the load which it is capable of carrying continuously with a temperature rise of 40° C.)

* By permission of the British Engineering Standards Association.

Margin of Capacity of Steam Turbine.

The steam turbine shall be provided with means for developing 10 per cent. greater load than the rated load of the generator with the specified steam conditions. This margin is provided with a view to allowing the turbine to drive the generator at its rated capacity when the steam conditions are worse than those specified, and is not provided with the object of obtaining overloads on the generator.

Output of the Turbine when Working Non-Condensing.

If the specified steam pressure is not less than 165 lbs. per sq. in. absolute, and the rated output of the turbine is not more than 3,000 kw., the turbine shall be capable of developing 30 per cent. of its rated output when exhausting to the atmosphere. For turbines of larger capacity the output must be settled between the purchaser and the manufacturer.

Note.—It is undesirable to work high-pressure steam turbines exhausting to the atmosphere and this should only be done in cases of emergency. Even under this condition, the turbine should not operate in this way for a longer time than is absolutely necessary.

Maximum Speed.

The turbine shall be capable of withstanding for five minutes, without injury, a speed 15 per cent. in excess of the rated speed.

Governing Characteristics.

When the rated load is taken off or on the permanent speed variation shall not exceed 3 per cent., nor shall the momentary variation exceed 6 per cent.

Governing Adjustment.

Means shall be provided to enable the speed to be adjusted by plus or minus 5 per cent., when working under synchronising conditions.

Emergency Cut-off Speed.

The emergency governor shall be set to shut off steam if the speed exceeds 9 to 11 per cent. of the rated speed.

Economic Rating of the Turbine.

The turbine shall be designed to give a minimum steam consumption at 80 per cent. of its rated output.

Guarantee Steam Consumptions.

If steam consumptions are guaranteed for various outputs, the average steam consumption shall be obtained by

Mutiplying the steam consumption at the rated output by 3.
" " " 80 per cent. of the rated output by 4,
" " " 60 " " " " 3,
" " " 40 " " " " 2,
and dividing the sum by 12.

Load at which Steam Consumption is Guaranteed.

The load or loads at whch the steam consumption is guaranteed shall be stated in the order. Unless otherwise specified, the guaranteed steam consumptions shall be deemed to be the average steam consumptions as defined above.

Tolerance.

For the purpose of comparing test consumptions with the guarantee performance a tolerance calculated as follows shall be allowed:—

Percentage tolerance (+ or —) =

$$\frac{\text{Arithmetical sum of percentage corrections} - 5}{4} + 2\tfrac{1}{2} \text{ per cent.}$$

Hydraulic Test for Parts Exposed to Full Boiler Pressure.

All parts exposed to the rated steam pressure shall be tested with a hydraulic pressure 50 per cent. in excess of the rated pressure. The machine as a whole shall be tested with a hydraulic pressure of 15 lbs. per sq. in. gauge.

Critical Speed of Shaft.

The critical speed of the turbine shaft shall not be within 30 per cent. above or 35 per cent. below the rated output.

TURBINE SPEED-REDUCTION GEAR.*

The speed at which it is most desirable to run a turbine is limited only by the strengths of the materials used in its construction. Unfortunately, this limit of speed cannot be approached when the turbine is employed for direct driving of propellers, D.C. generators of large output, rolling mills, line shafting, etc., and in such cases where comparatively low speeds are essential not only does the turbine become heavy, costly and inefficient, but direct turbine drive is often quite out of the question.

For this reason several systems of speed reduction have been introduced, and are being successfully applied.

Double Helical Gears.

Speed reduction by means of double helical gears was employed in the earliest days of turbine engineering by Dr. Delaval, whose turbines, running at speeds of the order of 10,000 r.p.m., could not be directly coupled to electric generators. The gearing of these turbines gave remarkably little trouble, and although the outputs were low it is notable that even to-day this is the most successful system of speed reduction.

Double helical gearing for large turbines was introduced by Sir C. A. Parsons, who with characteristic courage first introduced the system in the famous case of the propelling machinery of the s.s. 'Vespasian,' and the drive of a rolling mill at Calderbank Steel Works.

In the earlier installations difficulties were experienced through minute inaccuracies of the gear teeth, which gave rise to very noisy working. This was traced to errors in the gearing of the table of the gear-cutting machine by Sir C. A. Parsons, who has very materially reduced the trouble by arranging a 'Creeping' table giving the gear blank an advance of 1 per cent. relatively to the main table of the machine. The improvements in modern gear-cutting machines have eliminated the inaccuracies referred to, so that the creeping device is no longer essential.

The helix angle adopted varies from 20° to 45°, the usual angle in modern practice being 30°.

The teeth of modern double helical gears are of the standard involute type, the pressure angle adopted by different makers varying from 14½ to 22 inches.

If p = average pressure in lbs./inch tooth face.
L = total length of tooth face in inches.
D = diam. of pitch circle of pinion in inches.
R = revs. per minute of pinion.
V = pitch speed in feet per second $= \frac{\pi D}{12} \times R$.

Then

$$\text{Horse-power transmitted} = P = \frac{pLV \times 60}{33{,}000} = \frac{pLV}{500}.$$

Professor Stoney states that V should be kept between the limits 100 and 130 ft./sec. He also gives the maximum permissible pressure $p = 120d$ for pinions smaller than 5 inches diameter, and $p = 175\sqrt{d}$ for larger pinions.

Fig. 14 shows curves co-ordinating p and d, published by Mr. F. H. Hodgkinson (*Engineering*, Jan. 10, 1919).

With pinions having two bearings where E = Young's modulus of elasticity = 30 by 105 lbs./D inch,

$$I = \text{the moment of inertia of the pinion} = \frac{\pi D^4}{64}.$$

$$\text{Transverse deflection at the centre} = \delta_1 = \frac{5}{384} \cdot \frac{pL^4}{EI}$$

This is one of the determining factors in design, and, according to Stoney, should not exceed 0·0002 inches.

For pinions having three bearings, the maximum deflection on each portion of the pinion between two bearings should not exceed 0·0002 inches, and in most cases this is not the condition determining the diameter.

Another condition fixing the design of the pinion arises from the fact that the torsional deflection opens the teeth, thus preventing uniform distribution of pressure on them. This torsional opening, δ_2, according to Stoney, must be limited to less than 0·0001 inches, and is given by the following expressions :—

$$\text{For two or three bearing pinions } \delta_2 = \frac{OL}{10 \times 10^4} \text{ inches over one helix.}$$

In the Melville-McAlpine gear, manufactured and developed by the Westinghouse Machine Co., the pinion is supported in a floating frame which permits its axis to take up a slight inclina-

* See also 'Reduction Gear for Propulsion,' Section XXXIII.

DOUBLE HELICAL GEAR CURVES.

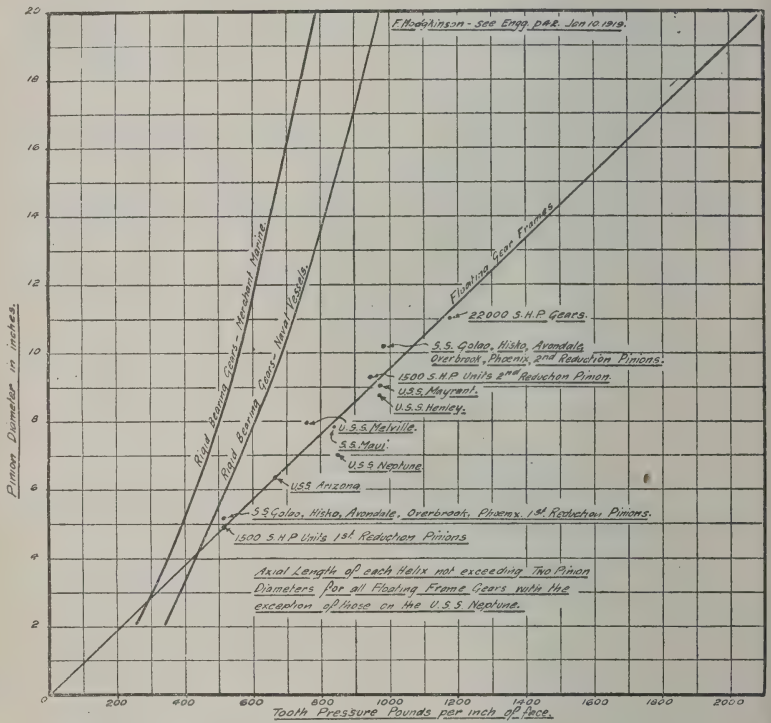

FIG. 14.

tion in the vertical plane relatively to the slow speed shaft. The torque on the pinion tends to increase the helix angle of one half of the pinion and decrease that of the other half, so that if the helix angle of the pinion is the same as that of the wheel, as load comes on, the helix angles become different. If the axis of the pinion is inclined in a vertical plane relatively to the wheel, the change in the helix angle with load can, it is claimed, be very largely compensated, so that with the floating pinion larger torques can be transmitted through a given size pinion than through a pinion supported in rigid bearings. According to the inventors, the floating frame also corrects to a certain extent errors in the teeth and in alignment of the gears.

The action of this gear is well explained, together with some authoritative notes on double helical gearing, in a series of articles by Mr. J. H. McAlpine, which appeared in *Engineering*, commencing May 5, 1916.

In these articles Mr. McAlpine suggests the use of the 'Power Constant' for comparing different gears; these he defines as follows:

If D = pitch diameter of pinion in ins.; L = length of tooth face in ins.; p = average pressure in lbs. per in. of tooth face; R = r.p.m.; C = power constant; P = horse-power transmitted;

Then

$$P = \frac{\pi D R p L}{33000 \times 12}.$$

For correctly designed gears, p and L vary as D, therefore

$$P = C (D^3 R),$$

and

$$C = \frac{P \times 1000}{D^3 R}.$$

For gears having the pinion supported in two rigid bearings, the power constant 'C' should not exceed 1·5.

'C' is usually from 1·2 to 3·0, for gears having three bearings on the pinion.

Gears having the pinion supported in a floating frame have worked very successfully with a power constant of 4.

The ratio $\frac{L}{D}$ should preferably be equal to 4-in. gears having the floating frame.

For best results the pinions for all sizes should have from 26 to 30 teeth; if the number is appreciably reduced interference takes place.

The efficiency in double helical gearing varies from 98·5 per cent. in large gears to 97·5 per cent. in small sets, so that from 1·5 per cent. to 2·5 per cent. of the heat equivalent of the power transmitted has to be dissipated in the lubricating oil cooling system.

The gears are usually lubricated by spraying the oil on the teeth at the point of contact.

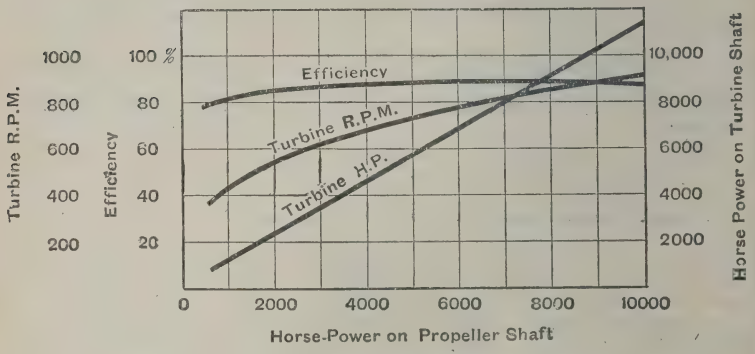
The success of a gear depends to a larger extent than is generally supposed on the rigidity and correct design of the gear-box and lubricating system, and where experienced engineers are responsible for these details every confidence can be placed in a turbo-geared proposition.

Table IX gives some particulars of notable installations of geared turbines.

Recently, rapid advances have been made in the application of steam turbines to the mercantile marine, by the introduction of double reduction gearing. Single reduction gears having ratios larger than 15 to 1 are scarcely practical for ship propulsion, but a reduction of, say, 42 to 1 can be commercially obtained by a double reduction gear having two trains of wheels, the first having a reduction of, say, 6 to 1 and the second 7 to 1.

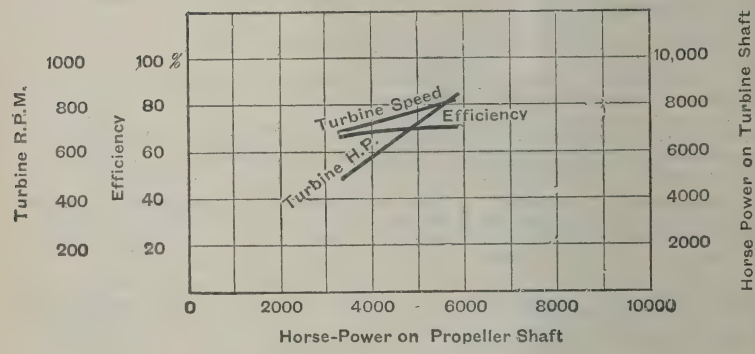
Such double reduction gears are now being used having efficiencies at full load of about 97 per cent.

Now that such large ratios of reduction are commercially practicable, both the turbine and the propeller can be run at the speed most suitable for each respectively.



See also pp. 885, 888, and 'Reduction Gear for Propulsion,' Section XXXIII.

Hydraulic Transmission.



Prof. Fottinger has invented an ingenious system of speed reduction in which the turbine drives a centrifugal pump which delivers water into a water turbine to which the propeller or generator is coupled.

The possibilities and limitations of this type of transmission are illustrated by the following figures given by Prof. Fottinger.*

No. of Stages.	Gear Rates.	Estimated Efficiency.
1	5 to 1	90 per cent.
2	7½ to 1	90 „
3	10 or 12 to 1	88 „

FORWARD ELEMENT

REVERSE ELEMENT

FIG. 15.

Unfortunately the ratios usually required for marine purposes are from 10 to 1 up to 20 to 1. and as it is doubtful if more than single stage transmitters could be commercially adopted, it will be seen the field open to this type is limited. A distinct advantage lies in the fact that the discharge from the turbine pump element can be diverted to a reverse water turbine, by which means reversal can be easily and economically effected. The water used in the transmitter is usually the boiler feed, and in this way some of the losses can be recovered in feed water heating, but it is difficult to see how the gain can possibly exceed 1 per cent. measured at the driven shaft.

Fig. 15 shows the results of tests on a 10,000 B.H.P. transmitter.†

Electrical Transmission.

Various schemes of electrical reduction of speed have been suggested at various times, for which an overall efficiency of from 90 to 92 per cent. is claimed.

The General Electric Company * have installed an electrical transmission of considerable importance in the collier 'Jupiter' for the U.S.A. Navy, the following particulars of which are of interest :—

The ship is of 20,000 tons displacement, and is driven by a six-stage Curtis turbine, in which each wheel has two rows of blades and runs at 2,000 r.p.m., coupled to a bipolar 3 P.H. generator supplying current at 2,200 volts to two motor-driven propellers. The motors have 36 poles, so that the ratio of synchronous speed reduction is 18 to 1. The efficiency of the motors is 95 per cent.

At the designed speed of 14 knots the propeller speed is 110 r.p.m., and the output at the propellers 5,600 s.h.p.

Under these conditions the consumption on test was 12 lbs. per s.h.p., with a steam pressure of 190 lbs. per sq. in., dry saturated steam, and exhausting into vacuum of 28½ ins. Hg., 30 ins. Baro. Thus the thermal efficiency of the turbine generator and motors is 19 per cent., but this does not include any loss in switchgear or cables.

Variations in speed are obtained by varying the speed of the turbine, the gear ratio remaining constant, and in the process of reversal water-cooled resistances are put in circuit with the rotors of the motors.

A system which is virtually an electrical speed reduction has been introduced where direct current is desired with steam turbines as the prime movers, in which the turbine drives an alternator which is electrically coupled to a rotary converter. As compared with direct-current generators driven by double helical gearing, it appears that in plants of over 1,500 kw. capacity the pure electrical scheme may be the more advantageous. Other considerations peculiar to a particular installation often arise demanding the electrical scheme for smaller outputs than 1,500 kw.

Very large installations of electrically driven ships are now being completed for the United States Navy, and this system may possess certain advantages for such ships as operate for a large proportion of their time at speeds very much less than the maximum which they are able to develop. In such cases the turbines can run at their normal speed independently of the speed of the propeller. Further, the main turbines can be disposed in any convenient position in the ship without reference to the position of the propeller. These conditions are not important in the case of the majority of ships in the mercantile marine.

(Revised by T. B. Morley, D.Sc., M.I.Mech.E.)

ENGINE DESIGN.

The type of engine is first settled from a consideration of duty, steam consumption, price of fuel, space available, working conditions, water supply, first cost, etc.

Cylinder proportions and speed of revolution are then fixed. Typical British cylinder ratios and mean effective pressures are given in the tables below. On the European Continent the cylinder ratios adopted are usually considerably below the tabular values. That is, a larger high-pressure cylinder is adopted. This makes for economy with superheated steam, but for a two-crank engine tends towards unequal distribution of load on the two cranks which is not altogether desirable. This objection does not apply in the case of tandem engines. These remarks are illustrated by the test results tabulated on page 1403.

TYPICAL MEAN EFFECTIVE PRESSURES AT NORMAL FULL LOAD IN LBS. PER SQ. IN.

Boiler Pressure—Gauge	80	100	120	140	160	180	200
Simple Condensing, about	30	34	37	—	—	—	—

I.P. to H.P.	—	—	2·3–2·36	2·36–2·45	2·43–2·5	2·45–2·67

(*Foster.*)

Having fixed the cylinder sizes the probable steam pressures on the pistons are put down, and from these the total piston loads are obtained. From these, by allowing suitable stresses and bearing pressures the principal sizes are fixed.

Usual stresses in high-class engines are as follows:—

USUAL ENGINE STRESSES.

Crank and crosshead pins, up to. . .	9,000 lbs. sq. in.	Connecting rod bolts .	4,000–6,000 lbs. sq. in.
Crankshaft journals .	7,000–9,000 „	Main studs and bolts .	5,000 „
Piston rod, net tension at cotter hole . .	5,000–6,000 „	Lesser „ „ .	4,000–6,000 „
Piston rod, gross tension (direct plus bending in body) . . .	9,000 „	Connecting rod body, small end . .	3,000–6,000 „
		Shear on cotters .	3,000–5,000 „
		Bending on cotters .	up to 7,000 „
		General forgings . .	4,000–8,000 „

Cast Iron in Tension.

Simple frames, direct pull	700–900 lbs. sq. in.	Flywheel arms (C.F.) .	1,500–2,500 lbs. sq. in.
Frames, with some bending	500–800 „	Cylinder barrels, new .	1,200–2,000 „
Complex frames, with bending	500–600 „	„ „ usual .	1,500 „

It should be noted that in calculating the above frame tensions only the direct pull is included. If bending is calculated separately and added on, very high figures are sometimes reached.

As an example, take the case of a cotton mill engine of 1,500 i.h.p. normal load, the engine to be of the cross-compound condensing type; boiler pressure 160 lbs.

The cylinder ratio we take to be 4 nominal, piston rods being ignored. We aim at equal loading on the two cranks so that of the total drop in pressure from stop valve to condenser one-fifth will take place in the low-pressure (l.p.) cylinder. Allowing 12 lbs. vacuum and losses of 5 lbs. and 8 lbs. at the steam pipe and intermediate receiver respectively, the total effective pressure drop is 159 lbs., of which 32 takes place in the l.p. cyl. and 127 in the h.p. If the engine has a stroke of 5 ft. and runs at 66 r.p.m. (higher speeds are coming into favour), the piston speed is 660 ft. per min., and the area of the l.p. cylinder for a m.e.p. of 30 lbs.

$$= \frac{1{,}500 \times 33{,}000}{660 \times 30} = 2{,}500 \text{ sq. ins.}$$

This is taken as the gross piston area, giving a diameter of 56·5 inches. The actual m.e.p. would therefore be about 31 lbs. The h.p. cylinder should then be 28·25 ins. diam., but odd dimensions are unsatisfactory, and the cylinders will be fixed at 28 and 56 inches, giving a nominal m.e.p. of 30·5 lbs., which is rather below modern practice, which tends rather to higher m.e.p. than given in the table above.

Ignoring the piston rods, the gross load on the l.p. piston is $32 \times 2{,}500 = 80{,}000$ lbs. The load on the h.p. piston is the same. Owing to the effect of the rods this value is rather high, but the difference may be ignored, and 5 per cent. added to cover variations in the load distribution, making the total piston load 84,000 lbs. Taking bearing pressures of 1,250 and 850 lbs. per sq. in. on the crosshead pin and crank pin, the projected areas of these become 67·2 and 98·8 sq. ins. respectively. We may thus fix the pin bearings (diam. × length) as 6·75 × 10 and 10 × 10 ins.

HORIZONTAL ENGINE BEARING PRESSURES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Crosshead pins . . .	1,200–1,300	Second motion bearings .	100–200
Crank pins	800– 950	Crosshead slides . . .	40– 50
Crankshaft journals (steam load)	100– 150	Intermediate piston rod slides	20– 40
Crankshaft journals (combined loads) . . .	150– 200		

USUAL BEARING PRESSURES FOR VERTICAL HIGH-SPEED ENGINES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Main bearings . . .	200– 300	Crosshead slippers . .	40–50
Crank pins	400– 550	Eccentric straps . . .	60–70
Crosshead pins . . .	1,000–1,200		

Inertia should be allowed for in special cases.

Journal speeds are rarely taken into account, but there is at present a tendency to do so, especially in Germany. The influence of speed is complex. In many cases it improves the load which can be carried, but it also increases the heat developed per second, and where the pressures are not such as to endanger the oil film, may limit the safe load on the bearing by the tendency towards overheating. For this a rule of the form—

Pressure per sq. in. × journal speed in ft. per sec. = constant,

is used, but the 'constant' varies so widely that its value in the present state of knowledge is limited.

We now turn to the size of the crankshaft neck. The bending 'arm' from centre of crank pin to centre of main crankshaft neck, we estimate at about 26 ins., so that the bending moment is $M = 84{,}000 \times 26 = 2{,}180{,}000$ inch lbs. The twisting moment is

$$T = 84{,}000 \times 30 = 2{,}520{,}000 \text{ inch lbs.}$$

The equivalent bending moment is

$$M_e = \tfrac{1}{2}\left[M + \sqrt{M^2 + T^2}\right] = 2{,}755{,}000.$$

Adopting a stress of 8,000 lbs. per sq. in., the modulus of the neck section is

$$Z = \frac{2{,}755{,}000}{8{,}000} = 344.$$

For a solid neck of diam. d, $Z = 0{\cdot}0982d^3$. Hence $d = 15{\cdot}2$ ins., say 15·5 ins. The length of the neck must be determined to give a suitable bearing pressure from dead weight and steam load.

The piston rod diam. is next fixed, and partly from it and partly directly from the load the proportions of the connecting rod. The piston rod is proportioned so that the stress round the cotter hole at the crosshead is about 5,000 to 5,500 lbs., whilst the total direct tension plus tension due to bending (assuming a tail support to the rod) does not exceed about 9,000 lbs. The net section of the frame will lie between about 100 and 170 sq. ins. according to type, the highest stresses being allowed where there is least bending.

The size of the crosshead slipper is determined as follows:—If the connecting rod is 5 cranks long, centre to centre, divide the total piston load by 5. The result, 16,800 lbs. in this case, is approximately equal to the maximum load on the slide due to piston pressure. To this should be added the dead weight in the case of a horizontal or inclined engine, giving, say, about 18,000 lbs. in all. Taking a pressure of 45 lbs. per square inch (less if the pressure is steady and not highly variable), gives a slipper area of 400 sq. ins.

Testing Crankshaft Alignment.

Place the crankshaft, fig. 1, on its top centre and set either a micrometer gauge or a gauge made of round iron between the crank webs at the bottom. Turn the crankshaft

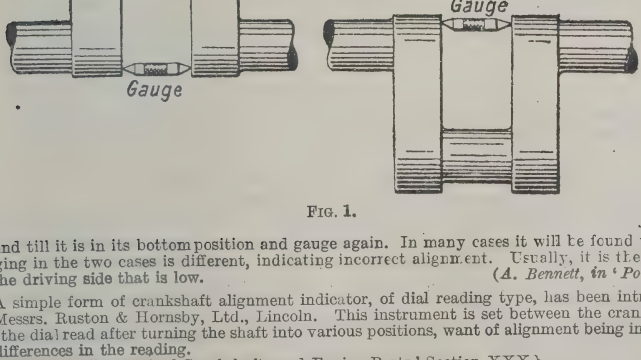

FIG. 1.

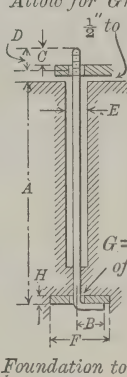
around till it is in its bottom position and gauge again. In many cases it will be found that the gauging in the two cases is different, indicating incorrect alignment. Usually, it is the bearing on the driving side that is low. (*A. Bennett, in 'Power.'*)

A simple form of crankshaft alignment indicator, of dial reading type, has been introduced by Messrs. Ruston & Hornsby, Ltd., Lincoln. This instrument is set between the crank webs, and the dial read after turning the shaft into various positions, want of alignment being indicated by differences in the reading.

(See also 'Alignment of Crankshafts and Engine Parts,' Section XXX.)



FRAMES.

Bedplates and other frames are almost invariably of strong cast iron. They should be so formed as to reduce bending to a minimum consistent with convenience for the engine attendant and reasonable cost. To secure this they should be as nearly as possible symmetrical on both sides, and also above and below the centre line. This does not mean strict geometrical symmetry, as this is very rarely attainable except as regards the two sides ; but it implies an approximately equal distribution of stress. Circular bored and turned joints make for truth in alignment and often for cheapness in manufacture. Ample bearing surface on the foundations must also be allowed.

Foundation Bolt Dimensions.

For bolts 2 ins. or over in diameter, a nut is used under the washer or anchor plate, instead of the bolt being clinched, as indicated by dimension *B*.

STANDARD DIMENSIONS FOR SETTING FOUNDATION BOLTS.

Bolts. (Inches.)						Washers. (Inches.)		
Dia.	A	B	C	D	E	F	G	H
¼	—	—	—	—	—	—	—	—

2½	60	Nut	3¾	5	6	12 by 20	3	1½

(*'Machinery,' Mar.* 24, 1921.)

CYLINDERS.

Cylinders should be hard and strong. Apart from questions of strength, for information on which see the table of stresses on p. 1590, the following important points should not be overlooked :—

(1) The clearance volume should be as small as reasonably possible.

(2) The clearance surface should be reduced to a minimum.

(3) The exhaust and inlet ports are better separated.

(4) The ports should be short, direct, and not too large. Large ports involve increased clearance surface.

(5) The covers which, however, are closely influenced by the piston details, should be free from recesses and curves.

(6) Where there are jackets the steam should be arranged to have a decided through flow, the more rapid the better.

(7) Proper relief valves and drainage should be provided.

(8) Metal bosses and projections connecting to the frames or atmosphere facilitate heat radiation, and should be kept small.

The clearance surface is specially important. Some particulars of usual practice are given in the table of tests on p. 1403, and in the following :—

TYPICAL CLEARANCE SURFACES.

Cylinder and Valves. (Piston Area × 2 = 100%.)	Surface, Per cent.	Authority.
H.P. slide valve	200	J. Stumpf
L.P. trick valve	180	,,
H.P. piston valve	300	,,
L.P. piston valve	220	,,
Double-beat drop valve	182	,,
Corliss valve	170	,,
Uniflow, double-beat valve	133	,,
H.P. Corliss valve	210–320	Foster
L.P. Corliss valve	180–300	,,
H.P. drop-piston valve	210–300	,,
L.P. drop-piston valve	200–300	,,

The port sizes are based on a steam velocity of 100 to 125 feet per second for inlet ports, and 90 to 120 feet per second for exhaust ports when using saturated steam. With superheated steam these speeds are increased to 130 or even 150 feet per second.

BEARINGS.

With very rare exceptions oil is dragged into a bearing by the relative movement of the two so-called rubbing surfaces by a kind of wiping or dragging action. The bearings of an electric motor provide an excellent example. To prevent loss of lubrication the oil must not be allowed to escape from the bearing except at the proper place. Ordinary crosshead pin bearings work mostly by suction. The slight pulsation of the pin in the bearing draws in oil on alternate strokes. On the return of the pressure the oil has not time to escape.

Oil grooves should be looked upon as local supply reservoirs.

Bearing clearances should not increase so rapidly as the diameter of the journal. They vary according to the class of work.

White metal for bearings (Section XXXVII) is a safety precaution in case of overheating. It also has constructive merits.

Usual bearing pressures are given on p. 1590.

For the Michell bearing see Section XXXIII.

Cooling Bearings.

'COOLORICID.'

This is a preparation (*Sterns, Ltd.*) expressly prepared to obviate the risk of seized bearings By an application of 'Cooloricid' it is claimed that the temperature of the hottest bearing will be reduced to normal, thus obviating seizing or fracture. The material is packed in ½-cwt. and 1-cwt. drums, price 2*s.* 6*d.* per lb. ; sample tins containing 10 lbs. are supplied at the same price.

Alignment Pins.

'Alignment,' 'steady,' or 'fixing' pins are brought into service in the erection of machinery details for the purpose of ensuring that one particular piece shall be superimposed upon another

piece in its precise and correct position, no matter how many times the respective pieces may be separated. The use of such pins is far preferable to fitting bolts to each and every hole; the holes for the bolts should be 'clearance' holes, i.e. holes through which the bolts can pass freely.

Fig. 2 shows a pin which has been used frequently in small engines, dynamo-electric machinery, and, notably, in the casings of large steam turbines, with unqualified success and approval.

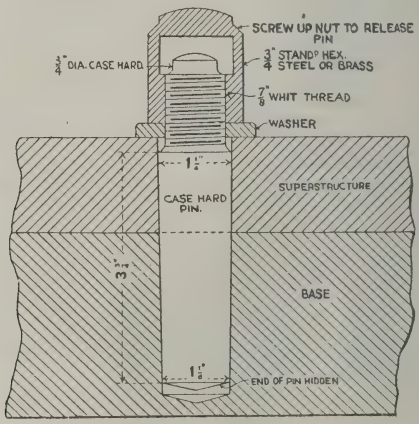

FIG. 2.

It will be observed by those familiar with the use and application of these alignment pins, that a pin such as is shown in the figure is all but imperatively necessary where it is required to fit it to a blind bottom, as represented above. ('*The Electrical Review*,' Sept. 17, 1920.)

FLYWHEELS.

A = Area of turning moment curve per revolution = Work done per revolution in ft. lbs.
a = Excess or deficiency of turning moment curve from resistance curve (usually taken as the mean steady load) = k A.
k = Coefficient of energy fluctuation.
I = Moment of inertia of flywheel in lbs. ft.^{2}
d = Diameter of gyration of wheel in feet.
D = „ rim face „ „
C = Number of complete turning-moment cycles per revolution.
G = Total weight of wheel in lbs.
W = Effective „ „ „ if placed at rim face, diameter D, velocity V.
V = Linear velocity of rim face, ft. per sec.
N = R.P.M.
X = Cyclic irregularity of turning.
Y = Angular deviation from true uniform turning.
F = Frequency of (electric) alternations per second.
p = Number of poles in alternator field magnets.

$$K = \text{Flywheel coefficient} = \frac{\text{Stored energy in flywheel}}{\text{Work done per revolution}} = \frac{WV^2}{2gA}.$$

Then (the suffixes $_1$, $_0$, and $_2$ referring to maximum, mean, and minimum),

$$X = \frac{N_1 - N_2}{N_0} = \frac{V_1 - V_2}{V_0} = \frac{k}{2K} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$K = \frac{k}{2X} = \frac{a}{2AX} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$Y_1 - Y_0 = 28{\cdot}65\,\frac{X}{C} \quad . \quad . \quad . \quad . \quad \text{mechanical degrees} \quad . \quad . \quad . \quad . \quad (3)$$

$$= 14{\cdot}32\,\frac{pX}{C} \quad . \quad . \quad . \quad \text{electrical degrees} \quad . \quad . \quad . \quad . \quad (4)$$

$$= \frac{1719\,FX}{NC} \quad . \quad . \quad . \quad \text{electrical degrees} \quad . \quad . \quad . \quad . \quad (5)$$

The above formulæ are based on sine curves for the turning moment, and are rarely strictly correct as regards the angular deviation $Y - Y_0$, but formulæ (1) and (2) are always correct if the value of a is properly determined.

Considerable uncertainty arises as to the value of a in the case of multi-crank engines.

Certain flywheel data are given in the three following tables. It will be understood that these are typical values, and that considerable variations occur in practice.

TYPICAL VALUES OF ENERGY COEFFICIENTS, k.

NOTE.—The values of k are based on the assumption of a uniform engine load, and do not apply accurately to engines driving pumps, blowers, or even electric alternators. (*Foster.*)

Example.—Tandem compound engine of 1,200 i.h.p. normal load at 94 r.p.m., driving an alternator of 50 cycles. The deviation must not exceed two electrical degrees on either side of the mean position.

From the tables we see that k is about 0·13, and C=2.
In formula (5) we have

$$C = 2,\ Y_1 - Y_0 = 2,\ F = 50,\ N = 94$$

Hence

$$X = 0{\cdot}00437 = \frac{1}{229}.$$

Inserting the value of X in formula (2) we obtain K=14·9.
The work done per revolution is

$$A = \frac{1{,}200 \times 33{,}000}{94} = 421{,}000 \text{ ft.-lbs.}$$

The stored energy in the flywheel is KA or 6,280,000 ft.-lbs.
If the flywheel is 18 ft. diam., the rim velocity is 88·6 ft. per sec., and the equivalent weight at this diameter is, therefore, 51,500 lbs. The actual flywheel weight should be about 70 per cent. in excess of this, say 87,500 lbs. This makes no allowance for the flywheel effect of the alternator rotor, which is usually considerable and need not be ignored.
Alternator builders commonly state the flywheel quantity of their alternators in terms of GD^2, which is short for weight multiplied by the square of the diameter of gyration. If the units employed are kilogrammes and metres, the corresponding GD^2 in lbs. and feet can be obtained by multiplying by 23·7.

$$\text{Stored energy} = GD^2 \times \left(\frac{\pi N}{60}\right)^2 \times \frac{1}{2g} = \frac{GD^2 \times N^2}{23{,}500}.$$

If G, D are in lbs. and feet, the stored energy is in ft.-lbs. The stored energy at the revolutions of the machine is readily calculated by assuming any convenient diameter of gyration, calculating the corresponding weight and velocity and thence the kinetic energy. The flywheel effect is sometimes stated as T tons (or lbs.) at 1 ft. radius. The GD^2 is then T × 4 in tons (or lbs.) × feet^2. The actual diameter need not be known, which is a convenience of this method of expression. Occasionally the moment of inertia is given, which is equal to GD^2 divided by $4g$, which is 128·8 in ft.-lb. units and 39·24 in kg. metre units. (This gives the moment of inertia in 'engineers' units,' i.e. mass × length^2 ÷ g.)

GOVERNORS.

It is the function of the governor to adjust the quantity of steam to the load on the engine. The sensitiveness of the governor should depend on the nature of the load, but in all cases the governor should be as free from friction (which also applies to all the valve mechanism operated by the governor) as possible. Friction tends to coarse governing and hunting. On the other hand, a very sensitive governor, especially if of great power on an engine with insufficient flywheel, tends to produce hunting, which should be corrected by an oil dashpot on the governor mechanism. In governor design attention must be paid to the levers and connections so as to give a reasonably equal ratio of governor movement to speed variation at all loads.
The plain Watt fly-ball governor is rarely used, being deficient in power. When loaded with a central weight (Porter governor) it is satisfactory on typical factory engines, especially

if carried on ball-bearings and knife edges throughout. The centre weight makes it somewhat sluggish in following changes of speed, and springs replace the weight in many modern governors. The springs need not be vertical.

If the governor is mounted on the crankshaft it may become bulky owing to its slow speed, but has some merits where eccentrics or valve rods have to be moved directly. Shaft governors, owing to their bulk, tend to be sluggish and to lag behind the engine when the speed changes. This inertia effect has been utilised in the inertia shaft governor, in which it is the falling behind of the governor weights due to inertia and not their outward movement under centrifugal force which operates the valve gear.

Relay Governors.

In relay governors the movement of the valve gear is effected by a motor, usually taking the form of a cylinder and piston operated by oil pressure. The movement of the piston is controlled by a small sensitive governor, usually of the centrifugal type. This governor has only to move the oil valve and can be relatively small, whilst the force exerted by the relay piston may be anything desired. The oil is supplied by a reciprocating or, more usually, a rotary pump. A simple drum or toothed-gear pump is entirely satisfactory. Any pressure can be obtained, but 50 or 60 lbs. sq. in. is a convenient value. In calculating the pump capacity allow for the maximum reasonable movement of the relay piston, and for 25 to 50 per cent. slip at the pump according to the speed, size, and pressure of the pump. These governors are common on large turbines and growing in favour for large oil, gas, and steam engines. Unlike the ordinary centrifugal governor insufficient power shows itself chiefly by slow action and not very much by a large difference in the rising and falling speeds. In short, the relay governor is, under these conditions, slow but accurate.

Governors are best driven by gears, but chains may be used and even belts or ropes if the last two are in duplicate or triplicate to minimise trouble in case of one belt or rope breaking.

Governors are best arranged to knock off at over speed, but this function may be arranged for by a simple separate governor.

Governors are often termed 'expansion' or 'throttle' governors, but these expressions refer to the valve gear rather than the governor. Expansion control is the more economical in most cases, but more difficult to arrange for except in the case of engines having Corliss or drop valves and running at moderate speeds only.

Area of Steam Passages and Valves.

The area is usually calculated from the mean piston speed. Thus if the pipe or valve area is one-tenth the piston area and the piston speed is 600 ft. min. or 10 ft. sec. the steam speed through the pipe or valve is 100 ft. sec.

Usual values for steam and exhaust valves, ports, and pipes:—

Saturated steam	100 ft. per sec.
Superheated steam	125 ,,

For drop-seated valves add about 50 per cent. at high speeds, and up to 100 and 150 per cent. for uniflow engines.

For steam turbines base on actual weight of steam, but assumed saturated, and allow 90 ft. per sec. This is equal to about 120 ft. sec. for steam superheated about 150° Fah. at the turbine. A rough rule is 1000 lbs. of steam per hour at rated load per sq. in. of pipe area.

For the main steam range, unless this is very short, base on actual volume, assumed saturated, flowing at about 90 ft. per sec.; rather less, say 75 to 80 ft. per sec., for reciprocating engines or pipes below 4 ins. in diameter.

PACKINGS.

General Notes.

A packing may operate on two principles. It may, as its name implies, pack the stuffing box as tight as possible, stopping every channel of escape and relying on the quality and lubrication of its materials to prevent undue friction; or it may employ accurately fitting stop-plates and rings adjusted to give minimum friction and thus permitting a very trifling leakage, which if sufficient to be noticeable is sucked away to the intermediate steam pipe or exhaust, as the case may be. All the old and many of the new packings were on the first principle. Some of the new are on the second; and for valve spindles, where friction is most undesirable, the second should always be adopted. In turbines the second is almost universal, the fitting being very slack but not casual, and the leakage considerable.

Asbestos Plaited Packing is made in coils in any diameter from ¼ in. upwards, round or square section. It is supplied either plaited throughout, with stranded centre and plaited cover, or graphited and lubricated throughout.

For high-pressure steam and superheat a white-metal cloth type is made, but it is also supplied in non-metallic and other styles, in many qualities to suit varying conditions of working. It is made in coils of about 60 ft. length, and in diameters ¼ in. and upwards.

THE UNITED STATES METALLIC PACKING.

This packing is made in four distinct forms: 1, block type of packing; 2, cone or locomotive type of packing; 3, duplex type, consisting of combination of the block and cone types; 4, atmospheric-duplex type, specially designed for use on low-pressure condensing cylinders.

Figs. 3, 4, show the duplex type of packing. The block portion consists of eight blocks which are held in strong rings, having pockets or horns holding springs. The packing blocks are put together in sections, four blocks to a section. Each section is, therefore, composed of two working blocks, babbit lined, and two guide blocks. The joints between the blocks in one section are at right angles to those in the other section, thus breaking joint. The blocks are regulated by springs, which merely keep the parts in place when steam is shut off, as when the steam is applied the steam pressure regulates and sets the packing. A ball-joint on one side and follower with springs on the other give the packing free play and keep it steam-tight, without regard to the vibration of the rod. It works equally well whether the rod vibrates or not, and, causing no friction, it does not wear the rod, but gives it a high polish. With efficient lubrication the blocks wear very slowly, many of the packings having given over twenty-four years' service without renewal of the blocks.

The United States Duplex Packing.

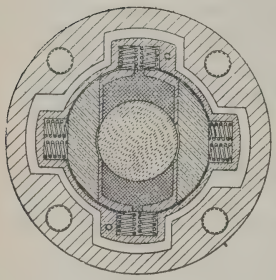

FIG. 3.

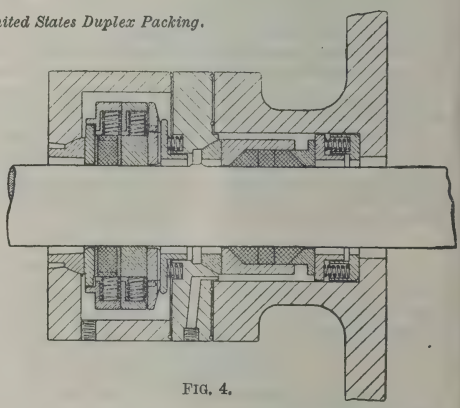

FIG. 4.

The cone portion of the duplex packing consists of three white metal rings placed in a floating cup, the interior of which is partly conical. This cup rests against ball and socket-ring, and the whole is kept in place by a follower with suitable springs, which allow the packing free play in all its movements. The whole is enclosed in a strong case, and bolted to the cylinder head with the usual stud bolts. The packing is steam setting, hence the friction is reduced at least 50 per cent. as compared with non-steam-setting packings. Drain valves are provided for removal of water, core sand, or other accumulations.

The block type of packing is used for pressures under 100 lbs. per square inch. The duplex type is employed for pressures over 100 lbs. Either packing can be arranged for working with steam superheated to 700° F.

Fig. 5 shows the cone or locomotive type of packing, which is practically similar to the cone packing described above. The white metal rings are the only parts which require renewal, and it is no uncommon thing for locomotives to run 80,000 to 100,000 miles without requiring adjustment of packing. All packings can be arranged to pass over enlarged ends.

THE UNITED KINGDOM SELF-ADJUSTING ANTI-FRICTION METALLIC PACKING (PATENT).

The Simplest and Most Durable Metallic Packing for all classes of Engines.

Perfectly Elastic. **Keeps Rods True.**
Prevents undue wear to Rods.
Admits of Drain Cock in spring space.

Small number of parts. **No multiplication of springs.**
Lasts for years without renewal.
Minimum of wear on Rod and least possible amount of friction.
Can be fixed and removed with less trouble than any other.

PACKING SUPPLIED TO HOME, COLONIAL, AND FOREIGN RAILWAYS AND LARGEST ENGINE BUILDERS.

Many Thousands in Use. *All Packings Guaranteed.*
Specially Adapted for Superheated Steam and Refrigerating Machines

F. 1599

The United Kingdom Self-adjusting Anti-friction Metallic Packing.

The arrangement of this packing is shown by fig. 6. The only wearing parts are the rings C, D, L, M, which are of special anti-friction metal. These rings are fitted on the rod in segments taking the shape of a truncated cone held together by gunmetal sleeves (B and K) and kept in their place by gunmetal spring rings (E and N), which in their turn are compressed by the steel coil spring (F) placed between them. At the end of the sleeves (B and K) are concentric spherical bearings which allow of free lateral motion where there is any inaccuracy in the running of the rod.

The angle on the rings for the purpose of wedging them on the rods to make a steam-tight joint being more than double that in general use in metallic packings, the friction on the rod is extremely small, thus reducing the wear on the special metal rings and the rod itself to a minimum.

For swell-ended and large rods a slightly different arrangement of the gunmetal rings is adopted, but under no circumstances are screwed packings necessary.

A special feature in the arrangement of the 'United Kingdom' packing is that it cannot be tampered with. It yields freely to all vibrations of the rod which it packs, and also tends

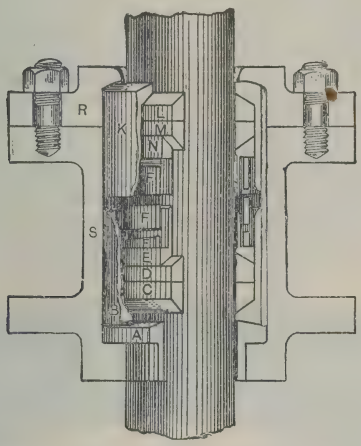

FIG. 6.—A, Neck Bush; B and K, Gunmetal Sleeves; C, D, L and M, Special Anti-Friction Metal Rings; E and N, Gunmetal Spring Rings; F, Steel Coil Spring; R, Gland; S, Stuffing Box.

to support it, because the concentric spherical bearings at the end of the brass sleeves, which contain the wearing parts, will not allow the packing to drop vertically, although it can angle in any direction, pivoting about the piston head.

It is claimed that the friction is less than one-fourth that with any other existing form of packing, this result being effected by the packing being double, an inner packing throttling the steam in the stuffing-box, so that instead of the outer packing having to withstand the full cylinder pressure, it has only the wire-drawn steam in the stuffing-box between the two packings to contend with.

In addition to the reduced friction, the wearing parts are much larger than is usually the case. It is stated that this packing has for a test been run for six months on an engine doing hard work, without any other lubrication than there is in the steam, and that it was in perfect order at the end of that time, the rods showing no sign of wear.

'Lion' Metallic Packing.

(James Walker & Co. Ltd.)

Fig. 7 (page 1601) shows the Block type of this packing. The packing is made in folds and not in layers, the fabric being taken and folded up on itself, so that the steam getting between these folds causes it to expand both to the rod and the box. This was the original type made by Messrs. James Walker & Co. Ltd., and it is still largely used.

Fig. 8 shows a more recent type of packing. This 'Lion' Expanding packing is made on an expanding principle, and in this instance, instead of the pressure acting upon the folds of cloth, there is a V recess in the top of the packing, into which the pressure finds its way and causes an expansion to the rod and the box.

It will be seen that with either of these types of packing, when there is no pressure there is no friction, and when the pressure is on, the friction is reduced to the smallest minimum on account of the internal pressure alone being required to ensure tightness, no pressure from an external gland being necessary. Both the above types of packing are used for steam purposes, and the expanding type for hydraulic work.

Fig. 9 shows a set of Block packing in section, and fig. 10 a set of the Expanding type in section.

The Automatic type of 'Lion' packing shown n fig. 11 is used principally for hydraulic work. The recess is made on the face of the packing, an arrangement which, it is claimed, is unlike any other type. The action of the Automatic packing is practically the same as that in a ram leather, and the pressure getting at the back of the lip causes it to swell out to the ram of the accumulator or pump.

Fig. 12 shows a set of packing in section; between each turn of packing there is a recess, and the pressure getting into these recesses is baffled. The Automatic packing will stand a test pressure of over 4,000 lbs. per sq. in.

One very important feature with regard to these packings is that a metallic wearing face is formed by the introduction of white metal studs or pins, in order to form in a stuffing-box the same principle of a white metal bearing that is obtained in an ordinary bearing; that is to say, there is a white metal lateral bearing. The studs are so placed that they touch the rod at all points, thus securing a complete metallic wearing surface which reduces friction, does away with the scoring of the rod, and lengthens the life of the packing.

Fig. 13 shows a new type of packing recently introduced and sold under the name of 'Lion' Two-Lip Packing. It will be observed that this packing has a lip on both back and front

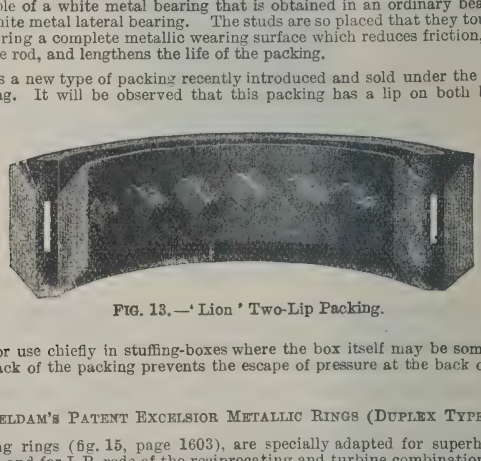

Fig. 13.—'Lion' Two-Lip Packing.

It is intended for use chiefly in stuffing-boxes where the box itself may be somewhat worn, and the lip at the back of the packing prevents the escape of pressure at the back of gland.

Beldam's Patent Excelsior Metallic Rings (Duplex Type).

These packing rings (fig. 15, page 1603), are specially adapted for superheat, the highest steam pressures, and for L P. rods of the reciprocating and turbine combination engines.

This packing has been designed in order that the pressure of steam through the neck bushes of the cylinders shall be gradually counterbalanced and cushioned by the pressure of the receivers.

With this system the rings are maintained in equilibrium, thereby preventing any undue wear, the rod being subjected to a minimum of friction.

All the rings are self-adjusting and interchangeable.

Fig. 15 shows the rings as fitted to high-pressure rods working at a pressure of 220 lbs.

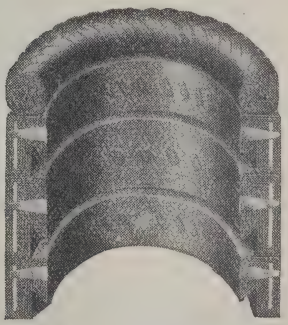

FIG. 12.—Set of 'Lion' Automatic Packing (in Section).

BELDAM'S PATENT 'V' PILOT PACKING (FOR HIGHEST STEAM PRESSURES).

This packing is constructed from a flexible white metal bar, pure asbestos, and high quality steam resisting rubber.

This packing ensures an entirely metallic bearing surface on the rod on the slightest pressure of the gland.

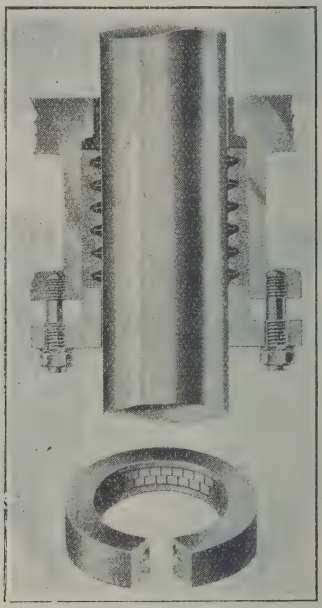

FIG. 14.—Beldam's 'V' Pilot Packing.

Although fig. 14 apparently shows two bars of metal, in reality there is only one bar, which is so constructed that when formed into the 'V' shape the slots on the face are staggered, thus preventing any possibility of the steam escaping down the rod.

These slots also serve a useful purpose in holding oil, thus ensuring the rod being well lubricated.

Rods will not be scored, but, on the contrary, will be kept in perfect condition by using this type of packing, which will be found very strong and pliable, and easily bent round the smallest rod.

Under steam this packing expands so much that the gland nuts require to be only finger tight, and the gland should enter the stuffing box the depth of one turn of packing to allow for slackening back of gland nuts.

'V' Pilot Packing is specially designed to stand the highest pressures, and is in use in a number of steamers, etc., working at 220 lbs. pressure.

For ammonia, low pressure steam, pumps, winches and hydraulics, it is manufactured from stout canvas in place of asbestos, and has been proved to be an excellent packing.

Packing Lubricants.

'GLANDOLINE.'

This composition (*Sterns Ltd.*) is an acidless packing paste for packings and piston rods of engines, steam hammers, hot and cold water pumps, hydraulic machinery, etc.; by its employment the frequent oiling of rods and the use of tallow is rendered unnecessary. It is claimed that the consumption of the composition in practice is extremely small, being but one-twentieth of that in the case where tallow is used. Packings are made by impregnating cotton, hemp, asbestos, linen, canvas, or other material with 'Glandoline.'

BELDAM'S PATENT EXCELSIOR METALLIC RINGS.
(DUPLEX TYPE.)

PISTONS.

The Rowan Patent Piston.

In the Rowan patent piston (*John Hind & Sons, Ltd.*) absolute steam tightness and absence of friction are obtained by the use of three separate springs, one contained within each packing-ring for outward expansion, and the third lying between the two rings and keeping them in close contact with the piston flanges. These springs are so arranged as to give a *predetermined pressure*

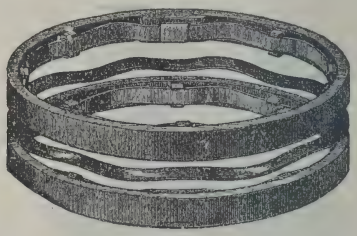

Fig. 16.

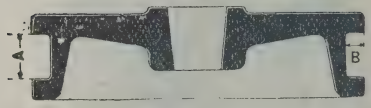

Fig. 17.

against the sides of the cylinder, which pressure is not increased (as in other types) by screwing down the junk-ring. It is stated that the cylinders in which these pistons are employed do not wear wide at the ends, but remain parallel and in perfect condition. By recent patented modifications, the Rowan piston has been rendered suitable for use in high-speed engines now employed for the generation of electricity. Fig. 16 shows the form of these rings for use with solid piston heads (fig. 17).

Nut-Lock Plate.

Fig. 18 shows a lock plate used to hold on the follower plate nuts of a steam engine piston. The circular ring, or plate A, is $\frac{3}{8}$ in. plate steel; the holes are drilled for the studs or bolts and a slot cut on the outside edge to within $\frac{1}{4}$ in. of each hole, as shown at B. The lock plate

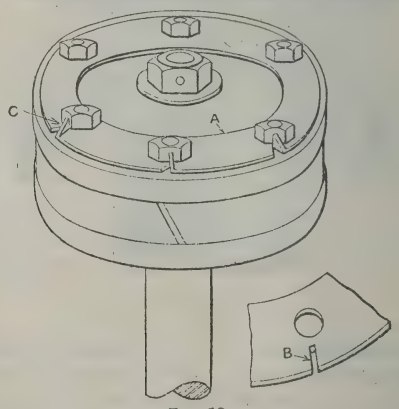

Fig. 18.

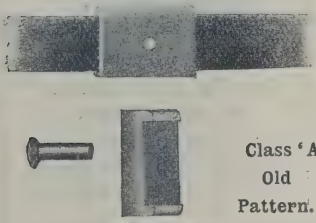
is put on and the nuts all set up tight; then with a cold chisel the tab is bent up against the flat of the nut side, as shown at C. (*Machinery.*).

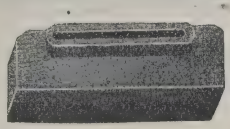
THE 'ROWAN' PISTON-RINGS



ARE MADE ONLY BY

JOHN HIND & SONS, Ltd.

75 Gt. George's St., Belfast, IRELAND.



All packings now supplied by us are fitted with our New Patent Combined Sleeves and Knuckles, which render it impossible for the knuckles to become detached from the springs. The advantages of this improvement are manifest from the illustrations given below.

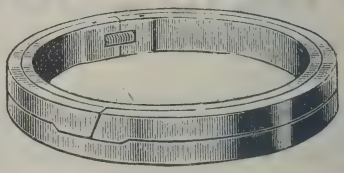
Class 'A.' Old Pattern.

In three parts: Sleeve, Knuckle and Rivet

Class 'A.' New Pattern

Knuckle and Sleeve in one piece.

The Packings are made in three Types, specially designed to suit the varying conditions of pressure, speed and superheat under which they have to work, particulars of which will be supplied by the makers on application.

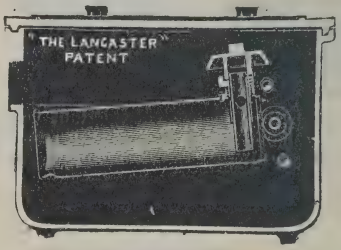


The 'ROWAN' Packing is the only one that can be fitted to solid pistons of all sizes, and in Fuel, Repairs and Renewals, the most economical in the market

Telegrams: 'PISTONS,' Manchester. Telephone: 794-795 Pendleton.

'THE LANCASTER' (R.T.M.) SUPER-LIMIT PISTON RINGS.

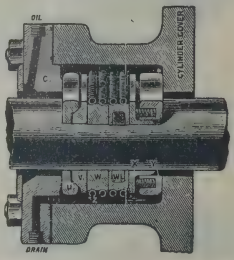
No loose parts.



Adjustment readily accomplished.

No tongue pieces required.

Specially designed to meet the increased pressures and speeds now obtained.



STEAM TRAPS

Have a world wide reputation for Reliability, Durability and Economy.

Supplied to all the leading Engineers and Manufacturers.

METALLIC PACKINGS

For Piston Rods and Valve Spindles.

Suitable for all Pressures, Speeds and Superheats.

SLIDE VALVE GEAR.

(Revised by W. C. Popplewell, M.Sc., A.M.Inst.C.E.)

The movements of an ordinary eccentric driven slide valve are shown by A, fig. 19. S and S_1 are ports leading from the steam chest to the back and front of the piston respectively; E is the port leading to exhaust. The valve itself is shown sliding on the port face. As shown by A, the valve is in mid-position; *ef* is the outside lap, and *gh* the inside lap. As the valve is moved upwards by the eccentric, it reaches a position B where *e* has come opposite *b*, and the steam port S_1 is opening to the steam chest; the amount by which the valve is open at the beginning of the piston stroke is the 'lead.' In position C the steam port is fully open; the valve then returns to D, thus shutting off the supply of steam to the cylinder. This point is 'cut off.' The movement continues until *h* reaches *c*, as at E, when communication is effected between S_1 and E. This point is called 'exhaust.' After opening S_1 fully to exhaust, the valve returns to F, where the exhaust is closed and the point 'compression' reached. This completes the cycle for one end of the valve.

The movements of slide and other eccentric driven valves are analysed by such diagrams as the 'Valve Ellipse' (II, fig. 20), 'Zeuner's Valve Diagram' (fig. 21), and several others designed for the same use. Of these the Valve Ellipse can be made to take account of obliquity of both connecting rod and valve rod, and so yield accurate results. Zeuner's Diagram makes no allowance for obliquity, and in consequence is only approximately accurate, but for purposes of design, where existing data are not available, the Zeuner is the more useful, as it enables the principal dimensions to be approximately fixed. In such a case final adjustments may be completed by using the Valve Ellipse.

Valve Ellipse.

To set this out, begin by drawing the crank circle as at I, fig. 20, and dividing it into a number of equal angles (in this case 8), the crank-pin points being 0, 1, 2, 3, 4, 5, 6, 7. Take the connecting-rod length $1, 1_1$, and set it off successively from the crank-pin positions, marking off points on the stroke line $0_1, 1_1, 2_1, 3_1, 4_1$. These are positions of the piston corresponding to 0, 1, 2, 3, 4, of the crank-pin, and are seen at II. A similar construction is followed out for the eccentric circle at III (fig. 21). This is turned through a right angle as compared with I, and the 'angle of advance' is marked 0°. The distances of the valve from its mid-position, corresponding to the successive positions of the piston, are shown below the eccentric circle. These are set up as ordinates from the horizontal points on II, and a smooth curve drawn through the points so found. Thus from 1_1 on the line of piston travel at II is plotted an ordinate which represents the distance of the valve from its central position when the piston is at 1_1; this is the distance from ZZ to the line marked 1 at III. Next draw a horizontal line at distance *l* above $0_1, 4_1$, in II, this is the 'lap' line; also a second line at a distance *p* beyond the lap line, which is the 'port opening.' Similarly below $0_1, 4_1$ are two further lines at l_1, 'inside lap,' and p_1, 'exhaust opening.' The points where the ellipse cuts these lines represent the chief incidents in the cycle. They are B (admission), where the valve is just opening to steam; C (full port); D (cut-off); E (release); F (compression).

In the case of the back plate of a gear of the Meyer type, separate ellipses must be drawn for the edge of the plate, and the points where these cut the main ellipse noted.

(W. C. Popplewell.)

Zeuner Diagram.

A few of the principal cases are given in what follows. The results are not strictly accurate, because they are vitiated by the angularity of the eccentric rod. But with reasonable proportions a design will be sufficiently near what the diagram shows. Fuller information may be found in Zeuner's treatise, or in the small book of Cowling Welch, who reduced Zeuner's methods to practice.

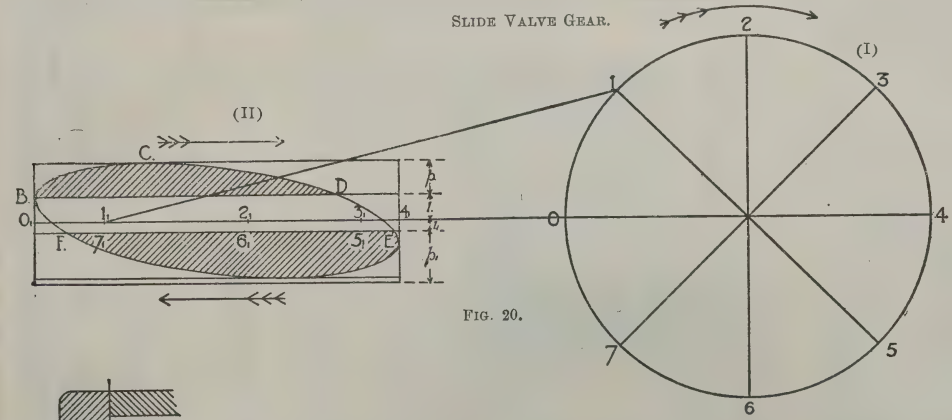

FIG. 20.

FIG. 21.

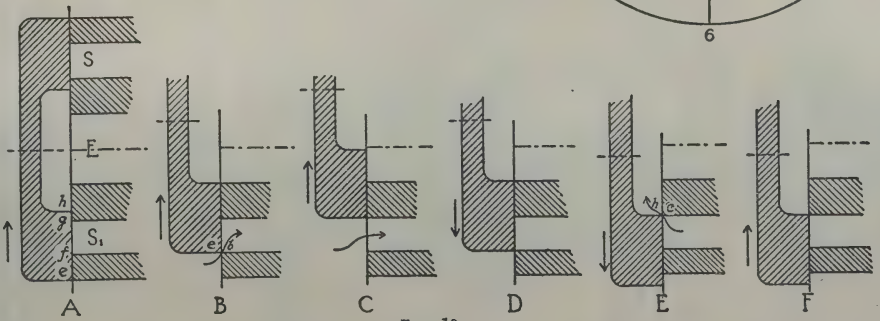

FIG. 19.

Reversing gears which do not employ two eccentrics usually derive motion from some point on the connecting rod. Such are the Joy gear and others, for all of which special advantages are claimed under certain conditions, though as valve movements it is doubtful if any give better results than plain link gears. The newer motions often involve considerable sliding movement of a block in an inclined link, this link being pivoted so as to reverse its inclination, whereby the valve, driven by the block which slides up and down in the inclined link, has its movement reversed or varied according to the degree of inclination either way of the link. Such valve movements are best studied by the aid of models, with variable dimensions; made from flat bars of cedar or baywood.

SIMPLE SLIDE VALVE.

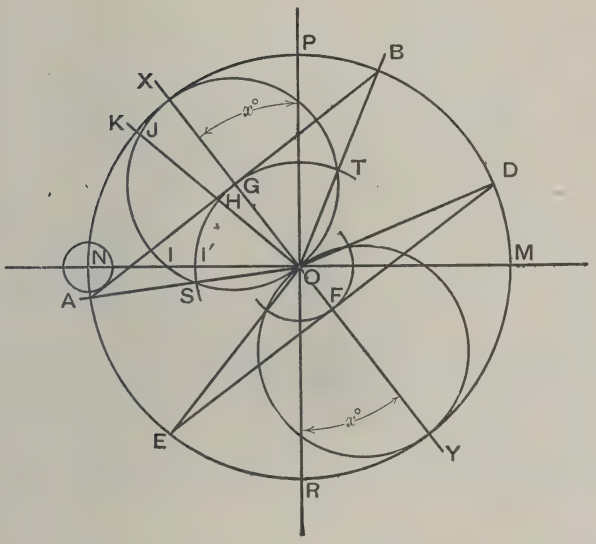

FIG. 22.

Fig. 22 shows Zeuner's diagram of slide valve motions, simple case.

Draw NM and PR at right angles; NM=piston stroke.

OP = OR = valve travel each side of centre point; OA = crank when steam is admitted; OB = crank at cut-off.

Bisect AB. Join OX, OY perpendicular to AB.

X° + 90°=angular advance of eccentric; SGT=outside lap circle: cuts 'valve' circle at ST; OS=position of valve from centre when admitting steam; OT=position of valve from centre when cutting off steam; OF=inside lap; OD=crank when exhaust commences; OE=crank when exhaust closes.

The intercena of any radius from O, cut off by valve circles, shows distance of valve from its midstroke for that crank angle. Thus when crank is at OK valve has moved a distance OJ from its centre and steam port is open a width HJ.

DY = YE. AX = BX. Lead = small circle N = 2 I.I'.

Double Back-Plate Cut-off.

Figs. 23 and 24 show Zeuner's expansion valve diagram, Meyer valve.

Draw AB, XY at right angles, OD at angular advance $\phi°$ = half travel of main valve OR = crank at admission : ON = lap circle. Draw OP slightly in advance of latest opening of main valve as shown by point *t*. This gives a minimum cover *ts*. Join PD, and draw OE parallel to it and DE parallel to OP. Then OE = half travel and position of the cut-off eccentric which will

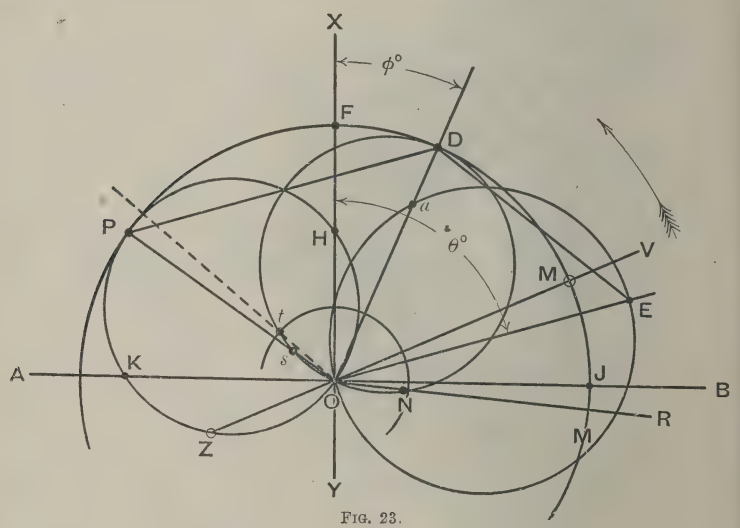

Fig. 23.

cut off steam when the crank, OR, reaches the position OP. It need not cut off later than this, for then the main valve has already acted.

The radius Oα or any other vector of the cut-off valve circle shows the movement of the cut-off valve from its middle position, OE being the half throw of the cut-off eccentric, and $\theta°$ its angular advance. Any radius vector of the auxiliary circle OP will show the relative displacements of the main and cut-off valves from each other. At the crank position OP the cut-off plates are drawn close together. Draw the large circle APDM through P. Then for any position OV of desired cut-off the length of the cut-off valve must be increased by separating the two cut-off plates of the right and left screw to the amount MZ. To cut off at OX of the crank would demand the movement FH, while to cut off at the dead point OB the movement of the plates would be JK. The length over the steam ports in the back of the main valve will be equal to the sum of the length of the cut-off plates plus twice OP. The edges of the cut-off plates when fully extended have a maximum distance from the main valve centre of JK (or MZ if OM is the earliest desired cut-off). But at no moment must the inside edges of the cut-off plates uncover the inside edges of the ports in the main valve. These ports have a width *a*. At the latest cut-off, viz. at OP, the cut-off plates will be drawn together so that x=nil.

To find movement of cut-off plates from centre for any point of cut-off, as with crank at OV, the plates must be screwed out a distance x = MZ. If cut-off is at OF position of crank, then x = FH.

Taking the position of earliest cut off at OV, to find the proportions L and l of valves which will be a maximum :—

Calling FE $= y = \mathrm{L} - l - x$ for earliest cut-off, the maximum relative movement of the valve centres by the eccentrics is OP. Since at the position OV the valve centres are the opposite way removed from cut-off by the amount OZ and that OP is the maximum relative movement, we have $\mathrm{L} - l = \mathrm{OP}$ when x=nil and x must be OP+OZ = MZ for earliest cut-off. When the crank reaches OP the cut-off valve is moved out already a distance $x = \mathrm{MZ}$ and it is moved a further distance OP by the eccentric, so that the outer edge of the cut-off plate is a distance OP+OP+OZ from the middle of the main valve. And when so far the inner edge of the cut-off plate must not overrun the inner edge of the back port a. Therefore $\mathrm{L}-a=2\mathrm{OP}+\mathrm{OZ}$ $\therefore$ $\mathrm{L}=\mathrm{OP}+\mathrm{OP}+\mathrm{OZ}+a$ and $\mathrm{L}-l=\mathrm{OP}$ $\therefore$ $l=\mathrm{OP}+\mathrm{OZ}+a$. Since the main valve has cut-off at the position Ot there is safety lap of ts on the main port below even if the inner edge of the cut-off plate then reaches the port a.

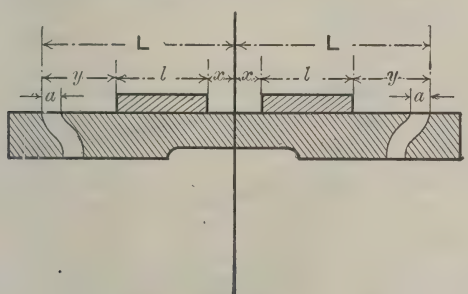

FIG. 24.

In the figure the main valve travels 4¼ ins. and the cut-off valve 5¼ ins. The cut-off plates are each moved out by screws at earliest cut-off $x=3\frac{1}{4}$ ins., and by eccentric movement 2¼ ins. relative to main valve, or a total of 5½ ins. The main valve has a length $\mathrm{L}=5\frac{1}{2}+a$ and the cut-off plate (or $\mathrm{L}-\mathrm{OP}=l$) a length of 3¼ ins. $+ a$.

If $a=1$ in. then L=6¾ ins. ; $l=4\frac{1}{4}$; $x=2\frac{1}{4}$ ins. maximum plus 3¼ screw-out.

If early cut-off is desired in the general working of the engine with quick action the auxiliary circle OP should be near to 90° from the cut-off position of the crank. Thus at the position OD the two valves are moving at high relative speed. It is usual to give the greater travel to the cut-off valve.

LOCOMOTIVE LINK MOTIONS.

These may be investigated also by the Zeuner method. A link motion is simply built up with two eccentrics, either of which may be made to bear fully and directly on the valve spindle and cause an engine to run forwards or backwards. This is accomplished by connecting the two eccentric rods by a link in which the end of the valve spindle is carried. At the extreme end position the spindle is wholly driven by one eccentric, while at intermediate positions the two eccentrics combine to give a gradually shorter movement to the valve.

There are three general link gears. 'Stephenson's,' in which the link is raised or lowered to give the desired position of the spindle block or link block ; and the link is concave to the axle and has a radius equal to the length of the eccentric rods.

'Gooch's,' with link convex to the axle and not movable up and down ; movement of the block being effected by a radius rod and the link having this radius of curvature.

'Allen's,' in which the link is straight and both link and radius rod are raised and lowered in opposite directions.

All three forms are made with open or crossed rods, the former giving greater lead of the valve near the middle position of the link block, and the latter giving less lead towards the middle position. In Gooch's motion the lead is of course always constant.

STEPHENSON LINK MOTION.

Open Rod Design.

In fig. 25, AE=link, BD=link block in forward and backward gear. OJ=virtual single eccentrics to give requisite travel to B or D in full gear. Join OB, cutting valve circle on OJ at K. Join JM through K. Then the arc struck from *c* through JMJ will contain the ends of all the eccentric radii or valve circle diameters for all positions of the slider B or D. Dividing this arc in the same ratio as B divides the link AE will give the ends of the valve circles for each point of the link. And the real eccentrics will have the position and half travel OF, OF just as the ends of the link lie beyond B and D. If the link end-pin comes opposite the extreme

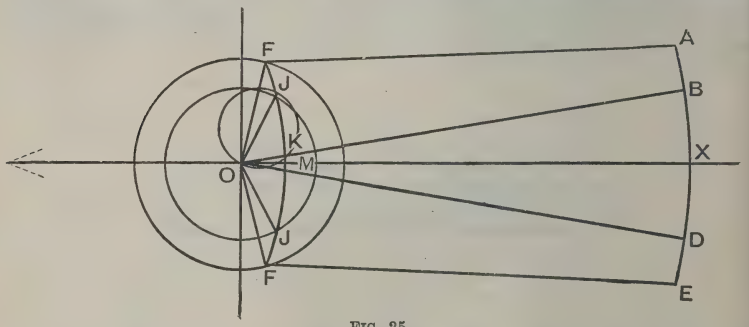

FIG. 25.

positions BD of the block then OJ become the real eccentrics in position and in half throw, i.e. XB : XA : : MJ : MF. Rods are said to be *open* when they are as FA, FE when the eccentric arms point towards the link. With open rods the valve lead increases with the expansion.

Crossed Rod Design.

In fig. 26, AE=link. BD=link block in full forward or backward gear. OJ=virtual single eccentric that would give requisite valve travel in full gear. Join OD, cutting upper valve circle on OJ at L. Join JN through L. N is on the line OX. Then the arc struck from C through JNJ contains the ends of all the valve circles for every position of the slide block, the arc JNJ being divided for each diameter in the same ratio as the slide block divides the link AE.

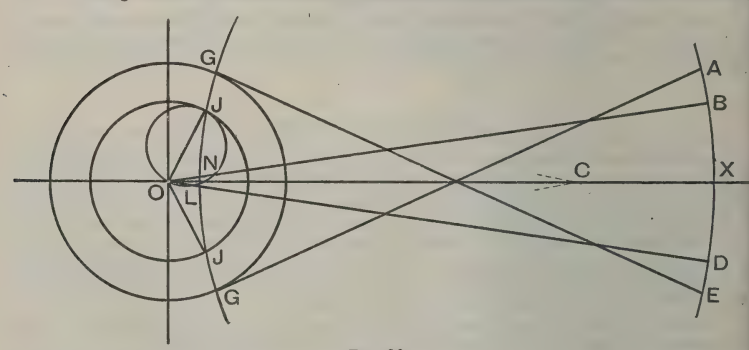

FIG. 26.

Thus OG, OG become the actual eccentric arms, and NJ : NG : : XB : XA. Rods are said to be *crossed* when they are as GA, GE, the eccentric arms pointing towards the link. With crossed rods the lead of the valve decreases with increased expansion. Specially note that OD cutting the valve circle at L is employed in this construction, whereas OB is the line used in the open-rod diagram.

GOOCH'S LINK MOTION.

In this motion, fig. 27, the 'curve' of valve circle centres is a straight line aa distant from O an amount $f = \frac{r}{2}\left(\sin\delta^\circ + \frac{c}{l}\cos\delta^\circ\right)$ for the open rod design, and $\frac{r}{2}\left(\sin\delta^\circ - \frac{c}{l}\cos\delta^\circ\right)$ for the crossed rod design, where

r = eccentricity of eccentric or OE;

m is the point from which the link is hung and is a fixed point;

the versed sine of the link arc is $\frac{c^2}{2l_1}$;

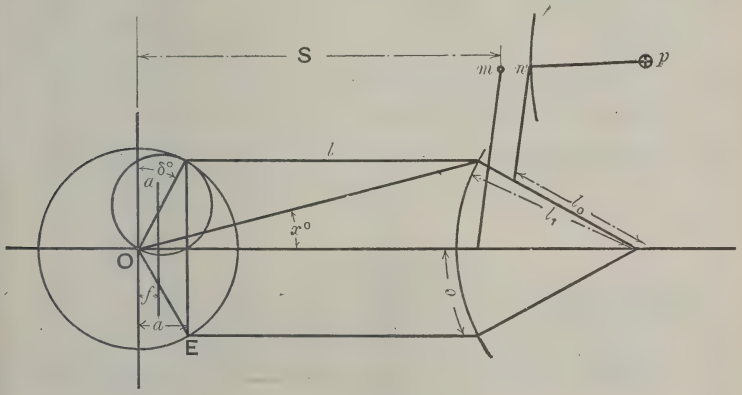

FIG. 27.

m is distant from O a length $S = -\frac{c^2}{2l_1}$;

n is the point from which the radius rod is hung;

$On = l + l_1 - l_0 - \frac{c^2(l+l_1)}{2ll_1}$.

The point n should move in a parabola whose parameter $= 2l_1$ or a circular arc of radius l_1.

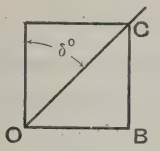

FIG. 28.

The co-ordinates of any point on the curve of centres are as per fig. 28, where

for open rods, $OB = \frac{r}{2}\left(\sin\delta^\circ + \frac{c}{l}\cos\delta^\circ\right)$;

for crossed rods, $OB = \frac{r}{2}\left(\sin\delta^\circ - \frac{c}{l}\cos\delta^\circ\right)$.

$BC = \frac{r}{2c}\frac{u}{}\left(\cos\delta^\circ \pm \frac{c}{l}\cos\delta^\circ\right)$, according as the rods are open for $-$ or crossed for $+$ signs, where c = half length of the link and u = the variable position distance of the slider block from the middle of the link.

The lead is constant at all grades of expansion. The link is so hung that its middle point moves to and fro horizontally by the combined effect of the arc of swing and the cant due to slope of the link, the suspension link being pinned at the centre of the chord of the link.

The radius rod l_o is so hung that its to-and-fro motion produces a minimum of sliding of the link block in the link. The extreme positions of n being known the actual arc in which it moves is arranged in practice with a shorter arm np than theory demands, the best compromise possible being accepted which can be arranged under the conditions. The Gooch gear, for any given distance between axle and cylinder, has very short rods compared with the Stephenson gear. Also the angle δ° in fig. 28 is equal to the angle δ° as found in fig. 22, p. 1607, for the simple slide valve, plus the angle x° in fig. 27, p. 1611.

ALLEN'S STRAIGHT LINK MOTION.

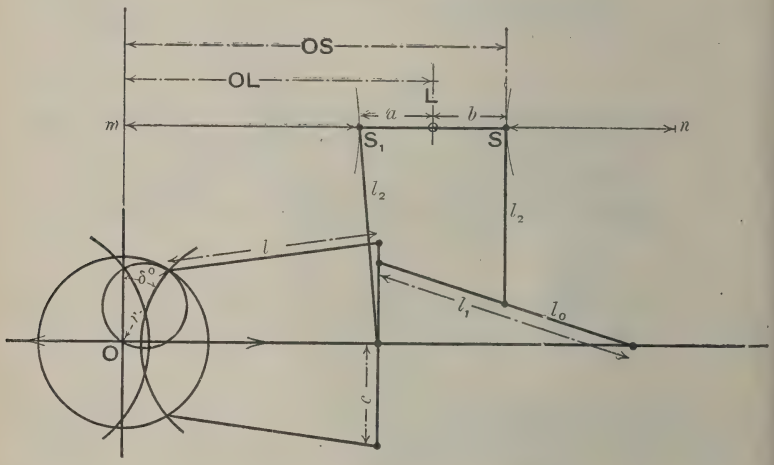

FIG. 29.

$$\frac{b}{a} = \frac{l_o}{l}\left(1 + \sqrt{1 + \frac{l}{l_1}}\right); \; n = 1 + \left(\frac{l_1}{l_o}\,\frac{b}{a}\right).$$

Curve of centres is a parabola whose vertex is distant from $O = \frac{r}{2}\left(\sin\delta + \frac{c}{l}\cos\delta\right)$ for open rods, and $\frac{r}{2}\left(\sin\delta - \frac{c}{l}\cos\delta\right)$ for crossed rods, and is concave towards O for open rods, and convex for crossed rods. Parameter for both open and cross rods $= \frac{nlr}{2c\cos\delta}\cos\delta \mp \left(\frac{c(n-1)}{nl}\sin\delta\right)^2$ for which a circular arc may be substituted of one half the parameter.

S and S_1 should move in parabolas of $2l_1$ and $2l$, or in arcs of l_1 and l radius.

As arranged in practice $a + b = (l_1 - l_o) +$ a little extra l_2 as long as possible.

$$Os_1 = \left(l - \frac{c^2}{2l}\right); \; OL = l + a - \frac{c^2}{2}; \; ms_1 = l; \; ns = l_1; \; Os = l + l_1 - l_o - \frac{c^2(l + l_1)}{2l\,l_1}.$$

Lead increases with expansion with open rods and decreases with crossed rods.

WALSCHAERT GEAR.

(See page 593.)

STEAM CONDENSERS.

(1.)

(Frank Foster, M.Sc.)

Jet condensers are preferred to surface if the cooling water is fit for boiler feed or if a suitable boiler feed, other than the condensed steam, is available.

Jet condenser capacity to be about half the volume of the low-pressure cylinder or cylinders.

Surface condenser cooling surface may be based on 6 lbs. of steam per square foot of surface. Ten pounds is sometimes adopted, but is too severe unless the temperature of the cooling water is low, say 60°F., or less. For tropical countries the lower rate of condensation should be taken and even less when very hot condensing water is anticipated.

Air pumps are usually single-acting, and low-pressure engine cylinders double-acting. On this basis for ordinary bucket pumps the piston displacement of the low-pressure cylinder is about 6·5 times that of the pump for jet condensing compound engines in this country and 5·5 times for India and hot tropical climates. For surface condensers this air pump ratio varies from 10 to 12, the lower figure for the smaller and less efficient engines.

Air pumps of the Edwards type usually have about 75 or 80 per cent. as much capacity as the ordinary pumps.

It is tacitly assumed that the vacuum aimed at is about 26 ins., and that considerably greater capacity is necessary for higher vacua.

Air pump bucket speeds rarely exceed 200 ft. per minute unless the buckets are of the solid plunger type. A usual value is 180 ft. per minute.

(2.)

Quantity of Cooling Water.

Let T_3 = temperature of steam at inlet, corresponding to the vacuum; H_3 = sensible heat at inlet; T_4 = temperature of the condensed water at outlet; H_4 = sensible heat of the condensed water at outlet; T_1 = temperature of cooling water at inlet to condenser; T_2 = temperature of cooling water at outlet of condenser; L = latent heat in B.Th.U. per lb. of steam; W = steam weight; Q = water weight; R = ratio of water and steam quantity; x = dryness fraction; then

Heat (in B.Th.U.) given up by exhaust steam = $W\{xL + (H_3 - H_4)\}$.

Heat (in B.Th.U.) gained by cooling water = $Q(T_2 - T_1)$.

In practice H_3—H_4 may be neglected, therefore

$$WxL = Q(T_2 - T_1), \quad \text{and,} \quad \frac{Q}{W} = R = \frac{x\,L}{T_2 - T_1}.$$

To allow a small margin, x—which generally varies between 0·8 and 1·0—can be neglected, and as L only varies slightly with the vacuum, it is generally assumed to be a constant for all vacua at 1,050 B.Th.U.'s per lb. of steam. Therefore the general equation for all vacua can be taken as

$$R = \frac{Q}{W} = \frac{1050}{T_2 - T_1}.$$

For surface plants, T_2—T_1 ranges from 8° to 20° F., and for jet plants, 4° to 8° F.

Condenser Efficiency may be expressed as the ratio of the vacuum at the condenser inlet to the vacuum corresponding to the outlet cooling water temperature, thus

$$\text{Condenser efficiency} = \frac{P_3}{P_2} \times 100;$$

where P_2 = vacuum corresponding to the outlet cooling water temperature (see page 1614).
P_3 = vacuum (referred to a 30-in. baro.) at the condenser inlet flange.

Vacuum Efficiency may be expressed as the ratio of the vacuum at the condenser inlet to vacuum corresponding to the temperature of the condensed steam, thus

$$\text{Vacuum efficiency} = \frac{P_3}{P_4} \times 100;$$

where P_4 = vacuum corresponding to the condensed steam temperature (see page 1614).

In jet condensers $T_2 = T_4$, therefore the vacuum and condenser efficiencies are the same.

The condenser efficiency is entirely dependent on the design of the condenser, while the vacuum efficiency is dependent both upon the design of the condenser and air pump.

It is important that the condensed steam should be at as high a temperature as possible, since this water is usually returned to the boilers, therefore it is essential that all the heat possible should be recovered.*

PROPERTIES OF SATURATED STEAM.

Degree of Vacuum.—The maximum vacuum obtainable is dependent upon the inlet circulating water temperature. For engine work 26 ins. to 27 ins. is the maximum vacuum desirable, owing to the limitations in size of the low-pressure cylinder and ports, etc. For turbine work high vacua are necessary. The most economical vacuum depends upon individual installations

* Every 8°–10° Fahr. difference in the hot-well temperature means approximately 1 per cent. difference in fuel consumption. The gain obtained with an increase in hot-well temperature can be calculated as follows :—

$$\text{Percentage gain in B.Th.Us.} = \left(\frac{100\,T}{H_T + T - T_4 + 32}\right) \times \frac{100}{B_P}$$

where T = difference in hot-well temperature (F.°); T_4 = final hot-well temperature (F.°); H_T = total heat of steam at boiler pressure (B.Th.Us. per lb.), reckoned from 32° F.; B_P = percentage boiler efficiency.

and is generally decided by the power required to be expended by pumping the cooling water, price of coal, available water supply, etc.

For general purposes the following may be taken under average conditions as being the maximum commercial vacua.

Temp. of inlet water, F.°	55	60	65	70	75	80	85
Vacuum in ins. (baro. 30 ins.)	28·8	28·6	28·5	28·3	28·0	27·8	27·5

Air enters the condenser in the following manner :—

1. With the steam entering from the boiler having been dissolved in the feed water ; this is usually a small amount in the nature of 1 to 3 per cent. of the total volume of feed water.

2. Air leakage from the atmosphere through the glands of the prime mover or other sources : this cannot easily be measured, and an allowance has to be made accordingly to cover contingencies.

3. In jet condensers air in solution with the cooling water which is released when in the vacuum space ; this varies from 1 to 5 per cent. of the total volume of water.

Due to air contained in the cooling water in the case of a jet condenser, a much larger air pump is required than for a surface plant of similar duty.

For turbine work to cover cases (1) and (2) it is usual to allow for 6 to 8, and, in the case of low-pressure turbines, up to 11 lbs. of air per 10,000 lbs. of steam.

For engines, about two or three times this amount is required according to the type of engine.

These figures are for one unit only ; if two or more turbines or engines exhaust to the one condenser an extra margin of 10 or 15 per cent. per extra turbine or engine, respectively, should be allowed.

(See also page 779.)

Surface Condensers.

Cooling water should be arranged to pass through the tubes and steam to flow over the tubes. It is usual to divide the tube element in two, three, or four passes according to the design of the plant, the passes being arranged so that the hottest water meets the hottest steam.

The rate at which the heat contained in the steam is transmitted through the tubes to the cooling medium is mainly dependent on :—

(1) The mean temp. diff. between steam and cooling water.
(2) „ water velocity through the tubes.
(3) The steam velocity over the tubes.
(4) „ size and condition of tubes.
(5) „ presence of air in the condenser.

The transmission rate and velocities should be arranged such that the steam condensed per square foot of cooling surface should not be more than 8 to 10 lbs. for average vacuum and cooling water conditions, or 5 to 6 lbs. for high vacuum with a high temperature of cooling water.

While the rate of heat transmission slightly increases as the tube diameter decreases, too small a diameter of tube should be avoided owing to the higher water frictional head caused in the condenser by their use. The generally adopted standard for condenser tubes for land work is $\frac{3}{4}$ in. external diameter by 18 S.W.G. thick.

Fig. 30 shows the head lost in friction per 10 foot of tube element for $\frac{5}{8}$ in., $\frac{3}{4}$ in., and 1 in. external diam. by 18 S.W.G. smooth brass tubes. For application it is necessary to take the total length of the tube element (the length of the tubes multiplied by the number of water passes) and add the 'loss at entry (including loss at exit also) per pass,' values for which are given on the bottom curve.

Large spaces should be allowed between the tubes at the condenser inlet to obtain a good flow of steam into the heart of the condenser. The steam flow should always be as direct as possible, changing the direction of flow should be avoided, and to ensure an evenly distributed flow over the top of the tubes a dome should be formed on the top of the condenser body.

Tube Plates.

These are usually of rolled brass alloy of copper 62 per cent., zinc 37 per cent. and tin 1 per cent., and are generally made of a thickness equal to tube diameter + 0·25 in.

Tubes.

These are of solid drawn brass alloy, of copper 67 per cent., zinc 32 per cent., tin 1 per cent., or where salt or corrosive water is used, of Admiralty mixture alloy, of copper 70 per cent., zinc 29 per cent. tin 1 per cent. For tube-plates the proportions of copper and zinc,

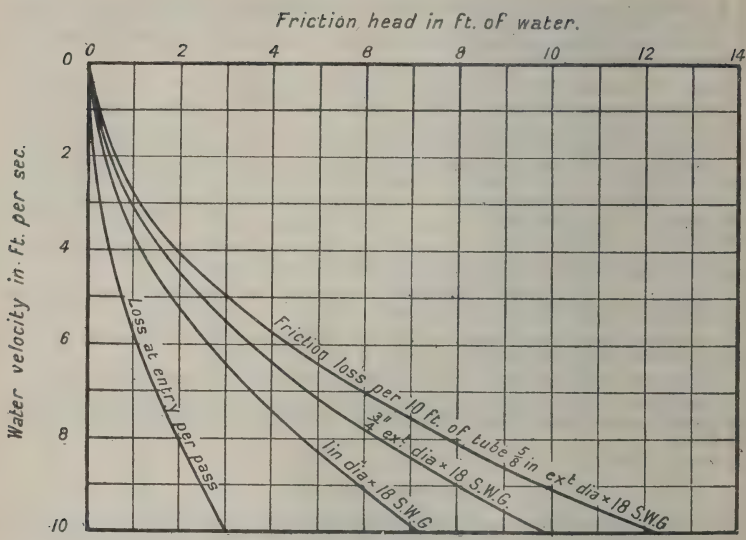

FIG. 30.

are altered, the former being reduced to 62 per cent. and the latter increased to 37 per cent., while tin remains the same. A still better tube to use where corrosion is liable to occur is copper of 99·5 per cent. purity, but the initial cost of these is often found prohibitive. Tinned tubes should be avoided, since unless the tinning is absolutely perfect, serious pitting is liable to occur. The Admiralty practice is to adopt untinned tubes of the alloy referred to.

The unsupported length of tubes should not exceed 100 times the diameter, and where the length of the condenser exceeds this dimension, tube-supporting plates should be fixed. The tubes should be secured in the tube plates by tape packing and ferrules, the latter having an internal lip to prevent 'creeping' of the tubes.

The pitch of the tubes should be such that they will allow sufficient area for the flow of steam without an excessive pressure drop through the condenser. The number of tubes which can be fixed in a square foot of plate can be obtained as follows :—

$$N = \frac{166}{p^2};$$ where N = number of tubes per sq. ft. of plate ; p = pitch of tubes in ins.

TUBE PACKING.

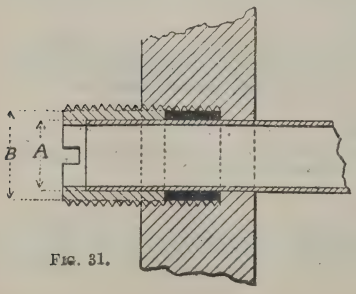

FIG. 31.

'Compressed Asbestos Fibre Tube Gromets,' fig. 31 (*Turner Brothers Asbestos Co. Ltd., Rochdale*), are an entirely new device. The Gromets are essentially for packing the tube ends of surface condensers, feed-water heaters, etc.; they are a sliding fit between the tube and the tube plate, making a perfectly tight joint with a few turns of the screw, after which no 'following up' is necessary.

When ordering, the dimensions at 'A' (the outside diameter of tube) and at 'B' (the apex of thread in socket), together with the length of Gromet required, should be given ; the necessary clearance is allowed for in manufacture.

Air-Pump.

The essential feature of a plant having a high vacuum efficiency is an air pump capable of operating without cooling the condensed steam. Excepting in small plants where the heat loss is not so appreciable, all surface condensers should be arranged with two pumps working on the vacuum side, i.e. an air-pump capable of dealing with all the air entering the condenser and a water-pump capable of dealing with all the condensed steam. This is what is known as a 'dry system.' Cases where only one pump is employed for the combined duty are known as a 'wet' system. In order to cut down the size of the air-pump in the latter system to reasonable proportions, the condensed steam is usually cooled by means of the last few rows of tubes in the condenser being arranged so that they are always flooded, or by an intercooler. This of course impairs the vacuum efficiency of the plant.

(See also page 1623.)

Capacity of Air-Pump in order to Remove given Amount of Air.

The diagram (fig. 32, p. 1618) shows the properties of mixtures of air and steam such as exist at the air-pump suction. Thus, if the temperature is 100° F., and the vacuum 26 ins., the volume of 1 lb. of air (together with the associated vapour) is 204 cub. ft. and the weight of air per lb. of steam is 1·75, i.e. 204 cub. ft. of the mixture contains 1 lb. of air and 0·57 lb. vapour.

The scale on the right provides a basis for calculating the air-pump capacity if the air leakage and the temperature and vacuum are known. For example, assume a surface condenser installation for a reciprocating engine in which allowance is to be made for 16 lbs. air per 10,000 lbs. steam, vacuum 27 ins., temperature at air-pump suction 100° F. From the right-hand scale the volume of air per lb. of condensate, measured at the conditions of the air-pump suction, is 0·395 cub. ft. for an air proportion of 10 lbs. per 10,000 lbs. steam. Thus in the present case the volume is $0{\cdot}395 \times \frac{16}{10} = 0{\cdot}63$ cub. ft. per lb. steam.

If the steam condensed is 15,000 lbs. per hour, the *effective* capacity of the 'dry' air-pump will then be $\frac{15{,}000}{60} \times 0{\cdot}63 = 157$ cub. ft. per minute.

For a 'wet' air-pump the volume of the condensate must be added. The actual capacity of the pump must be greater than the capacity thus found, on account of losses of volumetric efficiency due to clearance, slip, leakage, and valve or port resistance.

The diagram shows the reduction in volume due to cooling of the air-steam mixture before it passes to the air-pump.

In a jet condensing plant the air introduced by the injection water must also be allowed for.

Circulating Pump.

The pump for delivering the required water quantity to the condenser is nearly always of the centrifugal type. The head against which this pump has to deliver is made up of the static difference in water levels between the inlet and discharge points, plus the pipe and condenser friction. In cases where water is drawn from and returned to a river or canal, the discharge pipe end can be sealed, thus forming a closed or syphon system. In arranging syphon systems care should be taken to ensure that the highest point in the system is never above a vertical distance of 25 ft. from the water level, otherwise the air contained in solution with the water is liable to be released and accumulate, thus breaking the syphon and throwing extra head on the pump.

Jet Condensers.

Where the cooling water contains a large amount of foreign matter liable to choke the tube of a surface condenser, or is of such a nature that it would cause corrosion, a jet plant is the best proposition to instal. It is a cheaper plant as regards initial cost than the surface condenser but requires more power for operation. With low-level jet plants it is necessary that the cooling water should be drawn in by virtue of the vacuum, and an efficient vacuum breaker be fitted whereby in the event of the pumps connected to the condenser suddenly shutting down, the vacuum will be broken, thus stopping the flow of the injection water.

DIAGRAM SHOWING THE PROPERTIES OF MIXTURES OF AIR AND STEAM, SUCH AS EXIST AT THE AIR PUMP SUCTION.

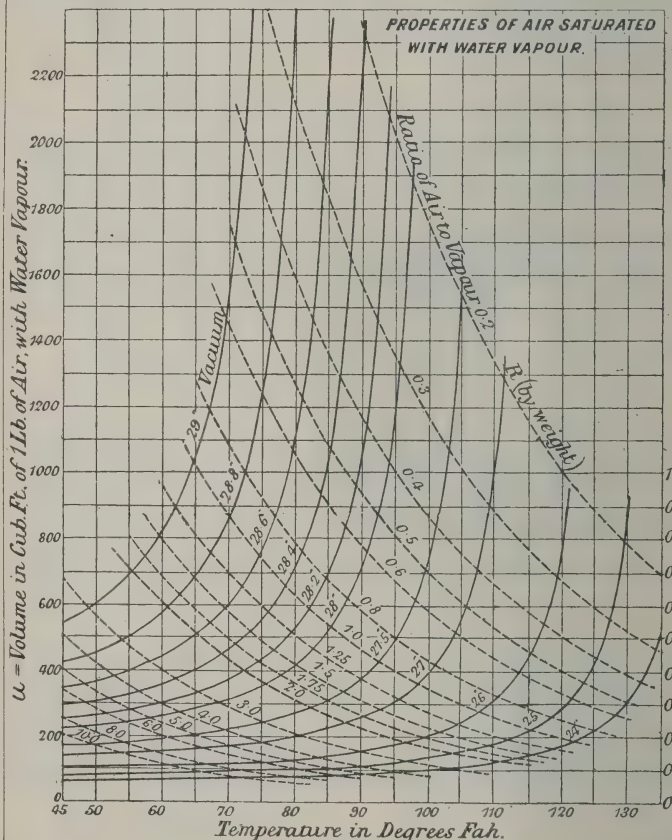

FIG. 32.

The mixture of cooling water and condensed steam is withdrawn at the bottom of the condenser, and the air is taken off near the top. Separate air and water pumps should always be installed in the case of this type of condenser. In the barometric or elevated type of jet condenser no water extraction pump is required, as the condenser being fixed at the barometric height is self-draining. Usually, however, an injection pump is required to lift the water partly up to the condenser, as the vacuum can be utilised to a certain extent for drawing the water into the condenser the same as in the low-level plant. These condensers are more expensive than the low-level type, and, due to a long exhaust pipe being necessary, require to maintain a slightly higher vacuum for an equivalent exhaust pressure at the turbine or engine exhaust flange.

STEAM CONDENSERS.—*continued.*

(3.)

(*W. H. Booth.*)

The vacuum in a condenser ought to maintain itself an hour with a drop of only 2 lbs.

The smallest air-pump found practicable by Mr. R. W. Allen had 0·5 cub. ft. of displacement per pound of steam condensed.

With circulation water at 65° to 70° F. a vacuum of 28½ ins. at full load with a single-stage air-pump can be maintained without special accessories. It is not advisable to allow less than 0·75 cubic ft. of air-pump volume per 1 lb. of steam condensed, and it ought to be possible to maintain a 98½ per cent. vacuum.

In a surface condenser the cooling water usually passes twice through, first through the lower part and then through the upper set of tubes.

Tube plates are made of rolled brass alloy of copper 62, zinc 37, tin 1 per cent., and are 1 in. to 1½ in. thick. Tubes are of brass ⅝ in. diameter and 0·048 in. thick (18 S.W.G.). They are secured into the plates by screwed ferrules with tape packing. Ferrules should allow a space for free movement of the tube ends.

Mr. Allen uses a short overflow pipe upstanding in the condenser so as to keep immersed the lower tubes which serve to cool the water going to the air-pump and so improve the vacuum. Tube surface is allowed at the rate of $\frac{1}{8}$ to $\frac{1}{10}$ sq. ft. per lb. of steam condensed per hour with circulation water entering at 65° F. Above that temperature the area allowed is ⅛ to ⅕.

The openings to a condenser should be large to allow for a slow velocity of entering steam. The tubes are more widely spaced at the top so as to give free admission for the steam among the tubes. It is specially undesirable to place a nearly continuous wall of tubes in the path of the steam. The tubes are heated and expel the steam molecules which do not find their way to the colder tubes below.

According to Stanton, in a condenser of a given surface for maximum efficiency, the tube length should be as great as possible. As regards tube diameter he says that condensers will be equally efficient in which the ratio $\frac{l^{n-1}}{d} = \text{constant}$, where l = length in feet, n = number of tubes, d = diameter of tube in feet external. Tube diameters should be chosen which offer the least aggregate resistance to flow. Resistance is, he finds, proportional to $l^{4\cdot2n}$, and is therefore least when the tubes are the smallest practical diameter. He considers the best position for tubes is vertical and the water movement downward.

The surface of a condenser should not fall much, if anything, short of 1 sq. ft. per 10 lbs. of steam hourly condensed. The modern tendency in condenser construction is to provide a more open way for steam to reach the heart of the tube bundles and to provide division plates to catch and drain away the water formed in several sections thus divided off, so that the condensed water shall not fall upon the whole mass of tubes but shall be led away, more nearly as formed to the bottom without touching any tube surfaces. Turbulent flow is given by such devices as the Rowe indented tube or by spiral strips of thin metal inserted in tubes to produce a rotary movement or mixing effect, so that pools of water with cold centres may not pass through the tubes. But tubes must not be too much obstructed, or the work of circulating the water through them will be increased.

The 'Weir-Uniflux' Condenser and Dual Air-Pump.

This arrangement is a new type of surface condenser introduced by *Messrs. G. & J. Weir Ltd., Cathcart, Glasgow*, based on a series of researches on heat transmission. The condenser secures the passage of steam over every part of each tube at uniform velocity, in practically a direct line from the exhaust inlet to the vapour and air outlet. There are no baffle plates or partitions to interfere with the steam flow. Owing to the high velocity of the circulating water, and the improved transmission rate per unit of surface, the Weir Uniflux Condenser is, duty for duty, claimed to be smaller and lighter than other types. The combination of these advantages with the special shape of the condenser make it specially adapted for use on board ship, while its high efficiency makes it specially suitable for turbine installations.

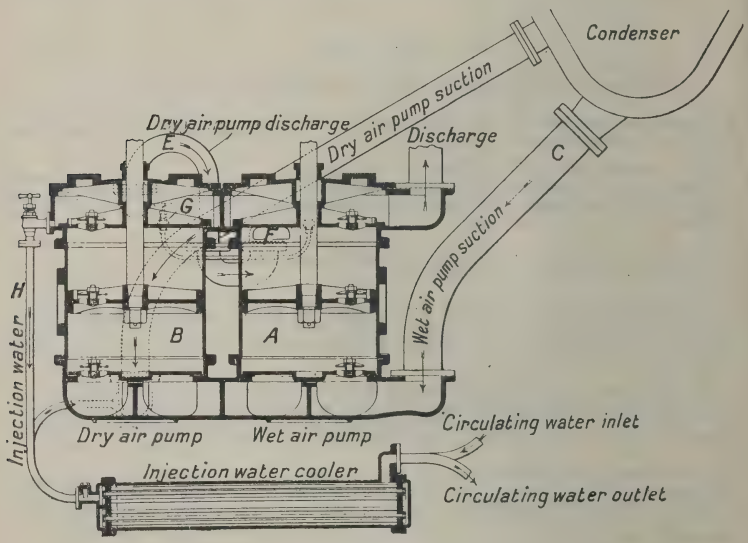

Fig. 33.

In conjunction with the Weir Dual Air-Pump, the Weir Uniflux Condenser enables the condensed water to be discharged at approximately the vacuum temperature if no air leakage exists, and at the minimum temperature loss under leakage conditions. The accumulation of scale on the tubes is minimised by the removal of the conditions favourable to scale deposition. The condenser is simple and free from fittings and complications requiring attention and adjustment.

The duty of an air-pump is to take from the condenser a mixture of air, water, and vapour, and to obtain economical working this should be done at the highest possible temperature. If a single pump is used to handle this mixture, the hotwell temperature for a given vacuum is dependent on the amount of air leakage and the air-pump capacity. Consequently, with a single air-pump the temperature of the mixture must be to a considerable degree colder than the theoretical temperature due to the vacuum.

By the use, however, of separate pumps handling the air and water, the dry pump having a cold injection non-returnable to the feed, the above conditions are changed, and higher thermal efficiency is rendered possible,

This method enables the wet (or water) pump to handle water at approximately the steam temperature, while at the same time the dry pump will deal with the air and vapour at the volume and temperature conditions imposed by the temperature of the injection water.

With the Dual Pump the above advantages are obtained, together with increased efficiency of the dry pump, due to its contents being densified or decreased in volume through cooling by the injection water, which circulates continuously, never leaves the system, and is never subjected to atmospheric pressure with consequent aeration. The dry air pump further works only at less than half the pressure range, as it discharges below the head valves of the wet pump. The apparatus, moreover, is compact, self-contained, and of good mechanical design.

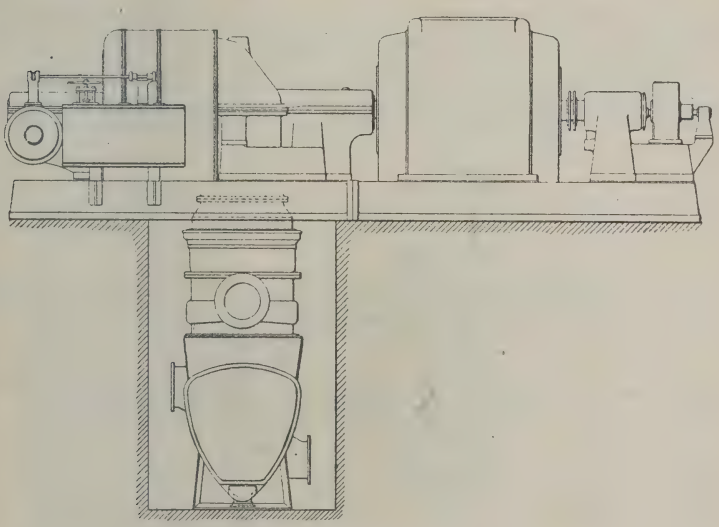

FIG. 34.—The Weir-Uniflux Condenser.

Fig. 33 shows in a diagrammatic form the arrangement of the Uniflux Surface Condenser Dual Air Pump, and Injection Water Cooler. In all cases the pump A, or wet pump, is situated below the steam cylinder, as this pump is the only one which works under any considerable load; the dry pump B is driven by the beam and links in the usual manner. A connection, C, is led from the condenser to the wet pump, and a separate branch pipe, D, is taken from a point higher up the condenser and led to the dry pump. Both pumps are generally of the three-valve marine type, but in certain cases the dry pump may be of the suction valveless type.

The first and most important difference from an ordinary twin pump consists in the dry pump discharging through the return pipe E, through a spring-loaded valve F into the wet pump at a point below its head valves. The next point concerns the supply of water to the dry pump for water sealing, clearance filling, cooling, and vapour condensing. When starting the pump the filling valve G must be opened for a minute or so to enable the vacuum to draw in a supply from the hotwell of the wet pump. The valve is then closed, and the water passes from the hotwell of the dry pump by the pipe H to the annular cooler, and after being cooled passes into the suction of the dry pump, then passing through the pump it becomes heated and again passes to the cooler, and so on in a continuous closed circuit, any excess passing over the pipe E to the wet pump. The spring-loaded valve F is adjusted to maintain about 20 ins. vacuum in the dry pump hotwell when the condenser is working at 28 ins. vacuum, and this 8 ins. difference of pressure is sufficient to cause the water to overcome the cooler friction and pass into the suction, and at the same time never allow any direct air connection between the dry suction and discharge.

Since its introduction in 1908, the Weir-Uniflux Condenser has been adopted by H.M. and by sixteen other Governments, and by the leading mail and passenger steamship lines. The ' Weir-Uniflux ' Condenser has now been fitted to approximately twelve millions h.p. Fig. 34 shows one of five sets of ' Weir-Uniflux ' condensing plant supplied to the Clyde Valley Electrical Power Company for their Motherwell and Yoker Power Stations to work in conjunction with 5,000 kw.. turbo-generators of the British Westinghouse Rateau type. The condenser has a capacity of 80,000 lbs. of steam per hour, and a cooling surface of 6,000 sq. ft. The air-pump takes only 12½ h.p. when the turbine is running full or on overload, and no trouble is experienced in maintaining a 96 to 96½ per cent. vacuum. The results actually obtained are stated to have shown a saving of 30 per cent. in the fuel consumption at the Motherwell Power House.

(See also Section XXXIII.)

The Ejector Condenser.

This condenser is at once an air-pump and a condenser. It acts on the principle that steam will flow into a vacuum at a velocity of many hundred feet per second. The water supply to the ejector should flow to it under a head of several feet. The steam condenses in the jet of water, and the combined jet has a velocity which is a mean of the velocity of the steam and of the

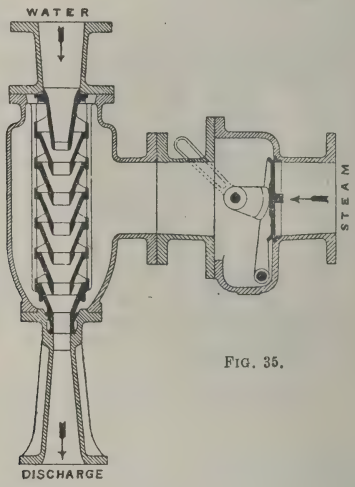

Fig. 35.

water. Thus let the water approach at a velocity 30 feet per second and the steam at 1,200 feet per second. Let the combined jet be assumed to have a temperature of 100° F. and the water to be supplied at 60° F. The water gains 40° F. The steam loses say 1,100 B.Th.U. Then $1,100 \div 40 = 27$ = ratio of water weight to weight of steam. The total weight of combined jet is 28. The velocity difference is $1,200 - 30 = 1,170$, to be divided over a mass of 28, or $\frac{1,170}{28} = 42$ feet per second nearly. Add the initial velocity of the water 30, and the final velocity is 72 feet per second. This corresponds with a head of $H = (72 \div 8)^2 = 81$ feet; and since 1 foot of water column equals 0·43 pounds, 83 feet will represent 36 pounds nearly. Since a perfect vacuum is only 14·7 pounds, it follows that with ordinary ratios of water and steam an efficiency of less than 50 per cent. should give an excellent vacuum.

The apparatus (fig. 35) consists of a converging water nozzle into which water is directed from a centrifugal pump or other pressure source, or from an overhead source of 15 to 20 feet head. This jet flows downwards through a series of steam cones to which the exhaust steam has admission at their upper wide portion. The steam flows down each of these short cones and imparts further velocity to the jet as it condenses, and finally the jet flows into a divergent

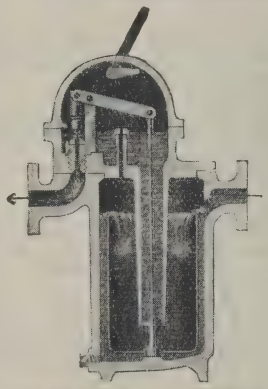
BAILEY'S PUMPS
AND VALVES

Patent Belt-driven Slide Valve Vacuum Pump.

'K' PATENT 'DRY'
VACUUM PUMPS



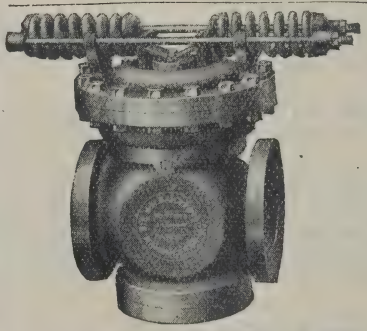
Will maintain a vacuum of over 29·8 ins. of mercury at normal temperature and with a Barometric pressure of 30 ins.

Remarkable for high Efficiency.

No delicate parts to wearout.

SIMPLE AND COMPOUND.

Steam, Belt, or Electric Driven



BAILEY'S VACUUM PUMPS are particularly suitable to work as Air Pumps for Condensers for Steam Engines, Central Condensation Plants, Cooling Towers, Condensers for Evaporating Plants, Vacuum Drying Plants, Distillers, etc.

BAILEY'S
'SCAVENGER' STEAM TRAPS
FOR PRESSURES TO 200 LBS.

LARGE CAPACITY, HAND BLOW-THROUGH WORKS WITHOUT ADJUSTMENT AT ANY PRESSURE. WORKING PARTS EASILY EXAMINED WITHOUT BREAKING PIPE JOINTS.

'POP' ACTION, NO DRIBBLING. RENEWABLE VALVE AND SEAT.

SAVES TIME IN 'STARTING UP' AS LONG PIPES CAN BE QUICKLY DISCHARGED OF COLD AIR AND WATER.

BAILEY'S CLASS 'W'
'FULL BORE'
REDUCING VALVE
FOSTER'S PATENT.

FOR SATURATED AND SUPER-HEATED STEAM PRESSURE REGULATION.

MAINTAINS CONSTANT DELIVERY PRESSURE IRRESPECTIVE OF VOLUME DEMANDED.

MOST SENSITIVE, DURABLE, AND EFFICIENT OF ALL REDUCING VALVES.

MADE IN ALL SIZES ½ in. to 24 ins.

MANUFACTURERS

Sir W. H. BAILEY & CO. Ltd., ALBION WORKS, SALFORD.

discharge cone at a velocity as above indicated, carrying with it any air that has come in with the steam, and discharging it. The degree of vacuum is of course that proper to the jet temperature, and the proportion of water can, as seen, be sufficiently great to admit of a moderate final jet temperature and therefore a good vacuum. The ejector condenser occupies very little space and for jet condensing is very simple. The centrifugal water supply pump is conveniently direct driven by an electric motor. While the jet final temperature is amply low for good vacua, the velocity of the combined jet is still more than sufficient to run freely against atmospheric external pressure; but it is always desirable to give the water a fair initial velocity, and there is nothing lost by giving the discharged jet a good fall in a long tail pipe.

The Barometric Condenser is a simpler form of ejector condenser, in which the water enters the head of the apparatus as a spray about the steam entrance, and the vacuum is produced by the fall of the water down a tail pipe of at least 30 feet in vertical drop. By suitable formation of the head the air which enters with the steam is entrained with the water, or, by means of a special surface condenser at the side of the head the air is drawn over cold tubes and carried down to a lower point in the draught tube, whereby it is withdrawn from the head at a minimum temperature, with the object of securing a maximum degree of vacuum.

AIR-PUMPS.

The Edwards Patent Air-Pump.

In the Edwards Patent Air-Pump, fig. 36, foot and bucket valves are entirely dispensed with. The only valves used are those which in the old type of pump are known as 'the head valves,' but which in the Edwards pump are simply called 'the valves,' as there is no need to distinguish them in any way.

The condensed steam flows continuously *by gravity* from the condenser into the base of the pump, and is there *dealt with mechanically* by the conical bucket working in connection with a base of similar shape. Upon the descent of the bucket the water is projected *silently and without shock* at a high velocity through the ports into the working barrel, as shown in fig. 37. The rising water is followed by the rising bucket, which closes the

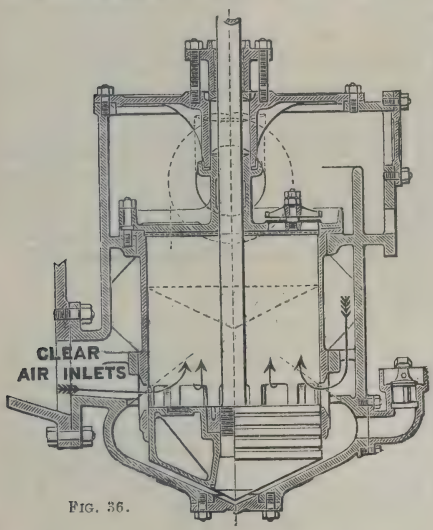


Fig. 36.

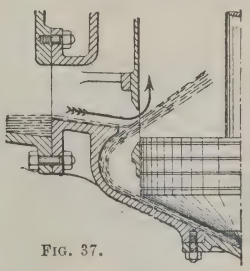

Fig. 37.

ports, and sweeping the air and water before it discharges them through the valves at the top of the barrel.

The essential feature of the Edwards pump is that the water is dealt with *mechanically*, and is in no way dependent on *pressure* in the condenser to drive it up into the pump; consequently increase of speed does not impair its efficiency. The speed of the water must correspond with the speed of the bucket, and the pump thus having a regular quantity of water to deal with at each revolution is particularly well suited to work at high speeds.

Another point of considerable importance in the design of the pump is that *clear air inlets are maintained*. As the bucket descends and the ports open there is absolutely no obstruction between the condenser and the pump. The air has a perfectly free entrance into the barrel, as

indicated by the arrow in fig. 37, while immediately afterwards the water is injected at a high velocity; thus, instead of obstructing the entrance of the air, the water tends to compress that already in the barrel, and to carry more air in with it.

Before any air pump can discharge, all the air in the barrel must be compressed to slightly in excess of the atmospheric pressure, and consequently the greater the amount of air remaining in the clearance water the more inefficient the pump becomes. By reducing the top clearance to a minimum, as is done in the Edwards pump, the efficiency is considerably increased.

By means of the door at the top of the pump the only valves used can be readily examined, cleaned, and, if necessary, renewed while the pump is at work.

The door also allows the engineer-in-charge to estimate the air duty of the pump, and after a little experience to tell whether there is any serious leakage into the system.

For marine pumps a weir is arranged between the door and the valves (see fig. 36); this enables the door to be taken off while the pump is at work, without loss of water, even when there is a heavy list on the ship.

The following table gives the dimensions of 3-throw pumps suitable for electrical and other land installations, and for dealing with the stated quantities of steam, when working in connection with *surface* condensers of the ordinary type.

SIZE, SPEEDS, AND APPROXIMATE OVER-ALL DIMENSIONS OF THREE-THROW EDWARDS AIR PUMPS WHEN WORKING IN CONNECTION WITH SURFACE CONDENSERS FOR VARIOUS AMOUNTS OF STEAM.

Lbs. of Steam per Hour.	Number of Pump Barrels.	Dia.	Str.	Revs. per Min.	Approximate Dimensions.

(*The Edwards Air-Pump Syndicate, Ltd.*)

THE LEBLANC AIR-PUMP, SIMPLE JET TYPE.

In the Leblanc Simple Jet Condenser and Air-pump, water is jetted across the exhaust pipe from the engine by means of a reversed turbine wheel which rotates in a closed casing alongside the pipe, there being an opening into the pipe at a portion of the turbine periphery. There are thus a series of flat sheets of water traversing down the vertical pipe, and serving both to condense and to draw off the steam and air. The water can be used over again if not too hot, and the pump is thus intended for use as a wet and dry air-pump. As there are quite a number of water vanes acting together and moving with great energy down the eduction pipe, there is only a small pressure difference between adjacent vanes, and there is quite a mass of water always acting. The vanes of water practically act like an extension of the metal vanes of the central fan, so that this fan is in a sense an absolute fit in the casing like a scoop wheel, and air is withdrawn between each such vane and the next following. The fan or turbine is practically a water-packed radial-bladed wheel which scoops out the air as it rotates.

THE LEBLANC ROTARY AIR-PUMP.

In the Leblanc type of Rotary Air-pump, section of which is given in fig. 38, the air from the condenser is trapped between thin sheets of water thrown out by a series of turbine vanes, which rotate at a high speed in an enclosed casing. The discharge opening in the casing uncovers a certain portion of the turbine periphery where the sealing water drawn in at centre and passing through the distributor nozzle, gets shot out in sheets from the revolving blade wheel, down the narrowing part of collecting cone discharge pipe, at a high velocity, trapping on its way a certain volume of air between the water sheets discharged.

A compact column is thus produced which passing through the throat of the converting cone into the diverging diffuser has its velocity energy transformed into work of compression, overcoming the atmospheric pressure and carrying away the gaseous products from the condenser. In

this type of pump the only moving part is the impeller or blade wheel mounted on its shaft. There are no valves or reciprocating parts, so there is little to get out of order. The pump readily lends itself to direct drive by electric or steam driven motors.

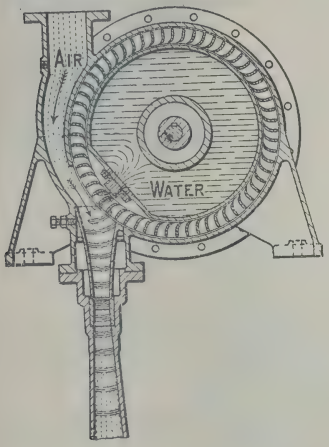

FIG. 38.

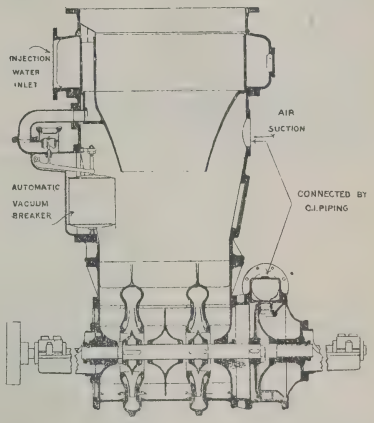

FIG. 39.

Fig. 39 shows the application of the Leblanc pump to a Multi-jet condenser. The air and incondensable gases collecting near the top of condenser are drawn off by the Leblanc Rotary Air-pump, and the injection and condensation waters are withdrawn from the bottom of condenser by special pump. The pump impellers are mounted on a common shaft and driven by one motor.

THE MIRRLEES-LEBLANC EJECTOR AIR-PUMP.

This apparatus, which is shown in fig. 40, is a steam ejector working in two stages placed in series and mounted in tandem. In the first and second stages a number of small nozzles are

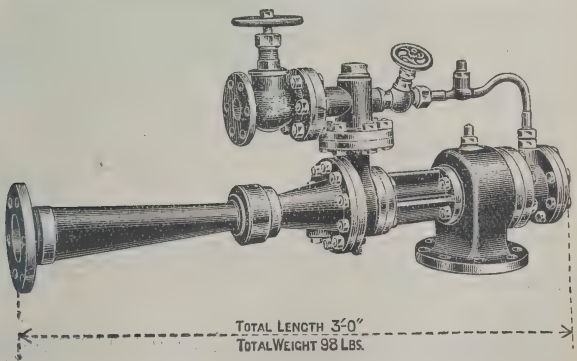

FIG. 40.

fitted, which are supplied with steam at a pressure of about 90 lbs. per square inch and upwards. The air suction from the condenser is placed on the first stage, the air being entrained by surface friction by the jets of steam issuing from the nozzles, the speed of the steam effecting compression

up to a limited degree. The compression to atmospheric pressure is completed in the second stage, which is specially designed to have a very high ratio of compression. By employing a large number of small nozzles the entraining surface of the steam is considerably increased, and therefore the efficiency of the Mirrlees 'Leblanc' Ejector is much higher than is usual with this class of apparatus.

When working on high vacuum installations, stability of the ejector is assured by means of an annular opening on the diffuser cone, and this opening may be either air or steam sealed. The centrifugal pump withdrawing the condensed steam from the condenser discharges into a small tank, and into this tank the exhaust steam from the ejector is led. By this system practically the total heat of the operating steam for the ejector is returned to the feed water, which in turn is de-aerated when passing through the filter tank. The ejector can be designed for either very high or comparatively low vacuum, and as there are no moving parts, it is extremely simple, while it has other advantages in the matter of weight and space occupied.

Condensing Plant with Hick-Breguet Ejectair.

(*Hick, Hargreaves & Co., Ltd., Bolton.*)

Modern high-vacuum apparatus is designed on one basic principle, viz. the extraction of air and water at different points, entirely independent of one another, a centrifugal pump being used for extracting the water, and a steam jet pump for extracting the air. The Hick-Breguet condensing apparatus, of the surface jet and barometric types, is fitted with pumps of the above types.

The water-extraction pump is single-stage, designed for efficient continuous running under all load variations, and is driven through a flexible coupling by an electric motor or by a steam turbine.

The 'Ejectair' air-extraction apparatus, fig. 41, is operated by two steam ejectors in series, with an intermediate condenser, giving a high degree of air-extraction combined with low steam consumption. The first ejector withdraws the air from the condenser, compressing it slightly and discharging it into the intermediate condenser, where the steam from the first ejector is condensed and the air reduced in volume, thus increasing the volumetric efficiency of the second ejector.

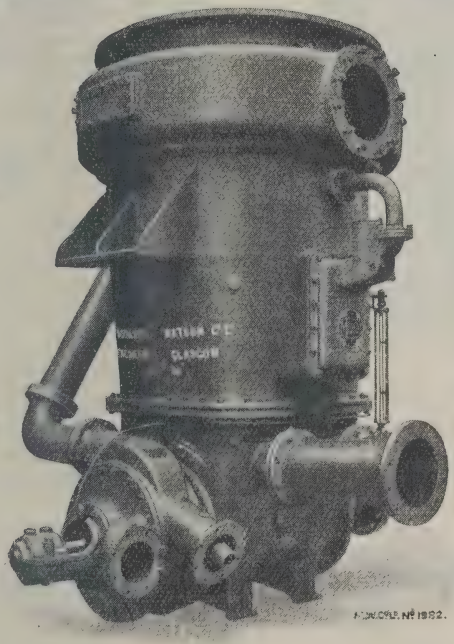
The water from the auxiliary condenser, along with the condensate of the first ejector, is delivered by means of a 'U' balance pipe direct to the extraction-pump suction, in this way raising the temperature of the condensate from the main condenser and conserving the heat in the first jet.

The steam from the second jet, along with the air, is discharged preferably into a surface heater, through which the discharge water from the extraction pump passes, in this way conserving the heat from the second jet and still further raising the temperature of the condensate.

A high thermal efficiency is thus obtained. At the same time the apparatus is extremely simple in construction, requiring no attention when put into service, there being no moving parts except the extraction-pump spindle.

The plant is put into operation by simply opening the steam valve to the two jets and closing the switches controlling the circulating-pump and extraction-pump motors. The amount of steam used by the jets is small, about 1 per cent. of that used by the main unit.

The surface condenser is designed to ensure the whole of the steam coming into intimate contact with the tubes, and the tubes are disposed so as to reduce to a minimum the resistance to the passage of steam. The condensate is withdrawn at as high a temperature as possible, usually that corresponding to the vacuum at the turbine exhaust, divided by 0·99. Thus, if the vacuum at the exhaust is 28·5 ins., the temperature of the condensate will be that corresponding to a vacuum of $28{\cdot}5 \div 0{\cdot}99 = 28{\cdot}78$ ins., or 85° approximately.



To ensure the air being withdrawn at maximum density, it is drawn through a 'devaporising' chamber, formed in the lower pass of the condenser by steel plates enclosing about 8 per cent. of the total number of condenser tubes. The reduction of volume of the air thus effected adds to the efficiency of the air-extracting apparatus.

The jet nozzles are designed for a steam pressure of usually 145 lbs. per sq. in. gauge, though they can be designed for any pressure from 70 lbs. per sq. in. upwards, and for either saturated or superheated steam.

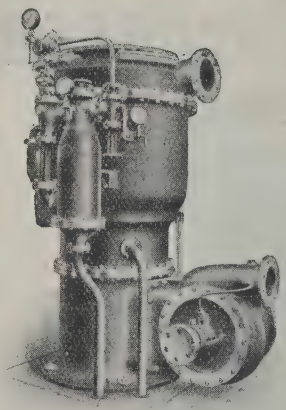
MIRRLEES

THE

MIRRLEES JET CONDENSER

THE MOST UP-TO-DATE TYPE OBTAINABLE.

THE MIRRLEES WATSON COMPANY LTD.



Specialists in Condensing Plant.

Head Office and Works : SCOTLAND STREET, GLASGOW.

London Office: 7 Crosvenor Gardens, S.W. 1.

P. 1626

CONDENSING PLANT

Surface and Multi-Jet. Fitted with the

HICK-BREGUET —EJECTAIR—

(*Patented*)

For high vacuum.

No reciprocating parts. Guaranteed reliability. Minimum up-keep charges. Absolute stability.

Vacuum unaffected by 20% fall in steam pressure. Patent Automatic Control ensures vacuum stability. The plant with lowest operating power.

We are specialists in the design, lay-out and manufacture of Condensing Plant for Power Installations of all sizes. The services of experienced Engineers are always available for advice in connection with new installations or improvements and additions to existing plants.

UNIFLOW DROP VALVE & CORLISS STEAM ENGINES. MILL GEARING IN ALL ITS BRANCHES.

HICK, HARGREAVES & CO. LTD.

BOLTON——————ENGLAND.

London Office:

90 TEMPLE CHAMBERS, TEMPLE AVENUE, LONDON, E.C.

The condenser inlet is usually connected to the turbine exhaust by means of a galvanised wrought-steel bellows pipe, which permits of relative expansion between turbine and condenser. The condenser may be mounted on springs and the bellows pipe dispensed with, but in this case expansion joints are required for all piping connected to the condenser.

To minimise depth of foundations the head of water required on the suction side of the extraction pump is reduced by careful design to 24 ins., measured from the pump spindle to the inside of the bottom of the condenser shell, and may in special cases be reduced to 20 ins.

The Hick-Breguet jet condenser is of multiple jet type, the number of nozzles being propor-

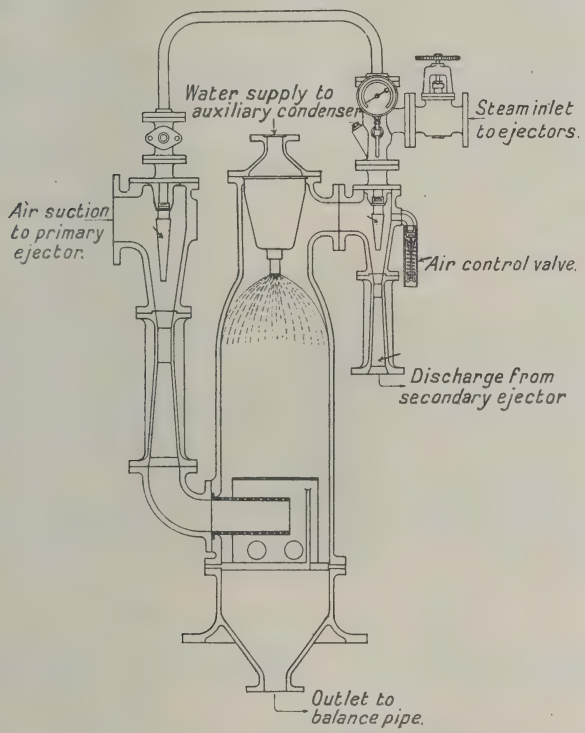


FIG. 41.—Sectional Arrangement of Hick-Breguet Ejectair.

tionate to the duty of the plant. The upper portion is designed to eliminate almost entirely resistance to the passage of the steam on to the finely divided water sprays, condensation thus being immediate and complete.

An ejectair is used as described above, but in this case the air is withdrawn from just above the surface of the water in the bottom of the condenser, and is cooled by a water jet connected to the main injection pipe, the air temperature at withdrawal being approximately that of the injection water. In this type of plant, the heat of the first jet is usually not conserved, the water from the auxiliary condenser being passed back into the main condenser, from whence it is discharged by the extraction pump to a cooling tower or pond. The loss so entailed is extremely small. The steam from the second jet may be used in a feed heater or open feed tank, as may be preferred. No lift pump is required, the extraction pump being capable of lifting the water to the usual height of a cooling tower.

THE BAILEY AIR-PUMP.

(See p. 1084.)

The Measurement of Condensed Steam.

The condensate may be measured by passing over a V-notch in a suitably arranged tank, the height of the water surface above the apex of the notch being measured at a point at such a distance from the notch that the water is nearly still.

If h is the height in inches, Q the flow in cub. ft. per minute, and the angle of the notch is 90°, then $Q = ch^2\sqrt{h}$, where c is approximately 0·305, but, more accurately, varies from 0·31 at $h = 2$ ins., to 0·301 at $h = 9$ ins. or over. Less heads than 2 ins. should not be used, it being better to increase the head by using a notch of narrower angle; the discharge is approximately proportional to the tangent of half the notch angle.

For the 90° notch the cubic feet of flow per minute $= 0{\cdot}305h^2\sqrt{h}$, where h is the depth from the water level in the still pond above the notch measured down to the point of the V.

If one notch will not pass the water, two may be used, and the reading of the instrument doubled.

THE LEA AUTOMATIC WATER RECORDER FOR STEAM ENGINES.

This instrument, made by *The Lea Recorder Co. Ltd.*, measures the discharge of the air-pump by means of a 90°, 60°, 30° or finer V notch. A float in a chamber connected to the tank-space above the notch plate rises and falls with the water. On the float-rod is a toothed rack. This turns a pinion on a drum spindle. The pencil of a recording drum is moved across the record paper, which is clock driven, by means of a spiral cut in the first-named drum. This spiral has an increasing pitch, starting at 0 when the water is down to the apex, and increasing in the ratio $h^2\sqrt{h}$; so that the pencil movement is always proportional to the volume flowing. The gravity of the water and drum approximately compensate for the expansion of the water, so that the instrument remains correct for changes of discharge temperature. By means of the recorder small changes in the régime of the engine, such as cut-off, jacket temperature, superheat temperature, vacuum, etc., are promptly shown by the record, and what are now long series tests can be made in a few minutes in rapid succession with an accuracy and certainty that cannot be secured over long periods of possible change in other conditions. The instrument is at its best when each engine has its own surface condenser, but good results can be secured with jet condensers, or even with condensers common to two or more engines, especially where general economy is sought for. A system of deductive calculation of a simple order enables this to be done.

TABLE OF FLOWS THROUGH 90° V NOTCHES.

Depth in Notch in Ins.	Flow per Hour.		Depth in Notch in Ins.	Flow per Hour.	
	Galls.	Lbs.		Galls.	Lbs.
2	654	6,540	9	27,300	273,000
3	1,785	17,850	10	35,600	356,000
4	3,640	36,400	11	45,000	450,000
5	6,350	63,500	12	56,050	560,500

7	14,650	146,500	14	82,600	826,000
8	20,300	203,000	15	79,900	979,000

(*Barr.*)

It is easy to make a correct allowance for time lags by making one or two observations on the time elapsing after making a change before the instrument records it. On a steady load, the addition of some further load can be made and its power absorption known in a few minutes. Information only acquired by weeks of testing, and then only approximately, can be acquired by means of the apparatus in a few hours, for it is only necessary to allow conditions to become steady between each test. The instrument is, of course, most readily applicable to surface

condensing engines, the record forming a jet condenser requiring the simultaneous observation of water temperatures, so as to discover how much of the discharge represents engine steam.

The apparatus is being extensively used for the measurement of boiler feed water, and can be obtained in two patterns, viz., the indicating and recording type, and the combined indicating recording and counting type. With the latter the total quantity can be read off directly, just as in the case of a gas meter.

Injection Cocks

Are usually of the hollow plug type, in gunmetal. One per condenser is sufficient. Two or three standard sizes are generally available to choose from. The minimum size can be checked, as in the following example:—

Maximum load under normal conditions	1,000 i.h.p.
Steam per i.h.p. hour	15 lbs.
Steam per second	4·17 lbs.
Condensing water per pound of steam	40 lbs.
" " per second	167 lbs.
" " "	2·67 cub. ft.
Vacuum in condenser, worst	24 ins.
" " in feet of water	27 ft.
Vertical height water level to injection cock	11 ft.
Head of water on injection service, 27–11	16 ft.
Assume spent in friction	50 per cent.
Net head at injection cock	8 ft.
Velocity of water at cock=$8\sqrt{8}$	22·6 ft. sec.
Hence area of opening	0·118 sq. ft.
" "	17 sq. ins.

If in doubt add a margin of 25 to 30 per cent. It is, of course, understood that the above level, steam consumption, etc., must be modified to suit the actual conditions. Thus in tropical countries 60 should be substituted for 40 lbs. of condensing water per lb. of steam.

Force or Feed Pumps.

When the boiler feed-pump is driven off the engine it is usual to allow sufficient capacity for other works purposes.

The following are frequently adopted:—

Textile spinning mills	25 lbs. water per i.h.p. hour.
Textile weaving sheds	40 " " "
Mixed spinning and weaving	30 " " "
Flour mills	35 " " "
Bleach works	50 " " "

It will be seen that an ample allowance is made, and for economical superheated-steam engines a reduction of about 5 lbs. can be made. The above are based on actual pump displacement. The plunger speed should not exceed about 200 ft. per minute.

Pump Openings.

The velocity of water in pump openings should not exceed 500 feet per minute.

Power Plant Thermal Efficiencies.

In the curve diagram (page 1630) the steam pressure is in *absolute* pounds per square inch, and the object is to divide up the overall thermal efficiency of a power plant between the boiler plant (which includes superheater and economiser) and the turbo-generator plant.

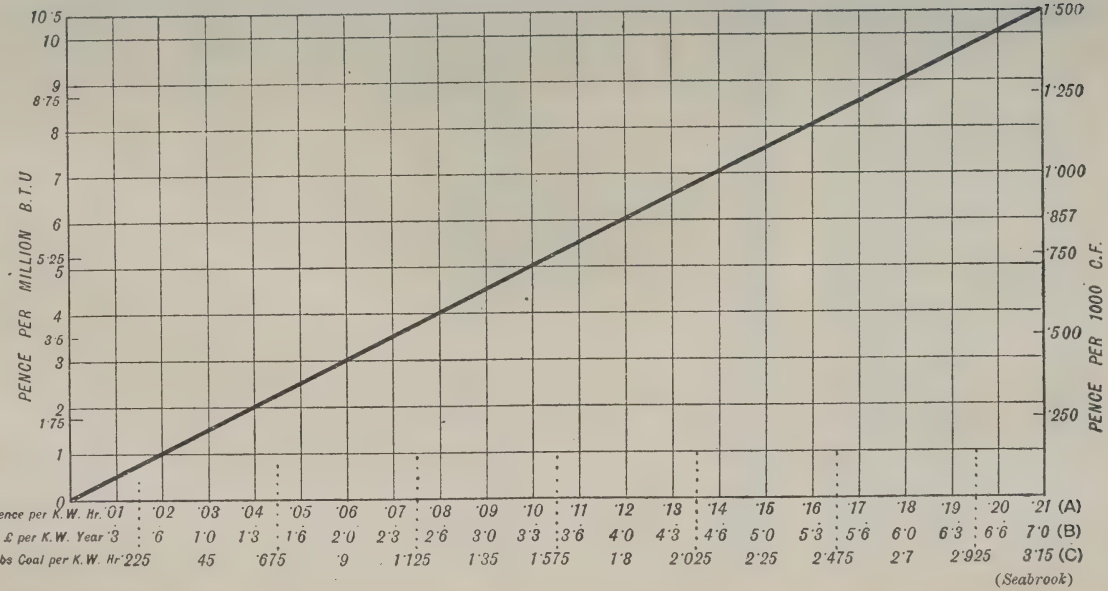
Take, for instance, the 80 per cent. boiler efficiency line, which is about as high as can be expected in year-in and year-out working. From this it will be seen that 1,595 B.Th.U. must be applied to the boiler furnace to obtain 1 lb. of steam at a total heat of 650° F.

POWER PLANT THERMAL EFFICIENCIES.

Ratio between Gaseous Fuel and K.W.H.

Curve showing—1. Pence per K.W. Hour (A) and £ per K.W. Year (B) with varying costs per million B.Th.U.

2. " " " " with varying costs per thousand C.F. Gas.



Assuming :—17 per cent. Thermal Efficiency. 143 B.Th.U. per C.F.

50 K.W. Hours per million B.Th.U. 8,000 Hours per annum.

3. Ratio between pence per K.W. Hour and £ per K.W. Year (A and B).

(Pence per K.W. Hour × $3\cdot\dot{3}$ = £ per K.W. Year.)

(C) Coal @ 12/6 T. and 11,000 B.Th.U. per lb. (B) ÷ 2·22 = (C).

(Seabrook)

The best thermal efficiency practicable year in and year out, and even then only obtainable on a very high load factor, is a turbo-generator consumption of 11 lbs. per k.w.hr. (See Curve B.) This, combined with the boiler efficiency, gives a thermal efficiency over all of 19·42 per cent., or 17,550 B.Th.U., applied at the boiler furnace per k.w.hr. It is questionable whether better results than this can be obtained until higher total temperatures than 650° F. can be worked to.

It is quite easy to arrive at a boiler efficiency and the efficiency of a turbo-generator separately, but these data do not give the power station engineer the year-in and year-out over-all thermal efficiency of a power plant from the fuel to the switchboard. This over-all figure, which has now reached 17 per cent. in some large power stations in this country, working on a load factor of about 60 per cent., is likely to be increased in the near future; it must take into account *all losses*, that is to say, the power required for operating a power station itself. These losses include lighting, motors, pumps (whether steam or electrically driven), condensing plants, cooling tower equipments, etc., also leakages due to blow-down of boilers, traps, drains, and so on. The station may have a high boiler efficiency, and a high turbo-generator efficiency, while the over-all efficiency may be very low, and very often is, because the consumption of power for driving the power station is frequently overloaded

(*A. Hugh Seabrook*, ***A.M.Inst. C.E.***)

At a discussion on Power Station Design at I.M.E.A. Convention, June 1920, the view was expressed by Selvey that 17,500 B.Th.U. per unit generated was then in sight, or 19·5 per cent. overall efficiency; and Mr. Ferranti was of the opinion that 28 per cent. would be attained with steam plant in the future.

PART I

GENERAL DATA RELATING TO POWER GAS.

Interrelations of Units.

In calculations relating to Power Gas, the following physical data and interrelations of units will be found convenient for reference:—

1 metre = 39·37079 ins. = 3·2809 ft. = 3 ft. 3¼ ins. (app.).
25·4 millimetres = 1 inch.
1 square inch = 6·4516 square centimetres.
1 cubic inch = 16·387 cubic centimetres.
1 gallon = 8 pints = 277·3 cubic inches (app.) = 4·5435 litres.
1 gallon of pure water at 62° F. weighs 10 lbs.
1 cubic foot = 6·23 gallons.
1 cubic foot of pure water at 62°F. weighs 62·3 lbs. = 28·315 litres.
1 cubic foot of average river water weighs 63 lbs.
1 cubic foot of sea water weighs 64 lbs.
1 litre = 1,000 cub. cm. = 61·03 cub. ins. = 1·761 pints.
1 pound (av.) = 7,000 grains = ·45359 kilogramme.
1 gramme = 15·432 grains = ·0022046 lb.
1 gramme per litre = 70·13 grains per gallon = 436·9 grains per cub. foot.
1 kilogramme = 15,432 grains = 2·2046 lbs.
1 British ton = 2,240 lbs.
1 metric ton = 2,205 lbs. = 0·9844 British ton.
1 atmosphere = 14·7 lbs. per sq. in. = 2116·8 lbs. per sq. ft.
" = 33·977 ft. of water.
" = 26,220 ft. of (homogeneous) air.
" = 30·0 ins. of mercury (app.).
" = 760 mm. of mercury (app.).
1 kilogramme per sq. cm. = 14·22 lbs. per sq. in.
" " = 0·9673 atmosphere.
1 inch of mercury = 0·490 lb. per sq. in.
1 inch of water = 0·0360 lb. per sq. in.
1 British thermal unit (B.Th.U.) = heat necessary to raise 1 lb. of water through 1°F.
" " " = 778 ft.-lbs. of work.
1 centigrade thermal unit (C.Th.U.) = heat necessary to raise 1 lb. of water through 1°C.
" " = 1·8 B.Th.U.
" " = 1400·4 ft.-lbs. of work.

1 (major) calorie = heat necessary to raise one kilogram of water through 1°C.
" = 2·2046 C.Th.U.
" = 3·9683 B.Th.U.
" = 3087·3 ft.-lbs. of work.
1 British horse-power = 33,000 ft.-lbs. of work per minute.
" " = 42·416 B.Th.U. per minute.
" " = 2,545 B.Th.U. per hour.
" " = 23·564 C.Th.U. per minute.
" " = 1,414 C.Th.U. per hour.
" " = 10·69 calories per minute.
1 metric horse-power = 75 kilogrammetres per second.
" " = 0·9863 British horse-power.
1 kilowatt = 1·34 British horse-power.
Absolute temperature °F. (T) = 460 + ord. temp. °F.
" °C. = 273 + ord. temp. °C.

The volume of 1 lb. of a gas varies with its pressure and temperature and for purposes of comparison a definite pressure and temperature are selected. If normal pressure and temperature be one atmosphere and 32°F., this may conveniently be denoted by N.T.P.

Mass and Bulk of some Gases and Vapours at N.T.P.

Air is by *weight*, composed of 77 per cent. nitrogen and 23 per cent. oxygen.
By *volume* its composition is 79 per cent. nitrogen and 21 per cent. oxygen.
One pound of oxygen is contained in $\frac{100}{23} = 4{\cdot}35$ lbs. of air.
One cubic foot of oxygen is contained in $\frac{100}{21} = 4{\cdot}8$ cub. ft. of air.
One pound of dry air at N.T.P. occupies 12·387 cub. ft.
One cubic foot of dry air at N.T.P. weighs 0·08073 lb.
The following table gives data relating to the heaviness and bulkiness of the more usual gases:—

HEAVINESS AND BULKINESS OF SOME GASES, ETC., AT N.T.P.

Gas.	Symbol.	Specific Gravity; Hydrogen = 1.	Heaviness of 1 Cubic Foot at N.T.P.; Lbs.	Bulkiness of 1 lb. in Cubic Feet at N.T.P.
Column:—	1	2	3	4
Hydrogen	H_2	1	0·00559	178·89
Methane (marsh gas)	CH_4	8	0·04472	22·36
Water (gaseous)	H_2O	9	0·05031	19·88
Acetylene	C_2H_2	13	0·07267	13·76
Carbon monoxide	CO	14	0·07826	12·78
Ethylene (olefiant gas)	C_2H_4	14	0·07826	12·78
Nitrogen	N_2	14	0·07826	12·78
Air	$O_{23}+N_{77}$	14·44	0·08073	12·387
Oxygen	O_2	16	0·08944	11·18
Carbon dioxide	CO_2	22	0·12298	8·13
Normal benzene	C_6H_6	39	0·21801	4·59

p = abs. pressure, in lbs. per sq. foot;
= 144 {14·7 + pressure in lbs. per sq. in. above atm.};
v = volume of 1 lb. of gas, in cubic feet;
T = absolute temperature in °F.;
= 460 + ord. temp. °F.

Then for a perfect gas:—

$$pv = c\,T \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Where c is constant for any, the same, gas.

For dry air at N.T.P.:—

$p = 14{\cdot}7 \times 144 = 2116{\cdot}8$ lbs. per sq. ft.
$v = 12{\cdot}387$ cu. ft. (Table, col. 4.)
$T = 460 + 32 = 492$°F. (abs.).

Whence, by Eq. (1), we have $c = 53{\cdot}29$. Thus the characteristic equation for dry air regarded as a perfect gas, is :—

$$pv = 53{\cdot}29\ \mathrm{T}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Equations (1) and (2) show that in a perfect gas the value of the product pv is proportional to the absolute temperature. If the pressure remains constant, the volume and absolute temperature are mutually proportional. So also, if the volume remain constant, the pressure and absolute temperature are mutually proportional.

The specific heat of dry air at constant pressure, k_p, is 0·2374 B.Th.U. per lb.

The specific heat at constant volume, k_v, is less than k_p by the heat equivalent of the external work of expansion under constant pressure.

If Eq. (1) be differentiated at constant pressure we have :—

$$p\ dv = c\ d\mathrm{T};$$

thus, putting $d\mathrm{T} = 1°\mathrm{F}.$, we have $c = p\ dv$; so that c expresses the external work of expansion under constant pressure in foot-lbs. As Joule's equivalent, J, is 778 foot-lbs. per B.Th.U., we have for dry air :—

$$k_v = 0{\cdot}2374 - \frac{53{\cdot}29}{778} = 0{\cdot}1689.$$

The ratio of k_p to k_v is important in the theory of gas engines, and is usually denoted by γ; thus for dry air :—

$$\gamma = \frac{k_p}{k_v} = 1{\cdot}4056.$$

Isothermal and Adiabatic Expansion.

The two fundamentally important modes of expansion of gases are :—

(1) Isothermal expansion.
(2) Adiabatic expansion.

(1) *Isothermal Expansion.*—When a mass of gas changes volume at constant temperature, the change is described as 'isothermal.' In the case of perfect gases, Eq. (1) shows that in this case the value of the product pv remains constant. If $p_o\ v_o\ \mathrm{T}_o$ be respectively the initial values of pressure, volume, and (abs.) temperature, and v any subsequent simultaneous values, we have in isothermal expansion :—

$$pv = p_o\ v_o = c\ \mathrm{T}_o \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The external work W done in expanding from volume v_o to volume v, is expressed by :—

$$\mathrm{W} = \int_{v_o}^{v} p\ dv \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

as, in isothermal expansion, $pv = p_o\ v_o$, we have $p = \frac{p_o\ v_o}{v}$; hence (4) becomes for this case :—

$$\mathrm{W} = p_o\ v_o \int_{v_o}^{v} \frac{dv}{v} = p_o\ v_o\ \mathrm{Log}_e \frac{v}{v_o} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$\frac{v}{v_o}$ is the volume ratio of expansion, and may be denoted by ρ; thus, from (5), we have in isothermal expansion :—

$$\mathrm{W} = p_o v_o\ \mathrm{Log}_e \rho = c\ T_o\ \mathrm{Log}_e \rho \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

As the internal energy of a perfect gas depends only on its temperature, it follows that in isothermal change the internal energy of the gas remains constant. Hence, in isothermal expansion of a perfect gas the heat given to the expanding gas is the exact equivalent of the

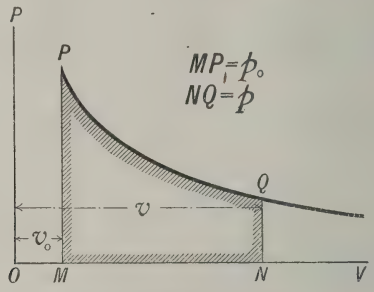

FIG. 1.

external work performed by the gas. And, conversely, in isothermal compression of a perfect gas, the heat that flows from the gas during compression is the exact equivalent of the work done on the gas in compressing it.

Frequently in engineering thermodynamics it is found that actual expansion and compression curves of diagrams can be closely represented by an equation of the form :—

$$pv^n = p_0v_0^n, \text{ a constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where the index n is constant in value.

When $n=1$ we have the particular case of isothermal change, which has just been considered. For all other values of n, the external work done during expansion from volume v_0 to volume v—represented by the hatched area MNQP of fig. 1—is given by :—

$$W = \int_{v_0}^{v} p\,dv = p_0v_0 \int_{v_0}^{v} v^{-n}\,dv, \text{ by Eq. (7)}$$

That is,

$$W = \frac{1}{n-1}\left\{p_0v_0 - pv\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

The expanding substance being assumed a perfect gas, we have $p_0v_0 = cT_0$, and $pv = cT$; hence, in expansion of this type Eq. (8) may also be written :—

$$W = \frac{c}{n-1}\left\{T_0 - T\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Thus if n be greater than unity, expansion is accompanied by a falling temperature. If n be equal to unity the temperature remains constant during expansion. While if n be less than unity expansion is accompanied by a rising temperature. Equation (9) shows further that in expansion of this type the external work done is proportional to the change of temperature of the expanding gas.

Again, the heat expended, H, is equal to the sum of the external work and change of internal energy of the gas ; thus we have :—

$$H = \frac{c}{n-1}(T_0 - T) + k_0(T - T_0)$$

as $c = k_p - k_v$, this becomes on reduction :—

$$H = \frac{n\,k_v - k_p}{n-1}(T - T_v) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

which shows that the heat expended is also proportional to the change of temperature of the expanding gas ; and that the gas expands with an apparent specific heat which is constant, and expressed by $\frac{nk_v - k_p}{n-1}$ B.Th.U. per lb.

(2) *Adiabatic Expansion.*—When a mass of gas changes its volume without any heat communication from without, the changes are said to be adiabatic.

Thus in adiabatic expansion the external work is done wholly at the expense of the internal energy of the expanding gas ; its temperature, and consequently its pressure, rapidly fall during expansion. And contrariwise, in adiabatic compression, the work done in compressing the gas appears as an increase of the internal energy of the gas ; hence, the temperature and consequently the pressure rapidly rise during adiabatic compression.

The adiabatic equation for a perfect gas is at once obtained from Eq. (10). For as, by supposition, there is in this case no heat communication with outside bodies, we have only to put $H = 0$ in Eq. (10), and then deduce the corresponding value of n. But if $H = 0$ we must have $nk_v - k_p = 0$, so that $n = \frac{k_p}{k_v} = \gamma$ in this case.

Hence, the adiabatic equation of a perfect gas is

$$pv^\gamma = p_v v_v^\gamma, \text{ a constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

By aid of Eq. (1) the following two equations are at once obtained from Eq. (11), giving the relation between change of temperature and volume, and change of temperature and pressure respectively, in adiabatic changes :—

$$T = T_v \times \left(\frac{v_v}{v}\right)^{\gamma - 1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

$$T = T_v \times \left(\frac{p}{p_v}\right)^{1 - \frac{1}{\gamma}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

For dry air, as $\gamma = 1{\cdot}4056$, we have accordingly from Eqs. (11) (12) and (13) :—

$$pv^{1{\cdot}4056} = \text{constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

$$T = T_v \times \left(\frac{v_v}{v}\right)^{0{\cdot}4056} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

$$T = T_v \times \left(\frac{p}{p_v}\right)^{0{\cdot}2886} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

Thus, in Diesel engines, the ratio is commonly about 13. Assume the initial temperature of the air to be 70°F., and the pressure to be atmospheric. Then $T_v = 460 + 70 = 530$; and $p = 14{\cdot}7$ lbs. per sq. inch : hence from (15) we have : $T = 530 \times 13^{0{\cdot}4056} = 1500°$F. or $1500 - 460 = 1040°$F. by ordinary scale. This is a sufficiently high temperature to at once ignite the charge of fuel oil on injection. The corresponding pressure from Eq. (14) is 540·8 lbs. per sq. in. abs. = 526 lbs. per sq. in. above atmosphere.

Moisture in Air.

Ordinary air always contains water vapour in greater or less degree, and the presence of this vapour modifies its physical properties.

The pressure of saturated steam formed at temperatures below 212°F. is usually described as the 'vapour tension' of water. In table, page 1640, some data are given relating to the vapour tension of water from 32°F. to 212°F.

When air contains a maximum of water vapour it is said to be saturated. The quantity of moisture depends only upon the temperature, and is estimated by aid of :—

DALTON'S LAW.—The pressure, and consequently the mass of vapour which saturates a given volume, is the same at the same temperature, whether the volume already contains a gas or is vacuous.

Consider a volume of V cubic feet of saturated air at a pressure of P lbs. per sq. in., and temperature t°F. By Dalton's Law this consists of (1) V cubic feet of water vapour at the pressure P' lbs. per sq. in. corresponding to t°F., as in column 1 of above table, together with (2) V cubic feet of dry air at pressure $(P-P')$ lbs. per sq. in., and temperature t°F.

Thus the weight, S, in lbs. of 1,000 cubic feet of saturated air at temperature t°F. and pressure P lbs. per sq. in. is :—

$$S = \frac{1000}{u} + 80{\cdot}73 \times \frac{492}{460+t} \times \frac{P-P'}{P} \quad . \quad . \quad . \quad . \quad . \quad (17)$$

the values of u being given in column 2 of table. If the pressure be atmospheric, P = 14·7, and in this case :—

$$S = \frac{1000}{u} + 80{\cdot}73 \times \frac{492}{460+} \times \frac{14{\cdot}7-P}{14{\cdot}7} \quad . \quad . \quad . \quad . \quad . \quad (18)$$

By aid of Eq. (18), table (p. 1640) has been compiled.

This table may be useful in connection with the heat expended in providing the moisture-laden air supplied to gas producers

SECTION XXX

PART II

GAS ENGINES.

Types of Gas Engines.

The many gas engines in existence may be classified under the following types :—

Type I.—Engines igniting their charge at constant volume, without compression. This type is obsolete ; it included the Lenoir and Hugon.

Type II.—Engines igniting at constant volume without compression, with free piston, and utilisation of vacuum during instroke. This type also is obsolete ; it included the Barsanti, Wenham, and Otto and Langen.

Type III.—Engines igniting at constant pressure, with previous compression of the charge. This type includes the early Brayton and Simon engines, and the modern Diesel engine.

Type IV.—Engines igniting at constant volume, with previous compression. This type includes the very great majority of gas engines in everyday use.

The vast majority of present-day gas engines are operated upon the Otto, Beau de Rochas or four-stroke cycle wherein the sequence of strokes is suction, compression, working, and exhaust ; and in most cases, particularly of British engines, the cylinders are single-acting ; the large double-acting engines have been perfected mainly by the great Continental firms.

A not inconsiderable number, especially of engines of large size, are now built upon the two-stroke cycle, both single and double-acting, and much attention has in recent years been devoted to this type.

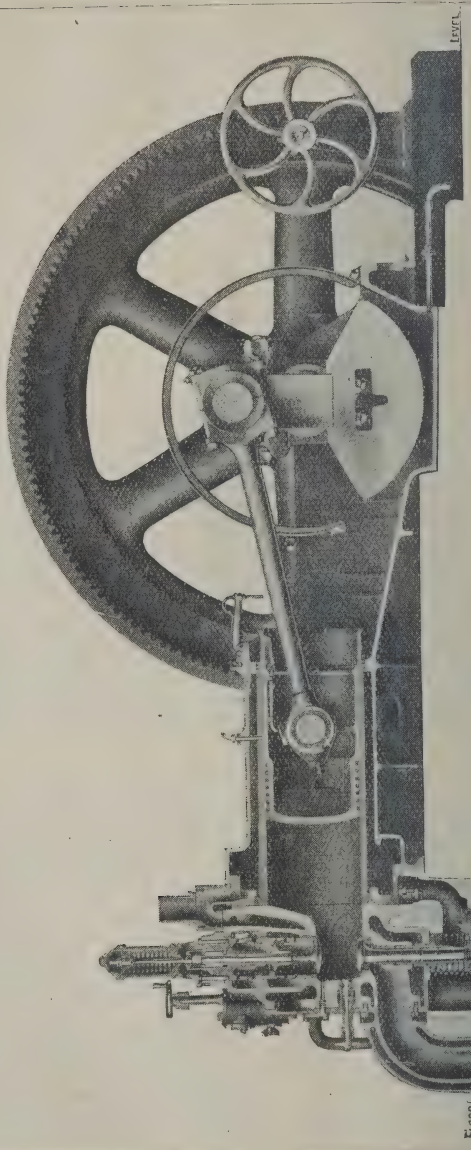
Crossley Gas Engines.

Messrs. Crossley Bros. Ltd., of Openshaw, produce annually a very large number of gas engines of horizontal and vertical design, working on the four-stroke cycle. The range of power is from 3½ to 260 b.h.p., and over 80,000 engines have been supplied.

Horizontal engines of 80 b.h.p. and upwards are also made with two cylinders, the flywheel being mounted on the crankshaft between the cylinders. These double-cylinder engines are specially suitable for all purposes where very steady driving is required, as they run with great regularity. The vertical engines, which are of the four-cylinder high-speed design, are also most suitable for driving dynamos.

The rated powers of the producer-gas engines are obtained when running on gas made from anthracite, bituminous coal, and wood fuel, but are reduced by six per cent. when running on gas made from coke. Working on town gas, the increase in power varies from about 20 per cent. on the small sizes to about 1½ per cent. on the largest size, which develops 130 b.h.p. in one cylinder. The weight of the standard horizontal engine varies from about 2½ to 3 cwts. per b.h.p., and the weight of the double-cylinder engines is about 2 cwts. per b.h.p.

The sizes from 6 b.h.p. and upwards are now all governed on the throttle, giving a smooth drive and low pressures at reduced engine loads. Fig. 2 shows a recent horizontal single-acting four-stroke design ; the girder-type bed and balanced crankshaft will be noted. Other features included are the absence of any liner bolts in the water jackets ; adjustable timing to the electric ignition ; double ring lubrication to the bearings with forced lubrication to the cylinders and other parts ; screw-down producer-gas cock ; hardened steel cams, rollers, and pins ; and a combustion chamber so designed that dust and oil cannot collect at the bottom and form troublesome deposits, but are swept out of the exhaust valve with the burnt gases.



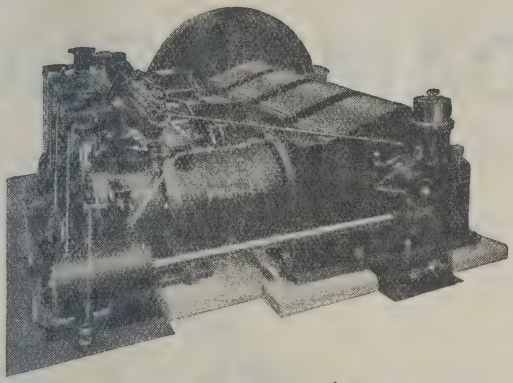


FIG. 2.—Section of Crossley Gas Engine.

The consistent reliability of

PREMIER GAS ENGINES

together with the low consumption of fuel and oil and their complete accessibility, have placed them in a class by themselves.

CAMPBELL

HORIZONTAL GAS ENGINES

Our Horizontal Engines are built with one, two or four Cylinders up to 400 B.H.P.

The design throughout is such as to secure the utmost reliability with high efficiency.

Governing is on our improved 'Variable Quality' system.

SUCTION GAS PLANTS

To work with Anthracite, Bituminous Coal, Coke, Charcoal, Peat, Lignite, Wood, Rice Husks, Cotton Seed, etc., etc.

THE CAMPBELL GAS ENGINE CO., LTD.

HALIFAX, ENGLAND.

F. 1645

Ruston-Hornsby Gas Engines.

The Ruston gas engines and the Hornsby-Stockport engines are now made by Messrs. Ruston & Hornsby, Ltd., Lincoln, the engines being of the horizontal four-stroke cycle type, built in single and multi-cylinder sizes. The range of powers is from 5 to 300 b.h.p. Figure 3 shows one of these engines in conjunction with a Ruston gas-producer. The engines supplied to the oil-fields are capable of working either on gas or on oil, so that the natural gas found when well-sinking can be used, and, when the supply of this diminishes, the engine can be changed over to oil fuel.

The bed-plate is in one piece, carrying the main bearings and cylinder liner, and the thrust of the connecting rod is taken by the bed-plate, as the cylinder is not overhung. The crankshaft is carried by three bearings, the outer bearing being provided to support the weight of the flywheel. Regular running is ensured by having a balanced crank, and by using high compression which allows of a weak charge being fired.

A special automatic device is used for starting the engine on compressed air, and this is also made use of for charging the air-receiver, by means of the engine piston acting as an air-pump

Fig. 3.—Ruston Gas Engine with Suction Producer.

for the time being. Efficient lubrication is provided for all of the bearings, the piston, and the exhaust valves. Governing is effected by the Ruston patent throttle gear which varies the opening of the gas and air inlet-valves to suit the load. This gear consists of a roller forming a movable fulcrum between a lever having a constant angular movement and the upper surface of the inter-valve plunger, the lift of the valve varying directly as the distance of the roller from the lever fulcrum. The roller and the pressing surfaces are of hardened steel, and the movements are arranged so as to avoid slip.

Campbell Gas Engines.

The Campbell Gas Engine Co. Ltd., Halifax, are builders of horizontal and vertical gas engines in the single-cylinder type from 3 to 156 b.h.p. and with two and four cylinders up to 575 b.h.p. The engines are of the four-stroke cycle type, and can be arranged for working on gas or adapted for oil.

The single-cylinder horizontal design has the cylinder well supported by the bed plate, which extends beneath the cylinder as far back as the combustion chamber, and the cylinder liner is removable. Horizontal engines are also made with two cylinders and four cylinders; these engines have the bed plate and crankshaft housing in one casting, to which the cylinders are bolted. The cylinders are also supported on a sole plate resting on the foundation, and the combustion chambers are detachable.

The governing of the horizontal engines is by the hit-and-miss system up to 24 b.h.p., which has the advantage of being simple and gives economical running at all loads. On all larger engines a throttle governor is fitted giving variable-quality governing, in which the piston receives an impulse at every cycle and the compression pressure is the same at all loads. The weights of the horizontal as well as of the vertical engines are about 2½ to 3 cwts. per horse-power.

Ignition is by high-tension magneto up to 10 b.h.p., and above this size low tension with timing adjustments.

Cylinders and pistons are fitted with forced lubrication, crankshaft and camshaft bearings with ring lubrication, and the big-end and small-end connecting-rod bearings with sight-feed automatic lubricators.

The Campbell vertical gas engines are of the enclosed crank-chamber type, and are built with two, three, or four cylinders from 75 to 575 b.h.p. Forced lubrication is fitted to the cylinders and all enclosed bearings. Ignition is by low-tension magneto with separate machine and operating gear to each cylinder. Governing is on the throttle, the governor being driven direct from the crankshaft by its own independent gearing. The vertical engines run at a higher speed than the horizontals, and are well adapted for direct coupling to dynamos owing to their good balance and low coefficient of speed fluctuation. The rotation is so uniform that it is claimed even alternators may be operated in parallel.

National Gas Engines.

Horizontal and vertical four-stroke cycle gas engines are made by the National Gas Engine Co. Ltd., of Ashton-under-Lyne, the power ranging from 1½ to 1,500 b.h.p. Up to 10 b.h.p. the engines are of the horizontal overhung cylinder design; for greater powers a special design of girder bed and supported cylinder is adopted.

The horizontal engines are built in various sizes up to 95 b.h.p. per cylinder. Ignition is by low-tension magneto, a sparking-plug being fitted in the combustion chamber. Governing of the smaller sizes is on the hit-and-miss principle but throttle governing can be supplied if desired, and the larger sizes of engines are fitted with a patent variable admission governing gear.

The National Gas Engine Co.'s vertical engines are of the tandem single-acting design. They are made in two standard parts, known as the 18-in. standard and 24-in. standard; that is, parts suitable for engines having these strokes and the power ranges from 300 to 1,500 b.h.p. The engines are suitable for working on the various gases mentioned above, and the cyclical variation is such that there is no difficulty in running electric alternators in parallel.

A recent test of an engine of this type furnished the following results :—

Engine.—A 750 b.h.p. National Vertical Tandem Single-Acting engine having three cranks and six cylinders, the three upper cylinders being each of 23 ins. bore, and the three lower each of 22 ins. bore. Piston sleeve 6 ins. diameter, stroke 24 ins.

The engine was driven by Mond gas. At full load 6·55 gallons of cooling water were raised 42°F. in temperature per b.h.p. hour, being 27.8 per cent. of the heat evolved by the gas used.

The pistons are unwatered. Forced lubrication is supplied to all parts, the oil pressure being about 20 lbs.

Vickers Gas Engines.

Large gas engines of the horizontal four-stroke cycle type are constructed by Vickers Ltd., Barrow-in-Furness. The engines are double acting, and range from 1,500 b.h.p. in single line tandem cylinders to 5,000 b.h.p. in twin tandem engines.

A number of these engines have been supplied for driving dynamos, alternators, etc. Eight of these engines for the Appleby Iron Co., of Appleby and Frodingham, have cylinders 1,100 mm. dia. by 1,200 mm. stroke, and develop 1,200 kw. when running at 100 r.p.m.

Separate cylinder liners are fitted. The inlet valves are located on top, and the exhaust valves at the bottom of the cylinder; they are operated by shaped rolling levers driven by eccentrics on the half-speed shaft. The crankshaft is forged in one piece and balance weights are fitted. The main bearings are in four parts, lined with white metal, and have self-aligning wedge adjustment. The main bearings of the 1,500 b.h.p. engine are 21 ins. diam. and the piston rod 10·75 ins. diam.; the latter is hollow to convey the cooling water to the pistons.

Governing is on the 'quantity and quality' system, and it is possible to run direct-driven alternators in parallel. Hand adjustment is provided for regulating the speed while running. Separate hand control for gas and air for each end of both cylinders is provided.

Ignition is effected by means of two low-tension 'make and break' ignition plugs in each end of each cylinder. A motor generator delivers current at 70 volts, which is distributed by a rotary wiper, and is fitted at the rear end of the side shaft.

The 1,500 b.h.p. blowing engine runs at 80 r.p.m. and delivers 27,000 cub. ft. of free air per minute against 12·5 lbs. per sq. in. The total weight of this engine is approximately 305 tons.

Hindley Gas Engines.

Messrs. E. S. Hindley & Sons manufacture vertical single-acting four-stroke cycle gas engines in sizes from 10 to 350 b.h.p. of the fast revolution type designed for direct coupling to high-speed machinery as dynamos, centrifugal pumps, fans, etc.

The engines are light and compact; special care has been given to the balancing, and the weight of pistons and connecting-rods has been reduced as much as possible to enable the engines to run freely and quietly at high speeds; being multi-cylindered, and having adequate flywheel inertia, the cyclic variation is small.

Governing is effected by varying the quality of the mixture of gas and air; ignition is by high-tension magneto, with variable timing; frequently high-tension coil ignition is also fitted as a stand-by.

The cylinders are cast in one with the valve-boxes, the construction of the water-jacket being the subject of a patent. The outer water-jacket, the cylinder, and the valve-box form one casting, so that there is no joint to cause trouble. At the same time the special corrugated form of water-jacket permits of unequal expansion between the cylinder walls and the jacket. All joints in the cylinder which are subject to the pressure of the power-stroke are ground-in metal-to-metal joints, no packing being used either in the case of the top cylinder cover, valve cover, or ignition plugs. The connecting-rods are of forged steel, and are so arranged that, together with the pistons, they can be withdrawn through the top cover, which can be easily removed without disconnecting any gear. The crankshaft is of special quality steel, machined from a solid forging, and is not bent or subjected to strain in manufacture. The governor controls the admission of gas, so that compression is practically constant at all loads.

The camshaft runs in three or more bearings, and is driven from the crankshaft by means of gearing, the whole being enclosed in the crankcase. The crankcase is of box section, strongly webbed, and carrying the crankshaft bearings; it is provided with large inspection doors, which give easy access to all the working parts. The lubrication is forced under pressure to all bearings by a valveless oil pump; this system of lubrication ensures economy in oil consumption, which is in some cases as low as ·0002 of a gallon per b.h.p. per hour.

Davey, Paxman & Co.'s Gas Engines.

The Paxman gas engine is of the single-cylinder horizontal type, operating on the four-stroke cycle, and for large powers two engines are coupled with a single crankshaft, having the flywheel between the cylinders. The sizes are given in the subsequent table, and the engine is illustrated in figs. 4 and 5. The powers obtained with coal gas, and with producer gas, are given in the table, the suction producers, suitable for anthracite and coke, being made by Davey, Paxman & Co., Colchester.

Special features of the engines are the shape of the combustion chamber, which gives an excellent combustion of the fuel together with freedom from fracture, and the patented timing arrangement for the spark to facilitate starting, the general design following accepted practice and having supported cylinder with removable liner.

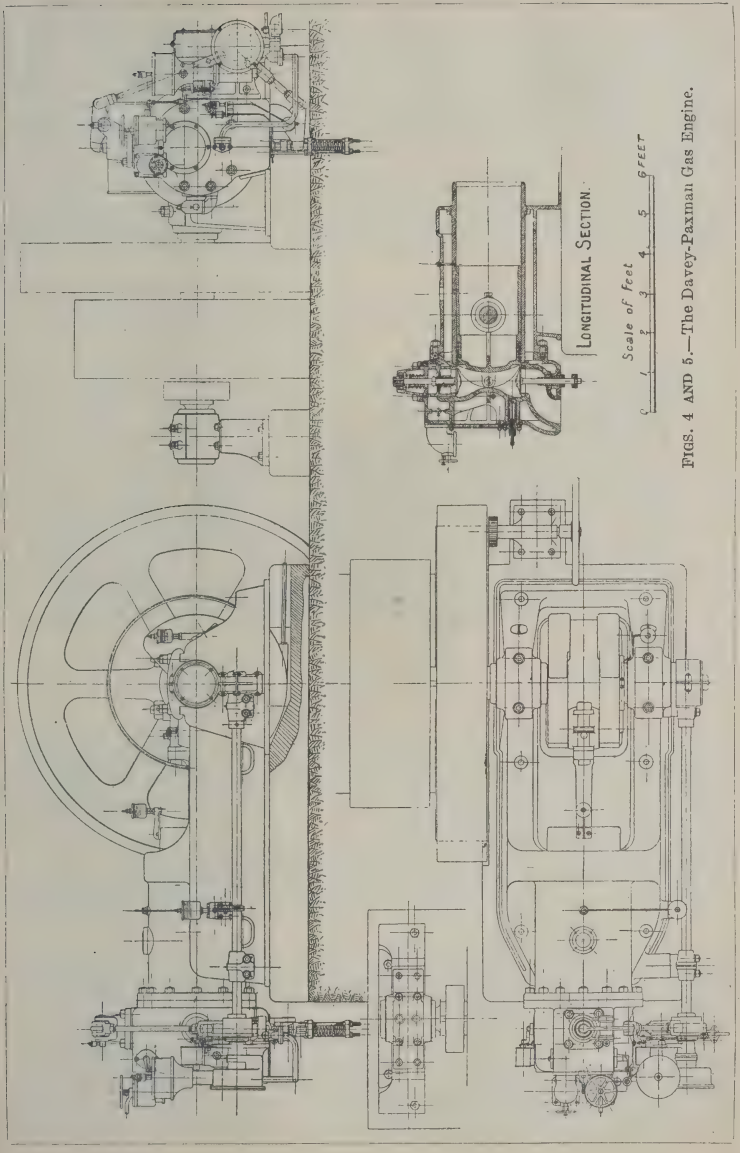
T	175	150	135	160	1	9 0	19	7 0	29	5,500

The flywheel sizes tabulated are as supplied for ordinary industrial service. Any of the standard types given can also be coupled with one flywhee between the two engines.

A large number of Davey, Paxman & Co.'s gas engines are in operation, working on a variety of fuels. The utmost attention has been given to securing reliability, and their design of combustion chamber makes the engines very economical.



FIELDING & PLATT'S GAS ENGINES.

Gas engines of the horizontal four-stroke cycle type are manufactured by Fielding & Platt, Ltd., Gloucester, in various sizes up to 130 b.h.p. For larger powers, two engines are coupled together having a flywheel between the cylinders mounted on the two-throw crankshaft, these engines being made in sizes up to 250 b.h.p.

The cylinder has a separate liner supported throughout its whole length in the water-jacketed extension of the bed. The variable-admission governor controls the opening of the gas-and-air-mixing valve, thereby varying the volume of charge admitted to the cylinder. The stroke of the mixing-valve is directly under the control of the governor, and, although the volume of charge is varied, the ratio of gas and air in the mixture remains practically constant. By this means an explosion takes place every cycle, and it is claimed that, when working with a suction plant, this steady method of drawing the gas ensures a better quality of gas, and avoids the possibility of trouble through insufficient gas under variable loads.

The cylinder jacket and combustion chamber have separate water circulation, and special care has been taken to reduce the number of parts. Ignition is by means of a low-tension magneto, and the ignition plug can be readily removed from the cylinder for examination. The engines are suitable for running on gas produced from a large variety of fuels, and the 'Fielding' suction gas plants have several important features, enabling the plant to be quickly started up and to respond instantly to all varying loads.

The Fielding gas engine installations are extremely simple to operate, and the makers state that any man of ordinary intelligence can be entrusted to work it, as they have made a special study of simplicity.

FIGS. 4 AND 5.—The Davey-Paxman Gas Engine.

Premier Gas Engines.

The Premier Gas Engine Co., Ltd. (*Crossley Brothers, Ltd.*), of Sandiacre, specialise in multi-cylinder gas engines of the horizontal type, ranging in powers from 126 to 1,000 b.h.p. Large numbers of these engines have been installed for all classes of work, including the driving of alternating current generators in parallel. The speeds of the engines are suitable for coupling to electric generators, and the engines have a small cyclic irregularity.

From the sectional view, Fig. 6, the arrangement of the cylinder, combustion chamber, valves, and cam operating gear can be seen. It will be noticed that the breech end and cylinder form one casting, and the usual joint in the combustion space is avoided. This removes any risk of water leaking into the cylinder.

These engines work on the four-stroke cycle and are made in two, three, and four cylinders, bolted to massive beds which support the crankshafts. The cranks are completely covered by oil splash guards, and the main bearings are supplied with oil by a pump, which is of the valveless oscillating type, operated by the side shaft. The cylinders, piston pin, crank pin, and exhaust valve spindles are also lubricated under pressure automatically.

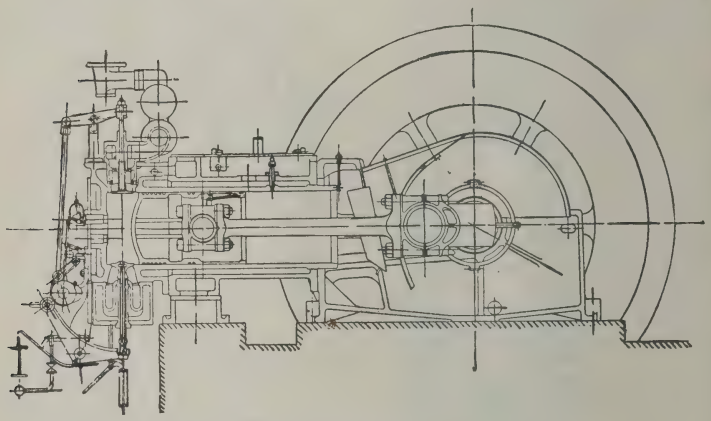


Fig. 6.—Premier Gas Engine.

The valves open directly into the cylinders, the inlet valve being directly over the exhaust valve, a design introduced by the Premier Co. as far back as 1893. A large throttle valve is fitted to control the air supplied to all the cylinders, and can be readily adjusted by hand; in addition, separate throttle valves are fitted on each cylinder. All the valves are operated by a shaft running in self-oiling bearings behind the cylinder, so arranged that the jacket inspection cover can be removed without disturbing it.

Governing is effected by controlling a throttle valve in the gas supply, and the governor is of the high-speed type, powerful and sensitive, driven direct from the crankshaft.

Starting is automatic by means of compressed air, which makes the engines easy to start.

These engines have the advantages of even turning moment, good balancing, forced lubrication, and they occupy little floor space for their power. Very high economy, both in fuel and lubricating oil, is claimed.

As will be seen from the illustration, the Premier gas engine is very accessible, both for cleaning and overhauling, as all of the working parts can be inspected and reached from floor level. This allows of good supervision, and as the piston and connecting-rod can be removed from the crankshaft end of cylinder, this operation can be carried out without disturbing any part of the valve gear or cylinder covers.

For powers of 1,000 b.h.p. and above the Premier Company manufacture a special type of double acting vertical engine. This engine is of the four-stroke type, and therefore with four cylinders there are four impulses per revolution. As there is a compression on every stroke smooth running is obtained as a result of this and also because of the forced lubrication system which supplies oil at a pressure to all motion joints.

The design is suitable for powers of 1,000–2,250 b.h.p. continuous load with four cylinders and one crank, and for twice these loads, 2,000–4,500, with two-crank and eight-cylinder design,

the speeds being from 125 r.p.m. for the smallest to 94 r.p.m. for the largest. A single crank for every four cylinders is one of the greatest innovations of the engine, and the small space required for this type of engine is a valuable characteristic.

It is specially adapted for the generation of electricity at steelworks and blast furnaces, especially where gases are available as a bye-product, and not produced artificially, and the rough usage of a steelworks is more readily resisted by this moderate speed engine.

The Premier Company is now engaged on the designs for some larger engines of the same type, which are to develop 3,000 horse-power per four cylinders.

Tangye Gas Engines.

Horizontal gas engines of the four-stroke cycle type are made by Tangyes, Ltd., Birmingham, in sizes from 3½ to 490 b.h.p. Four designs, AA, X, H, and HT, are supplied, and a large number of engines have been sold.

The smaller sizes of engines have horizontal cylinders bolted to the beds, and the liners are removable. Governing is on the hit-and-miss principle; the AA design have highly sensitive inertia governors; in the X design the governor is of the centrifugal type, arranged so that the speed of the engine can be regulated while running.

Engines of the HT type have the cylinders well supported by the bed, which extends up to the combustion chamber and forms the water-jacket. The cylinder liners are separate and are made of a special hard mixture of cast iron. Governing is on the variable-admission system with Tangye's patent operating gear, which controls the quantity of the charge admitted to the cylinder and an impulse is obtained every cycle.

Ignition is by means of low-tension magneto, the spark being produced in the combustion chamber by means of a mechanically operated make-and-break arrangement, with variable timing device. On the larger sizes the sparking-plug is arranged so that the internal sparking points can be cleaned while the engine is at work. The engines are designed so that they can make long continuous runs; they are very simple to operate and are easily started, compressed-air apparatus being supplied with the larger sizes.

Tangyes were among the first firms to call attention to the fuel economy to be obtained from the use of gas engines with suitable suction gas producers, especially as engines would work on such inferior fuels as wood refuse, etc. The economy may be gathered from the following table which gives the approximate cost of fuel in a plant developing continuously 50 b.h.p. for sixty hours:

Nature of Fuel.	Rate of Fuel Cost.	Consumption per b.h.p. per hour.	Cost of 50 b.h.p. for 60 hours per week.
'Town' gas	2/- per 1,000 cubic ft.	15 cubic ft.	£4 10 0
Anthracite	40/- per ton	·75 lb.	2 0 0
Gas coke	30/- "	1 lb.	2 0 0
Charcoal	40/- "	1½ lbs.	3 7 0
Bituminous non-caking coal	24/- "	1½ lbs.	2 0 0
Wood refuse	Nil	2½ lbs.	Nil

The figures given above are an average, but the cost of running will depend, of course, upon the size of the engine and the relative prices and qualities of the different fuels.

Grice Gas Engines.

The Grice gas engines are made in sizes between 9 and 110 b.h.p. in one cylinder, and from 100–220 b.h.p. with two cylinders, by the Anderson-Grice Co. Ltd., of Carnoustie. The engines are of noteworthy design, as the arrangement of the inlet and exhaust valves side by side below the combustion chamber makes an attractive and very simple appearance.

The engine operates on the four-stroke cycle and there is no cylinder overhang. The whole of the bed, which extends under the cylinder and forms the water-jacket, is solidly supported on foundation. The design is exceptionally substantial and the question of maximum rigidity has been carefully studied. Regular running is obtained by the patent throttle governor, which adjusts the quality and quantity of the mixture according to the load. The gas valve lift is controlled by a small die plate operating between two inclined surfaces.

The inlet and exhaust valves can readily be removed by taking off the cover on the top of the combustion chamber, allowing of immediate access for inspection and cleaning. Low-tension magneto ignition is fitted to all engines, and the usual make-and-break sparking-plug is fitted with variable timing.

The fuel costs of the Grice engine are low, especially when working in conjunction with their producer plants, which are very simple to operate. The generator is designed with a cast-iron

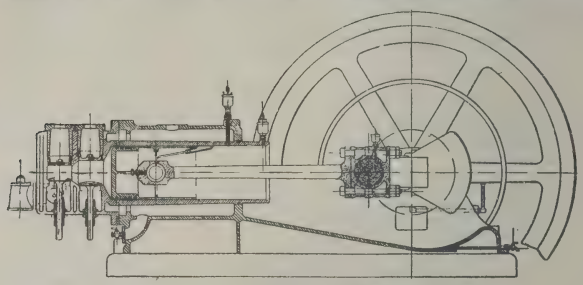

FIG. 7.—Grice Gas Engine—Longitudinal Section.

base and is square in plan, allowing the use of rectangular fire-bricks, which can be laid without skilled labour.

The jackets have large water-spaces, and when the liner is removed both the combustion chamber and cylinder jacket can be inspected. The engines are of very massive construction and the weights of the ordinary type vary from about 2½–3 cwts. per horse-power.

GARDNER GAS ENGINES.

The Gardner engines are made of both vertical and horizontal design and operate on the four-stroke cycle. The range of sizes is from ¾ to 110 b.h.p. Horizontal engines up to 14 b.h.p. can be supplied to work on either town gas, paraffin, or spirit.

The engines are of very neat design and substantially constructed. They give particularly smooth running, and a large number have been supplied.

The small sizes have been specially designed for gaseous and liquid fuels and are substantially constructed in order to make them suitable for heavy commercial duties and long continuous runs, such as for electric lighting, etc. The workmanship and design of even the smallest size are exceptionally high class, as the engines are intended for production in large quantities.

The larger horizontal engines are fitted with single fly-wheel and outer pedestal bearings. The special features are the sensitive centrifugal throttle governor, giving low-speed variation, and the silent-running that is obtained. They are easy to start, economical to work, and have a high efficiency.

In addition, a range of Gardner engines made in twelve sizes, from 10 to 110 b.h.p., have been designed for marine and stationary work. They are supplied for running on town and producer gas, paraffin, spirit, and heavy oils, and are most suitable for marine work, driving electric generators, and for industrial purposes.

PETER BROTHERHOOD GAS ENGINES.

Horizontal engines of the single-cylinder, four-stroke cycle type, developing 10 to 150 b.h.p., are manufactured by Messrs. Peter Brotherhood, Ltd., Peterborough. The engines are made with two cylinders in sizes from 172 to 300 b.h.p. Producer gas plants capable of working on a wide range of fuels are also made by this firm.

The engines are very simple and neat in appearance, being well proportioned. They are easily operated, and there are no parts liable to get out of order. Several patented features are embodied in the design, which make for efficiency and reliability.

The governor is on the variable-admission principle; the charge of gas and air admitted to the cylinder is varied in quantity to suit the load, but there are no cut-outs and the engine receives an impulse every cycle. Special attention has been given to all the working parts of the valve gear, etc., the cams are of hardened steel and the valves are made from nickel steel, alloy steel being used for the exhaust valve lever.

The bed of the engine is formed with the cylinder jacket and supports the cylinder liner throughout its length. The combustion chamber has specially large water-jacket spaces, which are quite accessible for cleaning, it only being necessary to remove a cover.

Ignition is by means of a low-tension magneto, having powerful double magnets; special timing gear is fitted so that the engine can be easily started. The ignition plug is arranged to prevent any possibility of the striking spindle bearings becoming coated with rust or deposit, and patented terminals are used on the plug and magneto.

Positive lubrication has been provided, so that when running the engine requires very little attention. A low-pressure self-starter can be fitted for engines of moderate powers, but, for engines of 100 h.p. and over, air starting is recommended, as with this it is claimed that even the largest engines start up as easily as a steam engine.

A number of improved features have been embodied in the producer, making it very simple to operate and capable of working with all grades of anthracite, coke, charcoal, and other inferior fuels.

Lilleshall Gas Engines.

Gas engines ranging in power from 500 to 4,000 b.h.p. are manufactured by the Lilleshall Co. Ltd., of Oakengates, Shropshire. The engines are of the tandem, horizontal, double-acting, four-stroke cycle type, and a working impulse on every stroke is obtained. A section is shown in fig. 8 of the 2,500 b.h.p. engine, from which the general disposition of parts can be clearly seen.

The Lilleshall Co. have recently introduced a number of important improvements, making for additional strength and reliability. The pistons and rods are, of course, water-cooled, the water supply being at a pressure of from 45 to 65 lbs. per square inch on account of the reciprocating motion of these parts; this is supplied by a pump worked from the crankshaft. For the jackets of the cylinders and covers the water is supplied at a pressure of about 15 lbs. per square inch. Each cylinder is provided with an open tank into which all exit water-pipes deliver, the discharge from each being thus always in view; each exit-pipe is fitted with a thermometer and regulating valve by which the temperature of the cooling water can be maintained at the desired degree.

These engines are installed to a very large extent in iron and steel works and collieries, as well as in electrical power stations.

An output up to 1,500 b.h.p. can be developed in one cylinder, the consumption of heat per b.h.p. hour amounting—at normal output—to about 9,900 B.Th.U.

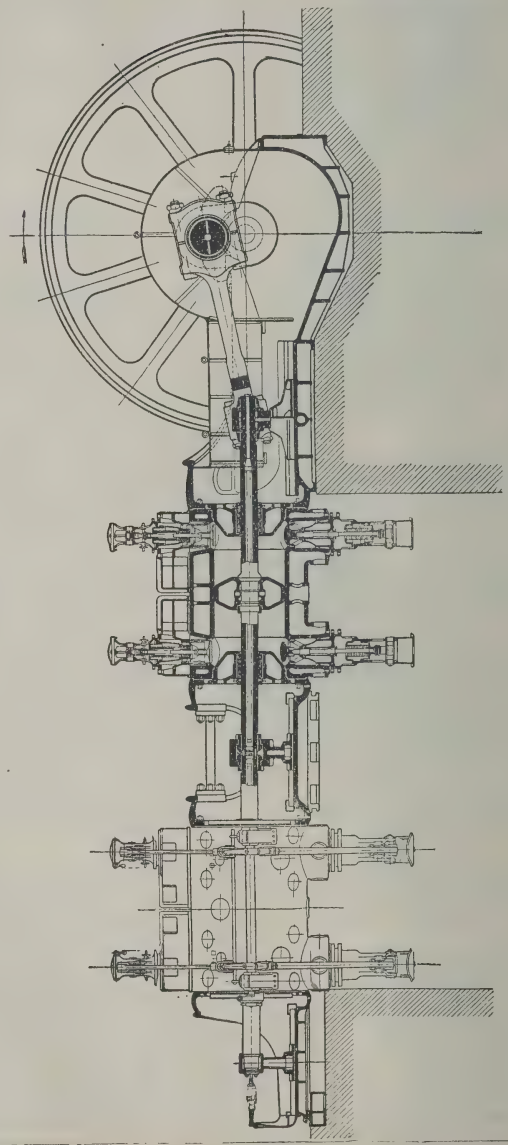
The engines are very strongly constructed, and simple in general arrangement as well as in each individual part. The surface pressures on the moving parts are small, and their lubrication is effected automatically. The frame, cylinder, connecting piece, and rear slide are centrically connected with one another, so that the engine axis is accurately fixed.

The cast-iron cylinders are symmetrically formed, in order to avoid undue strains caused by the heat, and are amply cooled. The cooling-water jackets are easily accessible for purposes of cleaning. In addition to the cylinders, the exhaust-valve seats, the hollow piston rod, and the pistons, are cooled.

The cooling-water consumption amounts per b.h.p. hour to 7·7 gallons at an inlet temperature of 60° F.

The weight of the pistons and piston rod is not carried in the stuffing boxes, but by special crossheads, in the frame, the connecting piece, and the rear slide.

The inlet valve gear consists of a positive action which opens the air valve and gas inlet valve. By means of the governor the valve lift, and consequently the quantity of mixture, is changed according to the engine output. The ignition is effected electrically by a small accumulator battery. The time of ignition can be easily regulated during operation.



By means of compressed air the engines are very easily started.

Alternate-current dynamos driven by these gas engines can be connected in parallel without any trouble.

From tests of a tandem double-acting horizontal four-stroke engine of this type, developing 1,200 b.h.p. on blast-furnace gas, and having cylinders of 33·46 ins. bore with 43·3 ins. stroke, the following results were obtained :—

Test Results from a 1,200 h.p. Engine using Blast-Furnace Gas.

Item.	Quarter Load.	Half Load.	Three-Quarter Load.	Seven-Eighths Load.	Full Load.
Duration in minutes	33	28	29	26·8	25·33

Lilleshall Gas Engine—Longitudinal Section.

Fig. 8.

Galloway Gas Engines.

Messrs. Galloways, Ltd., Manchester, took up in 1909 the manufacture of the large gas engines of the Ehrhardt and Sehmer type and have since introduced many improvements. The range of powers is given in the following table :—

Electric Generating Engine.

Cylinder Diameter.		Stroke.		R.P.M.	Normal continuous B.H.P.	Max. continuous B.H.P.	Max. Momentary B.H.P.	Blowing Engines.	
Mm.	Ins.	Mm.	Ins.					Max. R.P.M.	Normal B.H.P. at Max. R.P.M.
950	37·4	1,100	43·3	107	1,200	1,300	1,440	95	1,060
1,050	41·4	1,200	47·3	94	1,400	1,540	1,680	85	1,270
1,150	45·3	1,300	51·2	94	1,850	2,000	2,200	85	1,650
1,250	49·2	1,400	55·1	94	2,320	2,550	2,780	80	1,970

The standard Galloway engine is tandem double-acting four-stroke cycle with horizontal cylinders. For sizes over 3,000 h.p. a twin tandem engine is adopted, i.e. two lines of cylinders working on two cranks on a common crankshaft. The engines are designed to run on blast-furnace gas, coke-oven gas, and producer gas.

The special features of the engine are : (*a*) Patented built-up cylinder. The barrel is in two main parts, and the water-jacket is formed by a steel plate casing. Both casting and expansion stresses are eliminated. (*b*) Patent piston with internal diagonal ribs to prevent bending stresses. (*c*) Patented method of fixing piston on rod, allowing of longitudinal adjustment. (*d*) Improved piston rod packing. (*e*) Patented water-cooled exhaust valve box and seat, the exhaust valve itself not being water-cooled. (*f*) Simplified valve gear. (*g*) Powerful servo-motor governor.

The piston and rod are water-cooled and all water discharges are open for inspection purposes. The engine is of simple and strong construction, arranged for ease of accurate alignment, and free to expand when working without distortion or stress. All water-jackets and internal parts are easily accessible for inspection and cleaning.

Experience with a recent installation of these engines showed that they can be relied upon to run for 6,000 hours without overhauling, and on inspection after that period the cylinders and piston rings were found to be in excellent condition, and all the main working parts free from appreciable wear.

Browett-Lindley Gas Engines.

Messrs. Browett-Lindley & Co. Ltd., Patricroft, have developed a vertical gas engine of the ordinary four-stroke cycle type for direct coupling to electric generators and other purposes.

The engines are made with two, three, four, and six cylinders ranging in power from 60 to 750 b.h.p. A number of these engines have been supplied for such industrial work as driving mills, etc., and are very satisfactory in operation.

The sectional view of a four-cylinder engine given in fig. 9 shows the accessibility of these vertical engines. The design allows the piston to be easily removed and the cylinder covers are quite free from valves or other gear. The valve gear is quite simple, hardened steel cams are used to operate the valves and the cam roller guides are of the piston type. Both the inlet and exhaust valves can be readily removed for inspection when desired, and the latter are provided with renewable seats.

The governor fitted to these engines is very powerful and the working parts are lubricated by oil under pressure, so that reliable operation can always be expected. Forced lubrication is provided for all of the principal bearings on the engine, the oil being supplied under pressure from a valveless pump.

Features of the Browett-Lindley engines are the simple design, the absolute freedom from back firing, and the equal distribution of power to each cylinder at all loads. A large number of installations are at work on town and producer gas, and very economical running is obtained.

The lowest heat consumption recorded with these engines is 9,540 B.Th.Us. per b.h.p., and the highest 10,260. The mechanical efficiency of the engines is about 85 per cent. A cyclical regularity suitable for driving alternators in parallel can be obtained without the need of excessively heavy flywheels. The weights of the standard engines vary from about 2 to 2½ cwts. per horse-power.

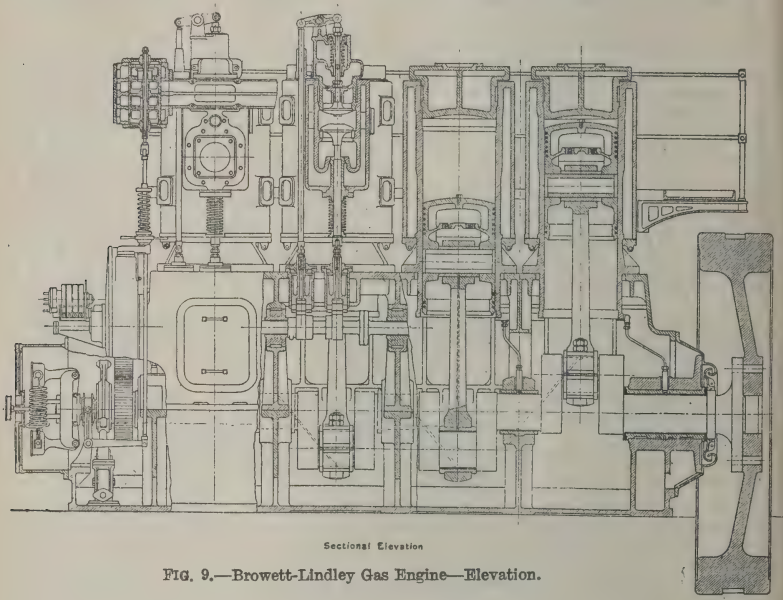

FIG. 9.—Browett-Lindley Gas Engine—Elevation.

FULLAGAR GAS ENGINES.

An important development of the opposed piston type of engine appears in the recent two-stroke design of the late Mr. H. F. Fullagar (fig. 10).

Each 'unit' comprises *two* open-ended cylinders placed side by side; each cylinder contains two pistons as in the Oechelhauser design, but in the Fullagar design opposite pistons of each cylinder are connected by diaginal rods as indicated, thus dispensing altogether with return connecting rods, while a *two*-throw crankshaft suffices for the four pistons of the unit.

The obliquity of the tie-rods is small, and the side thrusts due to this obliquity are taken by the crossheads and guides shown above A and C; it will be seen that pistons A and D are connected, as also are B and C, by long diagonal rods. An explosion between A and B drives B downwards, thus actuating the left-hand crank, and simultaneously drives A upwards, thus actuating the right-hand crank through the tie-rod connecting A and D; the crankshaft accordingly receives as the result of each explosion a practically pure turning couple, or 'torque.' It will also be observed that as the cylinders are open-ended there are no vertical stresses set up in the framing of the engine when running; hence the Fullagar engine may be expected to be light in relation to its power output.

The engine works on the two-stroke cycle, and thus each cylinder furnishes one working impulse per revolution. As a unit includes two cylinders, each *unit* furnishes *two* working impulses per revolution. Stationary engines for land installations usually comprise two or three units, furnishing four or six working impulses per revolution. In the case of great power, or where height is limited and the speed must be high, as e.g. in submarines, engines would consist of even four units. The usual inlet and exhaust ports are indicated in fig. 10; the charge is supplied at a pressure of between 2 and 3 lbs. per sq. in. by gas and air pumps, which may be driven by the engine.

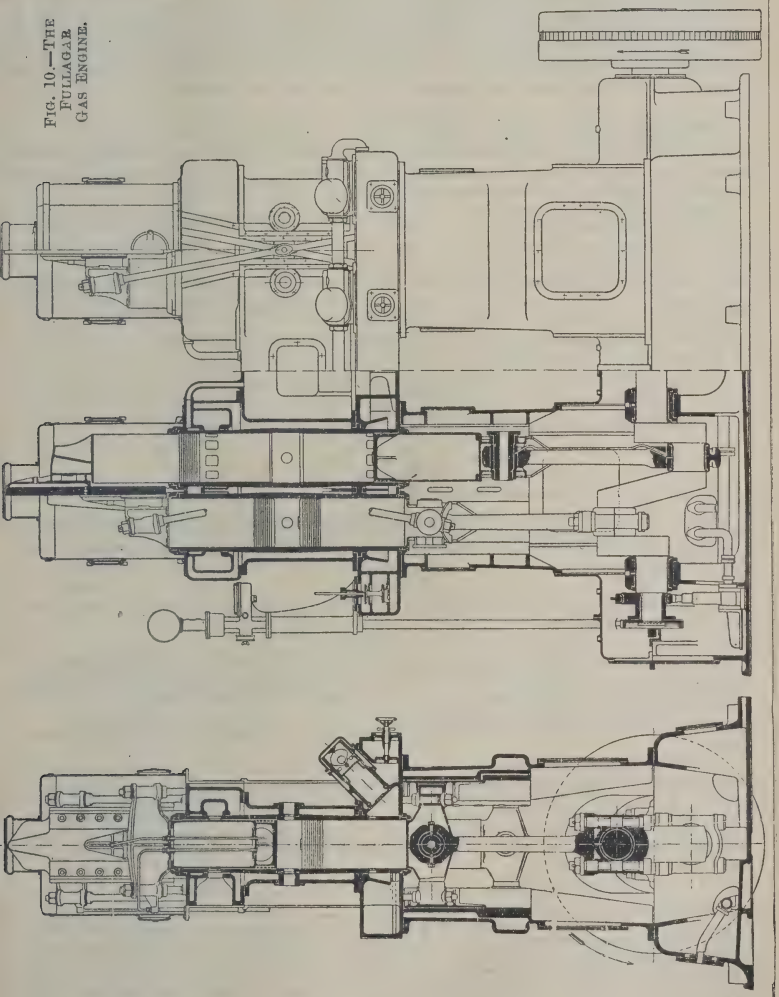

FIG. 10.—THE FULLAGAR GAS ENGINE.

The upper guides are modified to act as scavenge air pumps, the upper crosshead being fitted to operate as pistons, unless separately driven blowers or pumps are required.

The Fullagar engine may be arranged to run in either direction ; it is only necessary to alter the timing of the fuel admission valve and the ignition.

An experimental gas engine of 550 b.h.p., constructed by Messrs. W. H. Allen, of Bedford, to the designs of the Fullagar Engine Ltd., has been installed at the Newcastle Electricity Supply Company's station at Gateshead-on-Tyne ; this engine consists of *two* units, the cylinders being of 12 ins. bore, while each piston has a stroke of 18 ins. The normal speed is 250 revolutions per minute, corresponding to a piston speed of $\frac{250 \times 18}{6} = 750$ ft. per minute.

Sectional views of this engine are given in fig. 10.

If p denote the mean effective pressure in lbs. per sq. in. within a cylinder during the working stroke, then the work done upon *each* piston in foot-lbs. is $p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$. Where d and s are respectively the bore and piston stroke, in inches.

As each cylinder contains two pistons, the work done by each cylinder per working stroke is $2 \times p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$ foot-lbs., and this is the work done per cylinder per revolution of the crankshaft. Now a unit comprises two cylinders, and hence the work done by a unit per crankshaft revolution is $2 \times 2 \times p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$ foot-lbs., that is $\frac{\pi}{12} \cdot pd^2s$ foot-lbs. Accordingly if the crankshaft makes n revs. per minute, the indicated horse-power is given by :—

$$\text{I.H.P.} = \frac{1}{33{,}000} \cdot \frac{\pi}{12} \cdot pd^2sn \text{ per unit} \quad . \quad . \quad . \quad . \quad . \quad (19).$$

As the Gateshead engine includes two units, its i.h.p. will be twice this, or :—

$$\text{I.H.P.} = \frac{\pi}{33{,}000 \times 6} \cdot p.d^2sn \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (20).$$

Though the mechanical and thermal efficiency of this type of engine is high, the ratio of $\frac{\text{B.H.P.}}{\text{I.H.P.}}$ on the experimental engine was only about 0·8, as for experimental purposes the air blower and gas pumps were of a somewhat temporary character ; hence 550 b.h.p. corresponds to $\frac{550}{0{\cdot}8} = 690$ i.h.p. roundly.

Putting 690 for i.h.p., 250 for n, 12 for d, and 18 for s, in Eq. 20 we get as the value of the mean effective pressure :—

$$p = 67 \text{ lbs. per sq. in.}$$

A 30-hour test by Prof. Hopkinson showed that this engine has an overall thermal efficiency from heat supplied to b.h.p., of 30 per cent., while the indicated thermal efficiency attains the value 37·6 per cent., the difference being due to the somewhat inefficient pumps.

The weight of the engine, including flywheel, is roundly 21½ tons: this corresponds to only about 87½ lbs. per b.h.p., which is much lighter than other stationary gas engines of the same power.

A 2,000 h.p. engine, constructed by Messrs. Belliss & Morcom, Ltd., of Birmingham, to the designs of the Fullagar Engine Ltd., of Gateshead, was started during 1918 in a Waste Heat Station on the North-East Coast, using coke-oven gas of a calorific value of about 440 B.Th.U. per cubic foot (net value). This engine has six cylinders, i.e. three Fullagar engine units with 12 pistons. The cylinders are 18-inch bore and 27-inch stroke, the speed being 171·4 r.p.m. The engine is of the totally enclosed forced lubrication type, the overall dimensions over engine and alternator being :—

Length, 38 ft. 7½ ins. Breadth, 15 ft. 3½ ins. Height, 21 ft.

The approximate weight of the engine, including all auxiliaries but without alternator, is 110 tons. The piston heads are oil-cooled and scavenge air is supplied by a separate electrically-driven blower, the gas-charging pumps being coupled directly to the crankshaft of the engine. The preliminary full load trials have shown a gas consumption of under 30 cubic feet per kilowatt hour, with an electrical output of 1,250 k.w. net at the generator terminals (i.e. after deducting the amount of power required by all auxiliaries). The direct-coupled alternator supplies electricity to the Newcastle Electricity Supply Company's system.

The Fullagar system is being developed for use with liquid fuel by Messrs. Cammell, Laird & Co. Ltd., of Birkenhead, John Brown & Co. Ltd., David Rowan & Co. Ltd., Dunsmuir & Jackson, Ltd., and Palmer's Shipbuilding and Iron Co. Ltd. (*Merz & McLellan.*)

(See also Section XXXIII.)

Other Gas Engine Makers.

Among other manufacturers may be mentioned Messrs. Robson of Shipley, who build a number of horizontal engines, the Anderson Foundry Co., Glasgow, and Bates & Co., Denton. In addition there are a number of oil engine makers who developed their engines, under stress of war conditions, to use town and producer gas instead of oil, when the latter was so difficult to obtain.

Marine Gas Engines.

A certain number of gas engines have been built for marine work in Holland and in America, but very little has been done in Great Britain, although Messrs. Hindley, London and Bourton, Dorset, have constructed engines for such purposes. Marine gas engines are also made by Messrs. Gardner.

In 1919, ships propelled by gas engines first crossed the Atlantic. One, the *Bessie A. White*, is of a net tonnage of 594 tons, and has a 200 b.h.p. gas engine with suction producer. Another vessel laden with 1,400 tons of lumber propelled by a 200 b.h.p. engine made a most successful crossing.

The *Wilhelmina* is one of the largest ships fitted with gas engines, this being propelled by a 350 b.h.p. gas engine, and two suction producers are installed. The American plants usually consist of Wolverine engines and Galusha producers.

The type of marine gas engine most commonly employed is the Van Rennes, built in Holland, but this has not been manufactured in sizes beyond about 200 i.h.p. The 150 i.h.p. four-cylinder engine, of which many examples have been built for coastal cargo-carrying boats, has a cylinder bore of 290 millimetres and a stroke of 300 millimetres, the speed of revolution being 300 per minute. The compression pressure adopted is 150 lbs. per square inch and the mean effective pressure is about 95 lbs. per square inch. The fuel consumption is approximately 1 lb. of anthracite per b.h.p. hour. The motors are directly reversible.

Prices and Weights of Gas Engines.

The prices and weights of gas engines vary considerably, depending on the type and design, but may be taken as from about 15*l.* to over 20*l.* per horse-power at the makers' works. The weight is largely affected by the type and design, engines being single or multi-cylindered, slow speed or high speed, horizontal or vertical, the different designs being necessary to suit the various requirements.

Thermal Efficiency of Gas Engines.

The brake thermal efficiency of four-stroke gas engines has risen from 14 per cent. in 1812 to 32 per cent. in 1908; the following table from Sir Dugald Clerk ('The Gas, Petrol, and Oil Engine,' p. 243) illustrates the rise in efficiency:—

Indicated and Brake Thermal Efficiencies of Four-Stroke Gas Engines from 1882 to 1908.

(*Sir Dugald Clerk, F.R.S.*)

Year.	Experimenter.	Engine.	Bore & Stroke. inches.	Efficiencies per Cent.		
				Mech.	Indic. Thermal.	Brake Thermal.
1882	Slaby	Deutz	6·75 × 13·7	87·6	16	14
1884	Thurston	Crossley	8·5 × 14	84·2	17	14·3
1888	Soc. Arts	Crossley	9·5 × 18	86·1	22	18·9
1888	Soc. Arts	Griffin (6 cycle)	9·02 × 14	80·9	21	17
1888	Kennedy	Beck (6 cycle)	7·5 × 15	87·3	21	18·3
1892	Capper	Crossley	8·5 × 18	82·0	22·8	17·4
1898	Robinson	National	10 × 18	87·0	28·7	25
1900	Humphrey	Crossley	26 × 36	83·0	31	25·7
1900	Witz	Cockerill	51·2 × 55·1	81·7	28	22·9
1905	Inst. C. E.	National	14 × 22	85·5	35	29·9
1907	Burstall	Premier	16 × 24	77·1	41·5	32
1908	Hopkinson	Crossley	11·5 × 21	87·5	36·8	32·2

In tests made on a Crossley-Otto engine in 1882, 1 i.h.p. hour was obtained with an expenditure of 23·7 cubic feet of London gas, while at the Society of Arts trials, held in 1888, a Crossley engine consumed 20·55 cubic feet per i.h.p. hour. Sir Dugald Clerk found, in 1894, when testing a Crossley engine, that the consumption of gas (Openshaw) per i.h.p. hour was as low as 14·5 cubic feet.

At the present time it may be taken that the consumption of town gas per b.h.p. hour at full load varies from 15 cubic feet to 25 cubic feet per hour, according to the size of the engine, and also according to the heating value of the gas. In a test carried out by J. H. Greenhill, of Belfast, on a Stockport gas engine, the gas consumption was 16·83 cubic feet per b.h.p. hour, this being obtained on a 50 b.p.h. engine, which was not being worked up to its full capacity.

The increased efficiency that has been obtained in the best-known forms of engines is probably due to greater compression of the gas before it enters the cylinder, and to some lesser extent to improved means of displacing the burned gases from the cylinders.

Large stationary gas engines are now very commonly of the horizontal tandem double-acting four-stroke type, as with this arrangement a working impulse is obtained at every stroke. Pistons and piston-rods are of course always water-cooled in such engines.

Piston speed in large gas engines has reached 800 to 850 feet per minute. Mean pressures of 85 to 95 lbs. per sq. in. can be obtained in the cylinder with gas of 110 B.Th.U., though engines are usually rated on an assumed 70 lbs. only.

Gas Engine Starters.

Large gas engines are very usually started by means of compressed air pumped by the engine, when running, into a reservoir. They may be started by means of a small gas engine, after the fashion of the barring engine for steam-engines. This small engine must be able to compress the charge of the large cylinder or one of them sufficiently to ignite; or gas and air may be pumped into the cylinder by a small engine and ignited just as the engine is turned off its dead point.

The Wells Starter.—The Wells Bros. starter consists of a small hand-pump fitted at the rear end of the combustion chamber. The action of this pump is to force gas into the cylinder, the crank of the engine being already fixed in the forward position; the action of a valve then permits the pumping of air into the cylinder, and upon the proper mixture being obtained the charge is ignited by ordinary means.

The Clerk-Lanchester Starter.—The action of this starter depends upon a preliminary explosion in a separate vessel, which forces a compressed mixture of gas and air into the engine cylinder which is then exploded.

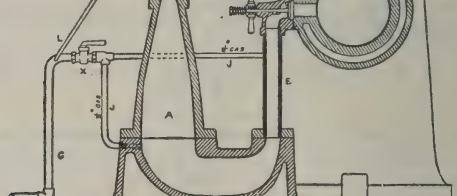

FIG. 11.—The Clerk-Lanchester Starter.

A (fig. 11) is a chamber outside and separate from the engine, and of a capacity rather greater than that of the cylinder, with which it is connected by a pipe E and check valve W. The crank being set at about 15°, gas is turned on by a tap X from the gas main G, and flows into the chamber by the pipe J, mingling with the air therein and forming an explosive mixture. At the same time gas flows into the chamber by the pipe shown. When the mixture is so far formed as to be inflammable it lights at the jet Y, and a little later becomes of sufficient explosive strength. The tap X is then closed, and, the ejecting pressure ceasing, the flame at Y shoots back, ignites the gaseous mixture in the chamber, and this forces the gas in E into the cylinder under a pressure of about 50 lbs. per square inch, and forms there a compressed mixture which, on ignition, gives an average pressure in the cylinder of about 85 lbs. per square inch, and starts the engine and its load.

THE GAS, PETROL, & OIL ENGINE

VOLUME II.

THE GAS, PETROL AND OIL ENGINE IN PRACTICE.

A Complete Treatise on the 'Explosion' Engine. 838 pp. and 481 Illustrations.

BY

Sir DUGALD CLERK, D.Sc., F.R.S., M.Inst.C.E.

Member of Council of the Institution of Mechanical Engineers; Vice-Chairman of the Royal Automobile Club and Chairman of the Expert and Technical Committee; Member of Council of the Royal Society of Arts, etc.

Manufacturers and Specialists in

HIGH-CLASS SCIENTIFIC MACHINERY

Specialities

AIR FILTERS.	For the ventilation of Turbo-Alternators, Generators, Air Compressors and Diesel Engines, etc.
AIR COOLERS.	For the ventilation of Cinemas, Hotels, Workshops, Offices and Mines; also for filtering and extracting micro-organisms in Breweries.
AIR HUMIDIFIERS.	For the humidification of air in Textile and Tobacco Factories, etc.
AIR DEHUMIDIFIERS.	For the ventilation of Ammunition Factories in humid tropical climates; also for Doping Shops in Aeroplane Works, etc.
DYNAMOMETERS.	For rapidly ascertaining the exact B.H.P. of any description of Engine.
ELECTRIC TRUCKS.	For use on Railway Platforms and Docks; also for General Workshop Haulage purposes.
OIL COOLERS.	For cooling the oil of quenching tanks in the Heat Treatment of Steel.
REFUSE DESTRUCTORS.	For the Hygienic disposal of Towns' Refuse with the maximum production of steam.
REFRIGERATING MACHINERY.	For Ice-Making and Cold Storage Equipment.
STRUCTURAL STEELWORK.	For Bridges, Steel Framed Buildings, Piers, etc.
WATER COOLERS.	For cooling the circulating water of Internal Combustion Engines, Air Compressors, Refrigerating Plants, etc. Also general Industrial purposes.

F. 1661

The Fielding and Platt Starter.—Arranged in close proximity to the engine is an air receiver, into which air is pumped under pressure. After gas has been admitted into the engine cylinder, indicated by a flame at a junction pipe, compressed air is admitted into the cylinder from the receiver, and the mixture is ignited at the moment of combination.

The Tangye Starter.—The action of this starter depends upon a previous mixture of air and gas in a separate receptacle, which is passed into the engine cylinder and there exploded.

The Simplex Starter.—A simple method of starting a gas engine is that used in the 'Simplex' gas engine. In this engine an explosive mixture enters the cylinder during the third or expansion stroke. Therefore, to set the engine in motion it is necessary to turn the flywheel by hand until the piston has moved through three-quarters of its second forward stroke : a mixture then enters the cylinder owing to the vacuum caused by the forward movement. The flywheel is then reversed, which has the effect of compressing the mixture, and the electric current (which is the ignition method used in this engine) is turned on and the whole charge is exploded. Although the explosion is practically one of low pressure, it is sufficient to start the engine on its work.

In engines considerably above 100 h.p. a small gas engine may be used as a starter.

Cooling Water for Internal Combustion Engines.

With stationary engines a cooling water tank or reservoir is usually provided, and in such cases the loss by evaporation varies from 0·2 to 0·4 gallon per b.h.p. hour ; with large gas engines it is usual to employ cooling towers. The water is pumped from a well through the engine jackets, etc., and passes thence to the top of the tower ; falling to the bottom, it returns to the well at but little above the atmospheric temperature. With a cooling tower the loss by evaporation is greater than with a cooling tank, and commonly amounts to from 0·4 to 0·5 gallon per b.h.p. hour. From 30 to 35 gallons of cooling tank capacity is required per b.h.p.

The 'Heenan' Water Cooler (p. 1107) is particularly suitable for these installations, and in addition to occupying small space has the advantage that it consumes only approximately 0·1 to 0·2 gallon of water per b.h.p. hour.

The ordinary standard sizes of these machines vary in capacity from 625 gallons of water per hour up to 55,000 gallons per hour, which the machines are capable of cooling from 120° down to 90° F. under temperate climatic conditions.

As an example, a *medium* size cooler of the type in question is capable of dealing with the following problems and providing the corresponding water temperatures :

Application.	Quantity g.p.h.	Water Temperatures.	Heat extracted per Hour.
1. Petrol engines and dynamometers . .	10,000	170°/100° F.	7 million B.Th.U.
2. Gas, oil, and Diesel engines . . .	,,	120°/90° F.	3 ,, ,,
3. Steam-engine condensers . . .	,,	105°/85° F.	2 ,, ,,
4. Air compressors	,,	85/°75°.F	1 ,, ,,
5. Refrigerating plant	,,	72°/67° F.	500,000 B.Th.U.

DATA RELATING TO COOLING WATER USED IN INTERNAL COMBUSTION ENGINES.

Type of Engine.	Bore and Stroke. Ins.	B.H.P.	Cooling Water Temperatures.			Gallons circulated through Jackets, etc., per B.H.P. hour.	B.Th.U. removed by cooling Water per B.H.P. hour.
			Inlet. °F.	Outlet. °F.	Rise of Temp. °F.		
Normal petrol car engines	—	15 to 75	160	200	40	7·5	3,000
Diesel, 3-cyl.	17·75 × 27	360	54	103	49	5·62	2,750
Diesel, 1-cyl.	11·8×18·1	40	60	100	40	6·25	2,500
Oechelhauser	26·5×37·5	500	72	108	36	5·9	2,125
Nuremberg double-acting tandem	33·5×43·3	1,200	60	100	40	7·5	3,000
National single-cyl. horizontal	22·5×30	140	60	140	80	3·5	2,800
National 6-cyl. tandem vertical	22×24	750	58	100	42	6·5	2,730

The water necessary for cooling the pistons and valves is also included in this table in the cases of engines so provided.

Rosseline.

This medium (*Boilerine, Ltd.*) is for the purpose of obviating the incrustation which takes place in water-jackets when salts are present in the cooling water. There are no acids in the preparation, so that joints or attachments cannot sustain any injury. Where scale is already in existence, the action of Rosseline is to cause it to flake and crumble. An average of a quarter pound of Rosseline per brake h.p. per week should be used, the proportion being one pound per 1,000 gallons of water, the approximate quantity of water used to keep a cylinder cool being four gallons per b.h.p. per hour.

Parts of Gas Engines.

In the following formulæ (mainly from Guldner), a maximum explosion pressure of 350 lbs. per square inch is implied.

1. *Cylinders* are of hard, close-grained cast iron; for the inner wall (i.e. working barrel) the working stress may be taken in design at 1,500 lbs. per sq. in. to reduce wall thickness and distortion under heat. If d be the cylinder bore, in inches, and t the wall thickness, then :—

$$t = \cdot 047\ d + \cdot 375 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

the ·375 being added as an allowance for reboring, etc. Cylinders up to about 8 ins. bore may have cylinder walls not less than $\frac{11}{16}$ in. thick if cast in one, or $\frac{5}{8}$ in. if with separate working barrels. For bores of 24 ins. and above, the wall thickness may be diminished gradually, or by steps, until at the open end it becomes :—

$$t = \cdot 02\ d + 0 \cdot 5 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

2. *Pistons* are of close-grained cast iron; in large engines cast steel is sometimes used. Piston rings are of medium hard, but not very brittle, cast iron. The rings are usually parallel and are of the Ramsbottom type.

3. *Gudgeon, or wrist pins* are usually of steel with a hardened outer surface; the diameter δ may be estimated from the formulæ :—

$$\delta = 0 \cdot 35 \sqrt[3]{d^2 l_o} \text{ ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

where l_o is the distance from centre to centre of the gudgeon pin lugs, in inches. The intensity of bearing pressure at the moment of explosion should not exceed about 1,800 lbs. per sq. in. of projected area of bearing; this leads to the formula for the length, l, of gudgeon bearing :—

$$l = 0 \cdot 15 \frac{d^2}{\delta} \text{ ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

The gudgeon bush is of phosphor bronze; sometimes white-metal lined in larger sizes.

4. *Connecting Rods* in small engines are usually drop-forgings of mild steel; in large engines steel forgings machined all over are used. Connecting rods are treated in calculations as long columns supported at the ends; a factor of safety of 12 is usual; Euler's formula then leads to the result that the full diameter, $\triangle$, of a rod of circular section may be :—

$$\triangle = 0 \cdot 128 \sqrt{d\,\mathrm{L}} \text{ ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

where L is the length of the rod in inches. Towards the gudgeon end, the diameter may be diminished to ·9 or ·8 $\triangle$. The big end of the connecting rod is very commonly of marine type; when of more than about 5 ins. diameter this bearing is usually of cast iron or cast steel, white-metal lined; for smaller sizes bronze is general.

5. *Crankshafts.*—For large engines high-grade steel forgings with an u.t.s. of at least 70,000 lbs. per sq. in. and 20 per cent. ductility in 8 ins.; or open-hearth steel of u.t.s. at least 65,000 lbs. per sq. in. and 18–20 per cent. elongation in 8 ins. may be used. Recently, in special cases, nickel steel has been adopted with an u.t.s. of about 98,000 lbs. per sq. in. and 21 per cent. elongation in 8 ins.

For ordinary steels the allowable working stress is about 12,000 lbs. per sq. in. If s be the stroke, in inches, then H. Allen gives for the crankshaft diameter, D :—

$$\mathrm{D} = 0 \cdot 42 \sqrt[3]{d^2 s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

With the higher pressures occurring in engines of the Diesel type (see p. 1667) the constant 0·42 must be increased to 0·52 in this equation.

Crank-pin diameter may be about 1·1 times the crankshaft diameter; the length should be about $0 \cdot 18 \frac{d^2}{\mathrm{D}}$ ins. The bearing pressure in crankshaft bearings should be about 400 lbs. per sq. in. of projected area of bearing.

The crank web may have a depth of 1·33 to 1·66 D and a thickness of 0·85 to 0·55 D.

Valves of Internal Combustion Engines.

The valves of present-day internal combustion engines of all kinds are practically all of the 'Poppet' or 'Mushroom' type. In small sizes the valves and stems are in one piece, and usually either of medium carbon steel or nickel steel. Large valves, especially when water-cooled, have cast-iron discs and medium carbon steel stems; such valves in some cases attain large dimensions, the Siegener Co., for example, having built Koërting type engines with valves 19·68 ins. in diameter and a lift of 3·14 ins. Valve cages and seats are of hard close-grained cast iron. Inlet valves are sometimes automatic; exhausts must be mechanically operated. It is preferable to place valves with their axes vertical whenever possible. The mean velocity of gas through the valves is 5,000 to 6,000 ft. per minute in good practice.

Flywheels.

6. *Flywheels* when of cast iron in one piece should not have a rim velocity exceeding 100 ft. per second. If b be the breadth, and R and r the outer and inner radii of the rim, all in feet, and if n denote the number of revolutions per minute, then the kinetic energy, or stored work in the rim, is:—

$$\text{Kinetic energy} = 0{\cdot}1205\,(R^4 - r^4)\,b\,n^2. \quad \text{Foot-lbs.} \quad (27)$$

The 'Cyclic Irregularity' or 'Coefficient of Fluctuation of Speed' is the ratio borne by the difference between the maximum and minimum angular velocity of the crankshaft in any one complete cycle, to its mean angular velocity.

The Cyclic Irregularity is often denoted by $\frac{1}{m}$; its permissible value varies with the nature of the work to be done by the engine; the following are a few typical cases:—

Nature of Work.	m
Ordinary workshops; wood-working, pumping, etc.	30–40
Belt-driven continuous-current dynamos in series	80
,, ,, in parallel	120
Belt-driven alternators in parallel	180
Cotton-spinning machinery	200
Direct-coupled alternators in parallel	250

Mathot has proposed the following formula for rapidly calculating flywheel sizes:—

$$W = C \cdot \frac{m\,P}{R^2 n^3} \cdot 10^6 \text{ tons} \quad (28)$$

where:—

W = weight of flywheel rim in tons.
R = mean radius of rim, in feet.
P = b.h.p. of engine.
n = normal speed, in revs. per min.
C = a numerical coefficient.

The following are suitable values for C:—

		C
1.	For single-cylinder, single-acting engines	265
2.	For two single-acting cylinders side by side; cranks at 180°	167
3.	,, ,, opposed; cranks at 180°	125
4.	,, ,, side by side; cranks at 0°	125
5.	,, ,, opposed; cranks at 0°	167
6.	,, ,, tandem; cranks at 0°	125
7.	For four single-acting cylinders opposed two and two; cranks at 0°	42
8.	For single-cylinder, double-acting engines	167
9.	For two double-acting cylinders side by side; cranks at 0°	42
10.	,, ,, tandem, on same crank-pin	42

The total weight of the flywheel is about 1·4 W tons.

Flywheels are frequently more massive than the above calculation indicates, especially in cases where the speed fluctuation must be kept small even although one or more explosions be missed due to governor action.

Breakages in Internal Combustion Engines.

The following table is compiled from a wide induction of cases from the records of Insurance Companies, and indicates the relative frequency of failure of the several organs of internal combustion engines:—

ANALYSIS OF FAILURES OF PARTS OF INTERNAL COMBUSTION ENGINES.

Description of parts which are believed to have given way first.	Average before 1904.	1904-1908.	1909.	1910.
	Per cent.	Per cent.	Per cent.	Per cent.
Valves and valve-gear	30·1	33·3	29·6	42·8
Cylinders and cylinder ends	19·3	16·1	15·4	8·5
Pistons	9·7	5·0	2·7	5·1
Connecting-rods and their bolts	11·9	10·3	9·4	9·1
Main shafts	5·1	11·2	13·4	7·9
Governors and governor-gear	5·1	7·0	5·4	3·4
Silencing-boxes and exhaust-pipes	2·8	3·6	1·3	2·8
Flywheels and driving-drums	5·1	5·4	0·7	2·8
Clutches and couplings	1·7	0·0	0·0	0·6
Frames and pedestals	3·4	1·8	1·3	1·7
Bolts *	4·6	1·5	2·0	1·7
Total wrecks, cause not ascertained	0·6	0·4	0·0	0·6
Main driving-ropes and belts	0·6	0·6	0·0	0·0
Miscellaneous	—	2·2	7·4	4·5
Gas-producer plants	—	1·6	11·4	8·5
	100·0	100·0	100·0	100·0

* These do not include bolts in connecting-rods, valve-gear, or other moving parts, the bolts in these parts being tabulated with the parts themselves.

Notes on Fixing a Gas Engine.*

(F. R. Parsons.)

Foundations.

The outline of the foundation of an engine will be determined by the over-all dimensions of its bed or framing. Races for the flywheels must be allowed for if their diameter is such that clearance cannot be obtained otherwise. In a general way a margin of from 3 ins. to 6 ins. all round on engines of from 5 to 25 b.h.p. will meet the case. Above this and up to 100 b.h.p. a margin of from 9 ins. to 12 ins., according to needs and the formation of the bed, will be required. The depth of the concrete foundation depends a great deal upon the character of the subsoil. An engine standing on a good gravel bed would require much less concrete depth than one standing on a clay soil, or made-up ground. Engines up to 10 b.h.p. should in a general way have a bed at least 2 ft. to 2 ft. 6 ins. thick; up to 100 b.h.p. this should be increased to from 3 ft. 6 ins. to 4 ft. Modern-type horizontal gas engines which have a box-section framing and little cylinder overhang are much less susceptible to vibratory troubles, hence the depth of the bed need not be so excessive.

Opinions vary considerably as to the composition of concrete for engine beds. Always, however, it is much more profitable in the long run to have a fairly strong mixture, thereby diminishing considerably the setting period, and ensuring a good firm job. The following mixture has been found to be a highly satisfactory one for any class of high-speed machinery or engines of any power: broken rubble (stones or bricks), 4; clean river sand, limestone, or granite chippings, 4; cement, 1. Dirt or loose soil adhering to the material detracts from its homogeneity and delays setting. It is a good plan to wash well the stones and larger material from a hosepipe before mixing. Each layer of concrete should be well rammed as it is laid, so as to force the material to the outer extremities of the bed. If the latter cannot be completed right out of hand, the old surface should be well wetted before proceeding with the new material.

Holding-down Bolts.

Always leave ample bolt freedom in the concrete bed so that there shall be no difficulty of getting the engine into position, and also permitting it within certain limits to be moved in either direction if so desired. Use square-necked bolts and washer-plates with square holes, the plates being of ample area in order to resist the pull enforced by the nuts. Grout the bolts in with a mixture of clean fine sand and cement in equal parts when the exact position of the engine has been found, and it has been levelled and set. Holding-down bolts are better not arranged below the concrete foundation, but embedded therein; say, allowing from 6 ins. to 18 ins. of concrete,

* *Mechanical World*, July 18, 1919.

according to the size and thickness of the bed, below them. Set the bolts and plates on this, then proceed with the filling in. Bolts need not be tied together with a single long plate unless one happens to come so close to the outside of any part of the bed as to have insufficient hold. Always set the bolts in a wood-frame templet having holes in it similarly placed to those in the engine bed.

Size of Gas Meter.

Given the brake horse-power of the engine, the size of a meter required to pass a sufficient quantity of gas per hour can be ascertained by the following rule: Multiply the b.h.p. of the engine by the constant 3·4, then add the constant 5, the result being the size of the meter in 'lights.' For example, suppose the engine we are erecting is 60 b.h.p., then $3{\cdot}4 \times 60 + 5 = 209$. As this rule allows ample margin, we should therefore decide upon a 200-light meter.

Size of Gas Service.

To find the correct size of gas pipe to connect between the meter and the engine, the following rule may be applied: Multiply the meter size, in lights, by the constant 0·008, then add the constant 0·75, the result being the bore of the service pipe in inches. Thus, using the previous example, we have $200 \times 0{\cdot}008 + 0{\cdot}75 = 2{\cdot}35$ ins. In this case, if the connection between the meter and the engine was fairly straight, and not over-long or containing many curves, a pipe 2¼ ins. bore would be ample. But if a considerable distance divided the two points indicated, or many bends were introduced, it would be better to use a 2½ in. bore pipe.

Exhaust Pipes.

Generally, engines from 1 to 5 b.h.p. may have an exhaust pipe from 1 in. to 1¾ ins. diameter; 5 to 30 b.h.p., from 1¾ ins. to 2½ ins.; above this and up to 100 b.h.p., from 2½ ins. to 5 ins. in the bore.

Circulating Water.

Almost all gas engines require on an average about 4½ gals. of water per indicated horse-power hour, in order effectively to reduce cylinder temperature, this assuming the temperature of the return water not to exceed 150° F. To effect this by means of circulating tanks would be equivalent to an amount of from 25 to 30 gals. of water per b.h.p. as the contents of the tanks. The effective height of a tank should not be less than 2½ to 3 times its diameter. The higher the tank is situated above the cylinder jacket the more brisk becomes circulation. To keep the bottom of a tank at or about cylinder level causes circulation to be sluggish, and promotes the accumulation of sediment and deposit. For this reason it is generally best to keep the tank bottom at least a foot above the centre of the engine cylinder. A ball tap should be provided to supply cold water to the coldest tank, and if the engine is heavily worked it may also be necessary to arrange for an overflow from the hottest tank. Engines up to 25 b.h.p. can be served from 2 ins. diameter pipes; above this to 50 b.h.p., 2½ ins.; up to 100 b.h.p., 3 ins. to 3½ ins. diameter pipes should be used. The return pipe should be sloped all the way to the tank.

General.

In setting a gas engine on its concrete bed it is advisable to keep the cylinder end slightly the highest, an amount of about ¼ in. in every 3 ft. being ample. This assists in draining the waste oil from the cylinder and other parts of the engine to a point where it may be drawn off and collected.

The exhaust box should not be built solid into the ground or in a pit. It is advisable to mount it on iron rollers placed upon a flat stone or on an iron plate. This provides the necessary means for expansion, without which the joints and connections might suffer.

The gas-inlet pipe to the meter, or from the meter to the engine, should on no account be placed close alongside the hot exhaust pipe. This tends to raise the temperature of the gas, thus making it more rarefied and of less heating value per cubic foot. The cooler the gas admitted the more dense is the charge and the more powerful the explosion.

SECTION XXX

PART III

OIL ENGINES.

DIESEL ENGINES.

A Diesel engine is a prime mover actuated by the gases resulting from the combustion of a liquid or pulverised fuel injected in a fine state of subdivision into the engine cylinder at or about the conclusion of a compression stroke. The heat generated by the compression to a high temperature of air within the cylinder is the sole means of igniting the charge. The combustion of the charge proceeds at, or approximately at, constant pressure.

The Diesel engine, fig. 12, although an internal combustion engine, does not work on the same principle as the gas or ordinary oil engine where the combustible charge drawn into the cylinder is ignited and burnt instantaneously. In the case of the Diesel engine, only pure air is drawn into the cylinder and compressed, and the oil is injected as a fine spray into this highly compressed air and burns gradually as long as the injection is maintained. During this whole period the pressure in the cylinder does not rise much above the compression pressure.

The engines work on the four- and two-stroke cycle, and run according to requirements at low or high speed. When working on the four-stroke cycle, air at atmospheric pressure is drawn into the cylinder during the first stroke. It is compressed during the second stroke to a pressure of about 480 lbs. per sq. in. Owing to this increase in pressure the temperature of the charge rises to about 1,000° F. which is sufficient to ignite the spray of oil injected during part of the third or working stroke. As soon as the injection stops, the gases expand and the exhaust valves open shortly before the piston reaches the end of the third stroke. The products of combustion are expelled during the fourth stroke of the piston.

In the case of the two-stroke engines the air, instead of being drawn into the cylinder by the engine piston, is delivered thereto under low pressure and is also used partly to expel the exhaust gases. After the air-inlet ports or valves have closed this charge of pure air is compressed to the same pressure (about 480 lbs. per sq. in.) as in the case of the four-stroke engine. The fuel is injected in the same manner as in the four-stroke engine. The gases expand as soon as combustion is completed and the exhaust ports are uncovered by the piston shortly before reaching the bottom dead centre, the gases being expelled by the entering charge of air.

The thermal efficiency at full load reckoned on the b.h.p. is about 30 per cent. and the fuel consumption at this load about ·44 lb. per b.h.p. The products of combustion are invisible and odourless.

Nearly all four-stroke engines are built of the vertical type, with a strong cast-iron 'A' frame, the upper part of which forms the outer cylinder of the water jacket; into this upper part is fitted a liner of special close-grained cast-iron, which is water-jacketed for almost its entire length.

TWO-CYCLE DIESEL MARINE ENGINES

M.S. CONDE DE CHURRUCA,
fitted with Two SULZER Engines 1,250 h.p. each.

DISTINCTIVE FEATURES:

1. Valve controlled port scavenging.
2. Cylinder Heads of simplest design.
3. Pistons effectively cooled by sea-water.
4. No valves opening into combustion space.
5. Can use cheapest grade fuel oils.
6. Fuel consumption ·480 lbs per B.H.P.
7. Small number of working parts.
8. Saving in weight and cargo space.

SULZER TWO-CYCLE ENGINES TOTALLING
500,000 H.P. ARE IN OPERATION
BUILT IN UNITS OF FROM 300 TO 10,000 H.P.

MANCHESTER: 21 Spring Gardens. **SWANSEA:** Castle Buildings.

F. 1669

The cylinder cover contains four valves, the two large ones being the exhaust and air-inlet valves. The central valve is a needle valve which admits fuel to the cylinder about 1° or 2° before the completion of the compression stroke, gradually to 15° to 20° of the working stroke. The fourth valve controls the admission of the compressed air which is used in starting the engine. The cover is thoroughly water-jacketed to prevent the valves from overheating.

The exhaust and air-inlet valves are of the mushroom type and are self-contained in cast-iron casings which bed on cone seatings in the cover, so that should it be necessary to replace a valve, with the minimum loss of time a complete valve and casing can be substituted.

The starting valve, like the suction and exhaust valves, opens into the cylinder. The fuel admission valve opens outwards, except in the Burmeister & Wain engine, in which it opens inwards; failures of cylinders occasionally occur through this valve sticking up and thus permitting leakage of fuel oil, and also of the very high pressure blast air, into the cylinder, causing either pre-ignition of the charge or the attainment of a compression pressure much in excess of the normal. To guard against these contingencies some makers of Diesel engines fit relief valves in the cylinder heads, and in view of some recent experiences with these engines this would seem to be a very desirable practice.

All valves are closed by springs and opened by rocking levers actuated from the horizontal camshaft, which is supported by ring-lubricated bearings, bolted to the cylinder frame. The camshaft derives a half-speed motion through spiral gearing from a vertical shaft, which in turn is driven by spiral gearing from the crankshaft. In some engines there is a direct gear drive from the crankshaft to the camshaft. This vertical shaft drives a centrifugal governor acting directly on the suction valve of the fuel pump.

A cast-iron trunk piston is adopted, made sufficiently long to be a guide in the cylinder and to take the side thrust due to the angularity of the connecting rod, and is provided with six to seven 'Ramsbottom' rings to maintain a gas-tight cylinder; in recent large engines the crosshead type is, however, becoming usual.

The fuel pump of the engine operates as follows:—

The plunger draws a full stroke of oil from a reservoir into the pump chamber past the inlet valve. This quantity of oil is in excess of that required for combustion. The excess is returned past the suction valve on the delivery stroke by the action of the governor which holds open the inlet valve for a sufficient length of time to allow the excess fuel drawn in to escape into the suction pipe. In this way the amount of fuel delivered to the engine is precisely the amount required to do the work taken from the engine at that instant.

This method of governing by adjusting the fuel supply in accordance with the demand of every working stroke permits of a power stroke at every other revolution in each cylinder, as there is never any actual cut-out.

A feature of the Diesel engine is the facility and certainty with which it starts, it being quite possible to start the engine within 45 seconds.

The engine is able to burn any class of oil, from refined to the cheap petroleum residue, as well as tar oil, and provided the calorific value is not less than 18,000 B.Th.U.'s per lb. the makers guarantee the consumption at full load not to exceed 0·4 lb. per b.h.p. hour in the larger sizes and 0·5 lb. per b.h.p. hour in the smaller sizes.

The following figures, given by the Diesel Engine Co., are from a test of a 300 b.h.p. engine:—

Fuel per i.h.p. hour	0·309 lb.
,, b.h.p. ,,	0·417 ,,
Mechanical efficiency	73 per cent.

or a thermal efficiency reckoned on the b.h.p. of 30·0 per cent. and a thermal efficiency reckoned on the i.h.p. 40·7 per cent.

The initial pressure being generated by gradual compression of atmospheric air, the engine runs quietly and without shock, and there is no sudden rise of temperature during the whole cycle. There is no danger of an explosion owing to the high flashpoint of the oil which is used as fuel. The engine is therefore safe for marine purposes.

The fuel consumption of Diesel engines increases per b.h.p. hour as the load decreases, but the increase is not so marked as in the case of steam engines. The following figures (p. 1670) relating to a test carried out by the writer on a 300 h.p. high-speed Sulzer-Diesel engine are representative and indicate approximately the average extent of the increase in specific consumption with a decrease of load. It will be noticed also that at the maximum overload of 30 per cent. the fuel consumption per b.h.p. hour is also increased. High-speed engines are always slightly less economical than those of the low-speed type. The amount of cooling water usually required in ordinary Diesel engines is in the neighbourhood of four to six gallons per b.h.p. hour, the outlet temperature being generally 150 to 120 degrees.

TEST ON 300-H.P. FOUR-CYLINDER HIGH-SPEED DIESEL ENGINE.

B.H.P.	Load.	Lbs. per b.h.p. Hour.
75	Quarter	·635
150	Half	·465
225	Three-quarters	·435
300	Full load	·42
330	10 per cent. Overload	·425
360	30 per cent. Overload	·44

MIRRLEES-DIESEL ENGINES.

The Mirrlees-Diesel engines are now built in large numbers at the works of Messrs. Mirrlees, Bickerton & Day, Ltd., Hazelgrove, near Stockport.

At the end of October 1921 Messrs. Mirrlees, Bickerton & Day, Ltd., had built and on order about 757 engines of an aggregate of 128,000 b.h.p.; the average h.p. per engine is about 170 b.h.p. The units supplied range from 40 b.h.p. to 750 b.h.p.

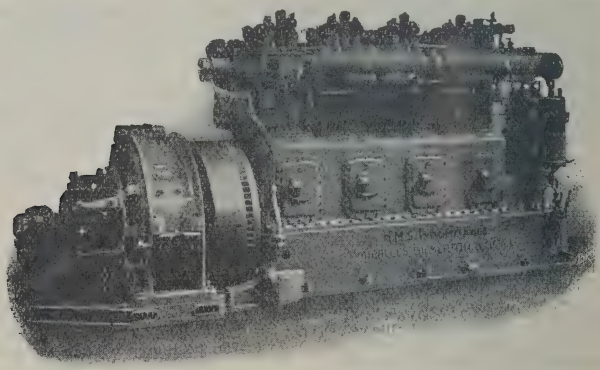

FIG. 13.—Mirrlees-Diesel Four-cylinder Type, direct coupled to a dynamo.

The larger engines are of the usual inverted vertical marine type; the standard open, three-cylinder, single-acting, four-cycle 150 b.h.p. engine runs at 250 revolutions per minute, and has cylinders 12 ins. bore with 18½ ins. stroke. With every engine a definite guarantee of the fuel consumption at various loads can be given, and with this size is as follows:—

Full load	0·44 lb.	per b.h.p. per hour.
¾ load	0·46	,, ,,
½ ,,	0·52	,, ,,
¼ ,,	0·69	,, ,,

The Mirrlees Company also specialise in enclosed high-speed Diesel engines, many of which have been supplied to the British Navy; fig. 13 illustrates the four-cylinder type direct-coupled to a dynamo, and engines of this high-speed type have been supplied to numerous British as well as to several foreign warships. Recent developments include the adaptation of engines to use tar oil as fuel, and the introduction of a 'crosshead' type engine for large sizes.

The crosshead type enclosed engine is a distinct advance in the construction of these Diesel engines and the largest size at present made is the six-cylinder 750 b.h.p. engine. The speed is 200 r.p.m. and the engines are also built in three and four-cylinder units.

The arrangement of fuel pump on Mirrlees engine using tar oil as fuel is illustrated on page 1816.

Belliss & Morcom Diesel Engines.

Diesel engines of 50 and 80 b.h.p. per cylinder are standardised by Belliss & Morcom, Ltd., Birmingham, in single, two, three, and four-cylinder units. They are of the vertical open design and run at 230 and 210 r.p.m.

Accessibility is one of the features of these engines; the control levers are within easy reach from the floor, and enable one man to start the engines. The platform, being bolted to the front of the cylinder, gives access to the valves and valve gear. The valve operating gear is self-contained on the cylinder head, and the cams run in oil baths. This obviates the necessity of lubrication by hand and results in a clean working engine.

The air compressor for injecting the fuel is fitted with disc valves and is of the three-stage type, the air from each stage being cooled and the oil separated. The suction and delivery valves can be removed quickly for examination.

The following are total works costs for one of the 220 b.h.p. four-cylinder engines, in their own power station, for the year ending September 30, 1915.

(1) *Fuel Oil.*—279,390 units have been generated in 2,404 hours with a consumption of ·725 lbs. per k.w. hour. The load factor for the year is 85 per cent., giving a corresponding mean consumption of ·47 lbs. per b.h.p. hour, taking dynamo efficiency as 87 per cent. at this mean load. 90·2 tons of fuel have been weighed in, and, based on the average price paid during the year, gives a figure of ·26 penny per unit generated.

(2) *Lubricating Oil, Waste, etc.*—Special care has been exercised to keep down the lubricating oil consumption, as much prejudice exists against the Diesel engine in this direction. By repeatedly filtering the used oil and afterwards disposing of it at sixpence per gallon to an outside firm the cost of oil, waste, polishing paste and all sundries has been brought to the low figure of ·014 penny per unit generated.

(3) *Wages.*—This represents the whole of one driver's time, which in a station of more than one engine could be reduced somewhat; it also carries part of the wages of the other drivers in the station, and works out at ·094 penny per unit generated.

(4) *Maintenance.*—This includes a thorough overhaul at Easter, repairs of water cooler, attention to dynamo, and motor for water pump, valve cleanings and various other odd jobs to plant. ·05 penny per unit generated.

Tabulated, these give the following total works cost:—

1. Fuel	·26
2. Lubricating oil, waste, etc.	·014
3. Wages	·094
4. Maintenance	·05
Per unit generated	·418*d.*

Cole, Marchent & Morley Diesel Engines.

Diesel engines ranging in power from 50 to 500 b.h.p. are manufactured by Cole, Marchent & Morley, Bradford, and are of the usual vertical open type. Four cylinder sizes developing 50, 75, 100 and 125 b.h.p. each are adopted.

The cylinder head is simplified by the method of operating the valves by levers worked from a camshaft located near the bottom of the water-cooled portion of cylinder. In addition, this arrangement makes it possible completely to enclose the cams, and the rockers and rollers, so that the whole of the gear can run in an oil bath, thereby reducing noise and wear. Starting is simplified by this arrangement, as the levers can be operated from below without any additional links.

The valves are arranged with their own independent casings, efficiently water-cooled, and all of the valves can be removed and replaced without disturbing the valve gear or pipe connections. The air compressor for injecting the fuel is of the two-stage inter-cooled type driven direct from the engine crankshaft. The engines are suitable for direct coupling to electric generators and for rope and belt driving.

Tests of a 100 k.w. three-cylinder engine taken at Basingstoke showed that the fuel consumption for full, ¾, ½ and ¼ loads respectively are ·646 lb., ·694 lb., ·705 lb. and 1·09 lb., per k.w. hour.

Hick, Hargreaves Diesel Engines.

Hick, Hargreaves & Co. Ltd., Bolton, manufacture Diesel engines of both the open and enclosed design in powers from 50 to 1,020 b.h.p., as shown in the following table :—

Symbol and Type.	B.H.P.	R.P.M.	No. of Cyls.	Net Weight of Engine in Tons.	Net Weight of Normal Flywheel in Tons.	Cyclic Irregularity.	Fuel Consumption. Full Load. Lb.	¾ Load. Lb.	½ Load. Lb.

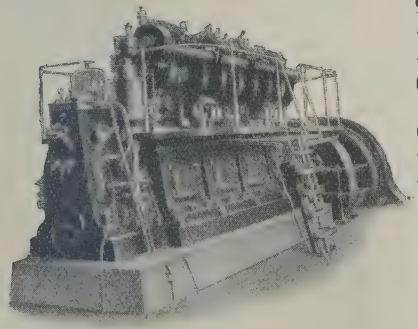
	1,020	,,	6	152·75	12	1/160	0·42	0·435	0·47

The engines are of the vertical four-cycle stationary type.

English Electric Co.'s Diesel Engines.

The Willans-Diesel oil engine is manufactured at the Rugby Works of the English Electric Company Limited, and since 1906 upwards of 45,000 b.h.p. have been supplied or are on order. These engines are in use in all parts of the world, driving all kinds of machines, centrifugal pumps, electric generators, etc., both direct coupled and by means of belts or ropes. They are made in the following standard sizes :—

B.H.P.	No. of Cylinders.	Speed R.P.M.	B.H.P.	No. of Cylinders.	Speed R.P.M.
100	2	250	335	4	220
150	3	250	500	4	200
200	4	250	300	6	250
250	3	220			



Up to and including 335 b.h.p., the engine is of the vertical open type, oil-ring lubrication being employed. In the 500 b.h.p. the crank chamber is enclosed and forced lubrication used. The air-compressor for supplying air for fuel injection and starting purposes is fitted on the end of the engine bedplate and driven from the crankshaft. The speed is controlled by a centrifugal governor, acting upon the inlet valve of the fuel pump, thus regulating the quantity of fuel exactly to the load. The consumption of residue oil is guaranteed not to exceed 0·41 to 0·46 lbs. per b.h.p. hour at full load, depending on the size of the engine, while at half load the consumption per b.h.p. hour is but 15 per cent. higher.

The engines are made to jigs and limit gauges, thus ensuring interchangeability of spare parts, which is of the utmost importance in cases where engines are installed in remote countries.

Schneider Diesel Engines.

Schneider & Co., Le Creusot, have had an extensive experience in the manufacture of large Diesel engines for land and marine purposes. One of the firm's experimental engines, a single cylinder two-stroke cycle type, has developed 1,200 h.p. at 150 r.p.m.

THE HICK - DIESEL OIL ENGINE

For Low Fuel Consumption.

Continuous heavy duty.

Ability to burn Low Grade : Fuels. :

The Hick-Diesel Oil Engine combines unique and distinctive features of design and construction, with the reputation of nearly a century for highest class Engineering. The most economical prime mover for the generation of Electric Power, Oil and Water Pumping, etc. Made in Standard Sizes ranging from 50 to 1,020 B.H.P. in both open and enclosed types.

DIESEL ENGINES FROM STOCK.

HIGHLY satisfactory reports from users in all parts of the world confirm our claim that by virtue of high economy in fuel and labour, ease of control and compactness, Willans Diesel Oil Engines are, for some purposes, greatly superior to any other type of plant.

We are now in a position to offer for immediate delivery Diesel Engines of the following sizes:—

1100 B.H.P. at 250 R.P.M.
150 B.H.P. at 250 R.P.M.
200 B.H.P. at 250 R.P.M.
335 B.H.P. at 220 R.P.M.

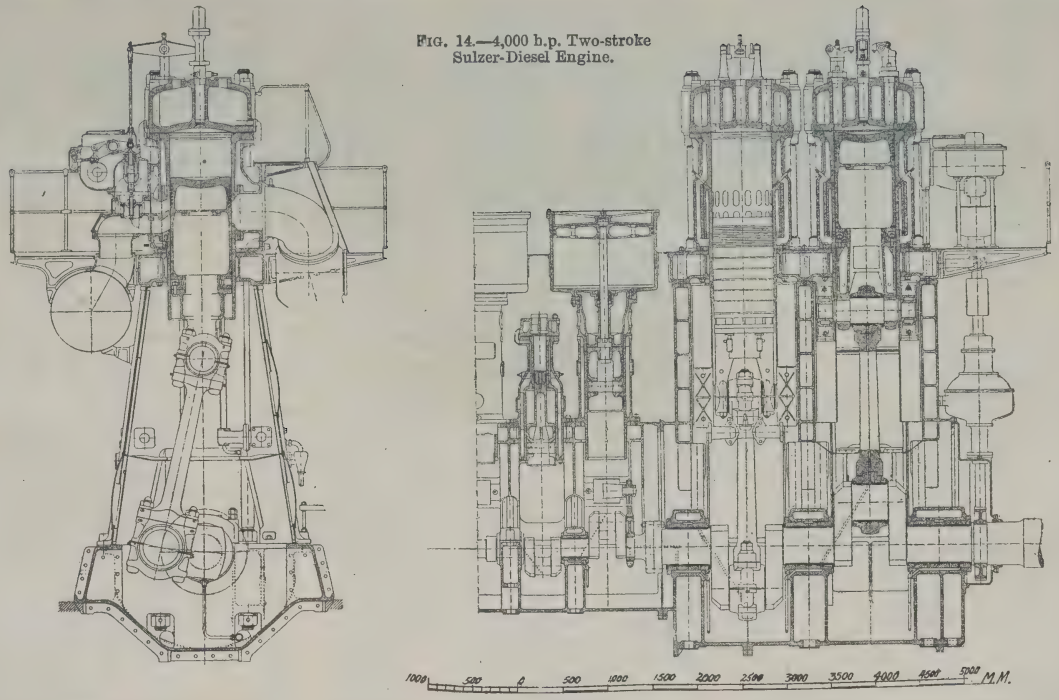

FIG. 14.—4,000 h.p. Two-stroke Sulzer-Diesel Engine.

Two-stroke cycle Diesel engines of various powers up to 2,400 h.p. have been made and a number of these have been in regular work for over seven years. Four-stroke cycle engines have also been made and give very satisfactory service.

The Schneider engines are of the vertical type, of both the open and enclosed design, and all of them are fitted with crossheads. The makers have also completed some double-acting stationary Diesel engines of the four-cycle type developing up to 2,600 h.p.

Sulzer-Diesel Engines.

Sulzer Brothers of Winterthur, Switzerland, make stationary engines of the four-cycle type from 50 to 1,000 b.h.p. Their wide experience has led this firm to employ the two-cycle principle for higher powers and for all marine engines.

Fig. 14 shows an early design of a 4,000 b.h.p. six-cylinder engine with direct-driven scavenging pump. Engines of this type have been running a number of years, but the design has since been considerably improved, notably in regard to the cylinder cover, which is now made in the form of a simple symmetrical casting as shown in fig. 50, page 2045, Marine Engines.

The reciprocating scavenge pumps are also replaced, in the larger engines, by rotary turbo-blowers, supplying scavenge air at a pressure of 1½ to 2 lbs. per square inch. This simplifies the engine, and enables a greater shaft horse-power to be obtained from a given size of engine using the same mean indicated pressure in the cylinder.

For further particulars of the Sulzer two-cycle engine see Section XXXIII, 'Marine Oil Engines.'

Beardmore-Tosi Diesel Engines.

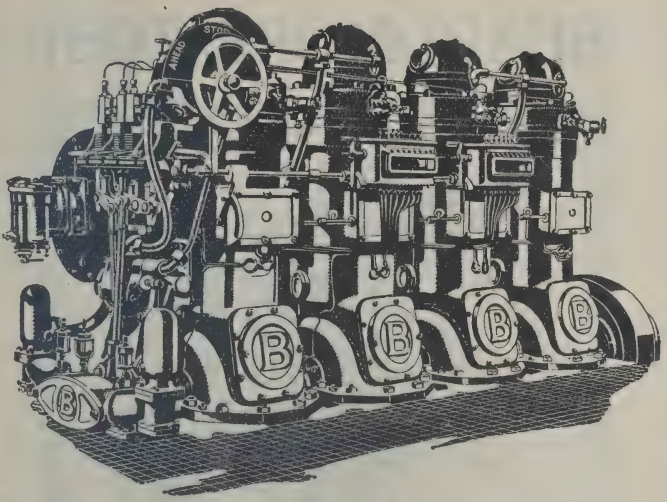
These engines are made in various sizes up to 2,400 b.h.p. and are of the four-stroke cycle enclosed type. The range of horse-power developed per cylinder is 15 to 400 b.h.p., the dimensions ranging from 180 mm. to 630 mm. Crossheads have been adopted in both the land and marine types. The Tosi design gives the greatest freedom from trouble for the piston and gudgeon pin.

Great attention has been paid to the design of the details of these engines, especially to the lubrication and water circulating systems. The consumption of fuel oil is between ·42 and ·45 lb. per b.h.p. per hour. The engines are also very economical in lubricating oil, as only about ·0045 lb. per h.p. is required for the slow-speed engines.

A feature of the Tosi engines is that they will fire regularly at speeds as slow as 40 r.p.m., at which speed compression pressure is 450 lbs., as against 485 lbs. per square inch at normal speed. One reason for the capacity to run at such a reduced speed is the fact that the phase and duration of the fuel injection period can be regulated according to the speed of the engine. At low speeds the quantity of fuel injection air is reduced and the cooling effect of the excessive quantity that would enter the cylinder, were no means of regulation provided, is entirely absent.

Other Makers of Diesel Engines.

Geo. Ansaldo & Co., Rome, manufacture Diesel engines of large powers, and a number are in regular use. One of their 1,100 b.h.p. two-stroke cycle engines running at 100 r.p.m. was recently subjected to severe tests to determine the flexibility and overload capacity. It was found possible to run the engine at as low a speed as 35 r.p.m., and the following are particulars of the overload trials:—



Overload Trial on 1,100 b.h.p. Ansaldo Diesel Motor.

Overload.	Duration of Trial in hours.	R.P.M.	B.H.P.	Fuel Oil consumption, lbs. per b.h.p. hour.	Lubricating Oil consumption, lbs. per b.h.p. hour.
47 per cent.	1	127·7	1,622·5	0·445	—
30 ,,	30	116	1,433	0·440	·006
12 ,,	5	104·7	1,232·5	0·425	—

These figures dispose of any doubt as to whether the Diesel engine as now constructed can be over-loaded for a long period without damage.

Diesel engines are also manufactured by Carels Frères, Ghent, in various sizes up to 3,000 h.p. and are made in both the four-stroke and two-stroke cycles. These engines are of the open vertical type and a large number have been supplied. The Carels engine is one of the best known Continental designs.

(For further information on Marine types of the Diesel engine, see Section XXXIII., 'Marine Engineering.')

Weight of Diesel Engines.

For land installations, considerations of economical production have resulted in cast iron being extensively used in the Diesel engine; due to this, and to the high pressures employed, the weight per b.h.p. is somewhat high; thus, including fly-wheels, Guldner gives as the weight per b.h.p. :—

A. In single-cylinder engines : 600 lbs.
B. „ two- „ „ 520 lbs.
C. „ three- „ „ 350 lbs.

In recent practice, and particularly in cases where weight reduction is of importance, as e.g. in Diesel engines for submarines, these figures have been largely reduced; this is effected by using materials of considerably greater tensile strength in place of cast iron, and weights as low as 300, 250, and 200 lbs. per b.h.p. for cases A, B, and C respectively, may be found. In high-speed engines the weight has even been reduced to as little as 60 lbs. per b.h.p. with four-stroke engines, and 45 lbs. with two-stroke designs.

The Diesel engine is more economical in fuel consumption than any other type of internal combustion engine, but in construction it is necessarily a somewhat costly type.

Cost of Diesel Engines.

The price of Diesel engines varies considerably, depending upon the design and speed, and may be taken as being from about 25*l.* to over 30*l.* per h.p. at the maker's works.

Diesel Engine Crankshafts.*

All shaft failures investigated owe their origin to lack of alignment of the main bearings. This is usually the result of unequal rates of wear of the several bearings supporting the shaft, though in some cases it can be traced to negligence during erection, or, in older engines, to defective foundations.

The following system of assuring perfect alignment of the shaft is recommended especially to those engineers who have no reserve plant and who have to get repairs done during the week-end.

If the engine is a 4-cylinder, take out bearing C first and micrometer it. Look up the log-book and ascertain how much it has worn since the shaft was last realigned. Then take out bearing A, micrometer it, and ascertain the extent of wear in the same period. If it has worn down $\frac{8}{1000}$ in., and bearing C has worn down $\frac{12}{1000}$ in., then scrape down bearing A $\frac{4}{1000}$ in. more, re-bed it to the shaft, or, preferably, to a special dummy journal, and then replace it. Treat all the bearings in like manner. If the engine is a 2-cylinder, or a single-cylinder unit, then probably the bearing adjacent to the flywheel is most worn. It therefore should be taken out first, measured up, and replaced, scraping only if found 'high' at one end. Then take out the other bearings and scrape them in accordance with the data obtained. In the case of a 3-cylinder engine, the probability is largely in favour of bearing B being the lowest, and this, therefore, should be taken out first.

Thus, where plant is not in excess, the engineer can readjust a bearing each week-end until the whole set is completely put in order, and he runs very little risk of heated bearings if he is careful. The system has its limits. It would not do to apply it in this manner if rate of wear were very variable.

It is necessary to dismantle the whole engine to make a good start with the system. If the engine has been very carefully erected, and is not more than a year or two old, then one may exercise his discretion and assume that any large differences in the thickness of the main bearing shells is due to difference in rate of wear.

As regards the subsequent adjustment, running clearance of main bearings, it is not usually feasible to measure this with feelers. Where possible, it is preferable to feel the lift in each bearing, and let the cap closer and closer until the bearing either heats (in which case scrape out the cap) or until the lift just disappears.

Recourse may be had to leads so long as they are considered only as a means of obtaining the *relative* and not the absolute clearance in a bearing. In the ordinary way, if one use 20 or 21 gauge lead wire, running clearance will be right if the lead squeezes out to $\frac{8}{1000}$ in. or $\frac{9}{1000}$ in. thick. If one uses 16 gauge, then this may squeeze to about $\frac{10}{1000}$ in. or $\frac{12}{1000}$ in. thick. The actual clearance is probably only $\frac{4}{1000}$ in. to $\frac{6}{1000}$ in. The difference between real and apparent clearance depends upon a number of factors. It should be borne in mind that leads do not show the true clearance in a white-metal bearing.

Best Proportion of Shafts.

Tensile strength, not less than 34 tons.
Ductility not less than 25 per cent. in 2 ins.

* Paper by P. H. Smith read before the Diesel Engine Users' Association, July 12, 1916.

Diameter of pins and journals, 0·525 to 0·54D.
Length of main bearings, 0·75 to 0·8D.
Length of big end pin, 0·525 to 0·54 D.
Thickness of webs not less than 0·32D, but centre to centre of cylinder made minimum possible, and any excess over the proposed length of pin and journal to be put into the webs.
Fillets to be not less than one-tenth the diameter of the shaft.
For details of Diesel engine parts see 'Marine Diesel Engines,' page 2035.

Alignment of Crankshafts and Engine Parts.*

(Geo. E. Windeler, M.I.Mech.E.)

Where small units are built up with separate bedplates and columns or crank cases, it is imperative to check the parallelism of the crankshaft journal from the planed surfaces of the bedplate. The other details which require alignment checking are the connecting rod and the piston, it being essential that the top and bottom bearings of the connecting rod are perfectly parallel and free from twist.

The following is a simple and efficient method for measuring the inaccuracies:—

Place into the bottom end of the connecting rod (fig. 15) an accurately ground mandril, say $\frac{5}{1000}$ in. or $\frac{6}{1000}$ in. less in diameter than the bore of the bearing. A similar mandril is placed in the top end bearing. Generally speaking this mandril is five to six times the length of

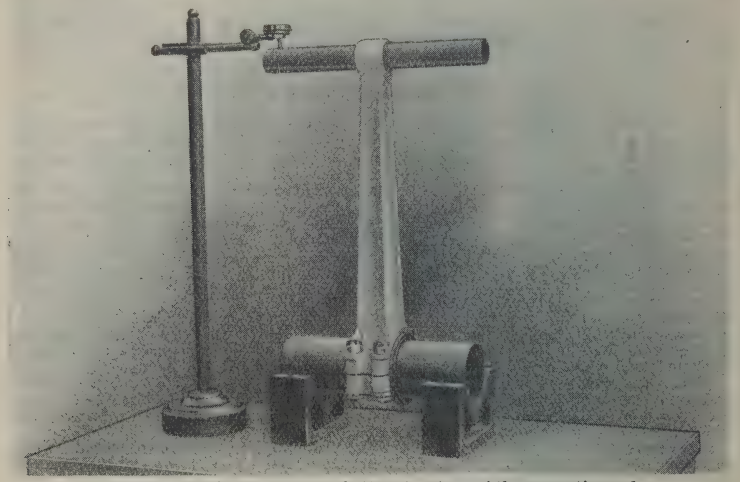

FIG. 15.—Testing the top and bottom bearings of the connecting rod.

the bearing. The whole is then placed vertically in two V blocks, and a scribing block fitted with a micrometer screw is then used to measure the height of the mandril at each end which projects through the rod. The difference between the two dimensions is the exaggerated amount of inaccuracy, and, assuming that the bar is five times the length of the bearing, then the actual amount of error on the connecting-rod bearing itself would be one fifth of the total error shown; so that if the test bar showed an out of parallel from one end to the other of $\frac{3}{1000}$ in., then the top end bearing of the connecting rod would be out of parallel with its bottom end bearing to the extent of $\frac{3}{1000}$ in. This is an instance of measuring, by exaggeration, very fine inaccuracies.

It is also desirable to test the rod to ensure that the holes lie perfectly parallel with each other in the vertical plane, that is to say, to ensure that the holes are not twisted with each other. To carry this into effect the rod is lowered down into a horizontal position (fig. 16) and a packing piece is placed under the rod immediately below the centre of the bearing. A scribing block with a micrometer screw is then used to test the height from one side to the other, in

* Abstract of paper on Alignment of Machinery read before the Manchester Association of Engineers, December 8, 1917.

the same way as the vertical test was carried out. If any twist occurs with small rods, this can be corrected by twisting the rod, but in large rods other means have to be adopted to remove the error.

The same method is adopted for testing whether the piston pinhole is at right angles to the piston (fig. 17).

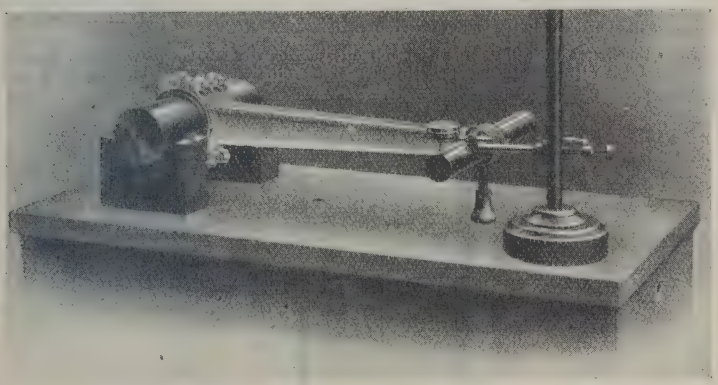

FIG. 16.—Testing the alignment of the holes with the vertical plane.

In moderate sized units the alignment of the cylinders and parts is often carried out by means of dummy parts which are accurately made, and may be regarded as a form of jig for testing the parts during the course of erection. With larger sized units this is not always practicable and other means have had to be resorted to to obtain the same degree of accuracy.

In large units such as are in general use to-day, and in which the rate of revolution is high and the running clearances very close—as, for instance, in a large vertical engine, say

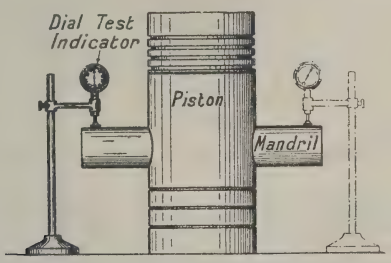

FIG. 17.—Diagram showing method of testing alignment of hole in piston for gudgeon pin.

20 ft. above the crankshaft, with the piston clearance $\frac{1}{1000}$ in. diameter when cold—it is imperative that the cylinder and guide should be at right angles to the shaft, and that the readings of the alignment should be accurately taken for tabulation. A fine wire is generally used for the alignment of the vertical compoents, but as it is a flexible member and gives to slightest pressure of contact really reliable data is not obtained from its use in the ordinary way.

The following describes a simple audible electrical device used in conjunction with the fine-wire system for accurately checking the alignment of engine parts :—

It is assumed that the engine bedplate is machined on the under side and parallel with the top side of the bedplate. The bedplate is then accurately levelled on parallel strips, both longitudinally and transversely, and supported by such strips at defined points. The crankshaft

is then placed in its bearings and tested for parallelism with the planed surface of the bed, and at the same time the shaft journals are tested for concentricity with each other by similar means to that described under small engines. Assuming this to be satisfactory, the columns are placed accurately in position and the cylinders placed on top of the columns. A fine wire is then stretched over the whole length of engine, the ends passing over uprights secured to the engine bed and adjacent to the ends of the crankshaft. Suspended at each end is a non-magnetic 'plumb bob' of sufficient weight to keep the wire taut. The wire is then set so as to intersect the centre lines marked on the end of the crankshaft.

The cylinders are then lined true longitudinally to this wire and correctly pitched one with another. Long wires are then passed through each cylinder, of sufficient length to pass

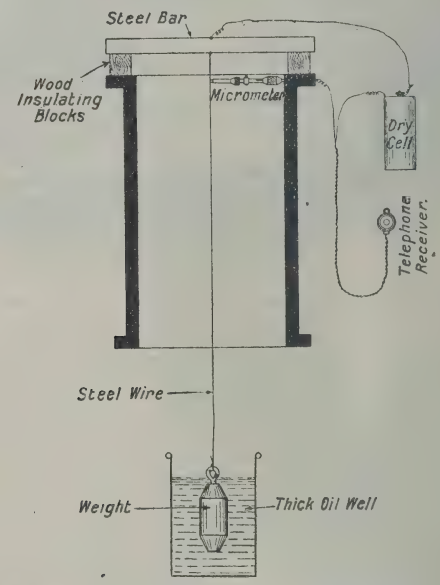

FIG. 18.—Diagram showing method of aligning cylinder using audible warning device.

between the crank webs, and a heavy 'plumb bob' is secured to each wire and immersed in viscous oil contained in a small vessel, to prevent oscillations of the 'plumb bob' and the wires. These wires are set accurately to the centre of the top end of the cylinders by means of the audible device, and readings are then taken at the top and bottom of cylinders and between the crank webs. The wire is suspended over a rounded knife-edge metal bar at the top end of the cylinder, in such a way as to prevent kinking and cutting of the wire, and this metal bar is supported on hard wood blocks from the top face of the cylinder. The use of wood blocks is necessary to insulate the metal bar from the engine parts. Connected to the metal bar by one of its terminals is a dry battery (fig. 18), the other terminal of which is earthed to the engine frame with a telephone receiver in circuit; then contact between the suspended wire and the cylinder will cause the electrical circuit to be closed.

The micrometer gauge is then set to half the diameter of the cylinder, less half the diameter of the wire, plus say $\frac{1}{2}$/1,000 of an inch. This setting allows $\frac{1}{2}$/1,000 in. pressure against the wire when the wire is set dead central at the top of the cylinder. The micrometer gauge is then inserted between the wire at the points named above, and if the gauge touches the wire the electrical circuit becomes closed by this contact and a distinct noise is transmitted through the telephone receiver. To enable the operator to have the use of both hands, the receiver may be held to his ear by means of an elastic band passed round his head. The micrometer gauge being adjustable, any 'plus' or 'minus' readings can be taken at will with a definite known amount

of contact pressure on the wire. The readings obtained are entered on a chart. By reference to this chart the foreman decides what action should be taken to rectify the error shown, and the preliminary and final records are filed for reference.

With this device it is possible to obtain the same readings consistently, and it has the advantage that it is portable and adjustable to any engine, either horizontal or vertical. It can be sent out to inspectors to check the alignment of engines which have been some time at work. Also the wear of the bore of the liners can be accurately recorded with the exact position at which the wear has taken place.

In multi-cylinder engines it is important that the crankshaft should be properly supported at each journal, otherwise springing of the shaft takes place at each compression and power stroke, which may ultimately result in fracture of the shaft. It is therefore important that the shaft and bearings should be periodically examined. One of the insurance companies has adopted a simple means of measuring the amount, and proceeds in the following manner:—

The engine is barred round with each crank on its respective top centre, and the distance between the crank webs is measured with a micrometer gauge at a definite point and recorded. Each crank is then barred down to its bottom centre, the distance between the crank webs again taken, and the difference between the two readings noted. A simple calculation gives a close approximation of the amount that the shaft is clear from its bearings, and a new bearing can be fitted by gauging the thickness of the existing shell from outside diameter to inside diameter and then making the new bearing thickness plus the amount calculated from the figures taken between the crank webs. This method can also be used to detect any want of alignment of outboard bearings of gas and oil engines, and is invaluable for this particular difficulty. It is a very accurate and reliable method, and has saved many cranks from ultimate fracture.

Cyclic Variation Recorders.

A number of arrangements have been made for the purpose of accurately recording the cyclic variations of the rotational speed of an engine; the first attempts were mainly with tuning-forks, and this form of apparatus was well developed by Manlove, Alliott & Co. A variation of this was first used by the writer to test the cyclic regularity of steam engines built by Davey Paxman & Co. in 1907.

In this apparatus the tuning-fork was replaced by an electric motor running at a constant speed and the records were taken on the peripheries of the flywheels, the flywheels having been suitably prepared.

Mirrlees, Bickerton & Day have taken tests of the cyclic variation of their Diesel engines in a similar manner, and the arrangement of the apparatus is as follows:—

On a base is formed a V, so that an ordinary lathe compound tool rest can be fitted to same, which tool rest is operated across the face of the wheel by a quick-pitch, square-thread screw, actuated by a heavy handwheel, so as to obtain as near as possible uniform movement across the space to be traversed, though this is not essential to the accuracy of the results.

Mounted on the compound rest is a small electric motor arranged in such a manner that it can be worked towards or away from the surface of the wheel by the compound rest. Secured on the end of the motor spindle is mounted a carefully balanced disc into which is inserted a hardened steel, accurately-ground pointer. Immediately below this is fixed a small bracket which holds another adjustable pointer vertically below the point of the rotating pointer on the disc when touching the face of the flywheel of the prime mover.

The object of the fixed pointer is to scribe a line in the form of a helix circumferentially on wax on the rim of the flywheel, whilst the duty of the rotating pointer is to cut short intersecting marks across these lines at constant intervals of time. These objects are obtained by moving the slide rest parallel to the surface of the wheel whilst the prime mover is running at normal revolutions and the electric motor at uniform speed.

The fixed pointer marks a helical line in the wax deposited on the periphery of the flywheel and the pointer marks off distances on this line at equal intervals of time. These distances are a record of the average speed of the flywheel during small intervals of time and from them a speed curve can be plotted.

It is essential that the points are in line vertically, so that the mark cut by the revolving pointer is bisected fairly accurately by the helical line. The electric motor, which is run at a high speed of revolutions, is supplied with current from an ordinary 12-volt motor-car lighting battery, which forms part of the equipment.

Generally speaking, the length of the record should be not less than 4 or 5 revolutions, though the number is only limited by the width of the flywheel surface and the pitch of helical line, which is usually about $\frac{1}{2}$ in. The motor is arranged at such a speed as to give a suitable number of readings on the periphery of the wheel, so that slight variations in the velocity of the rim can be detected. The distances between the marks are then carefully measured off with a steel tape and

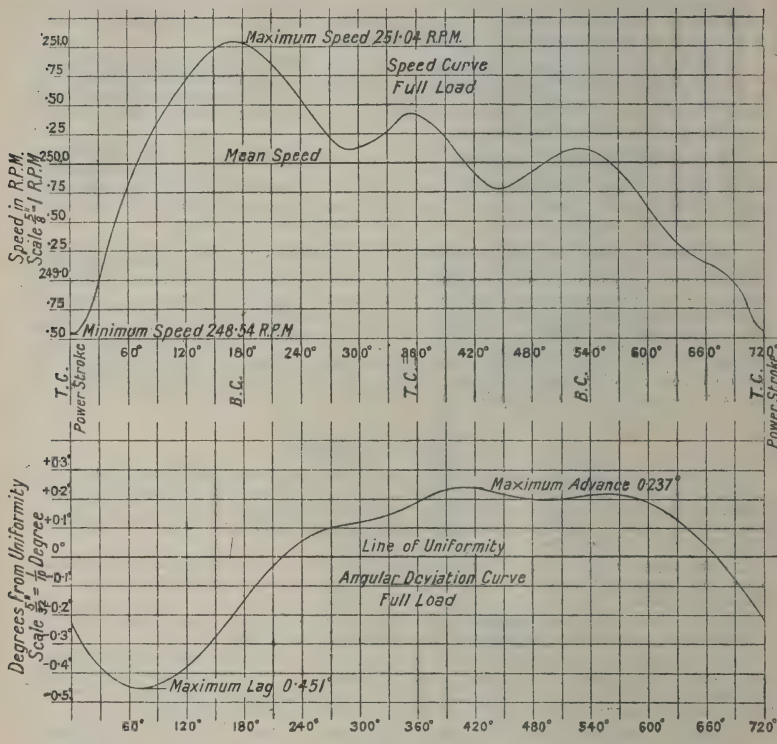

FIG. 19

Scale.—$\frac{5}{8}$ in. (i.e., one square) = 30° of angular movement.

vernier, and the figures obtained are plotted in graph form and show clearly the variations that occur in the speed of the prime mover.

This device has been used on different types and sizes of engines with good results.

The theoretical figures and graphs were based on information obtained from diagrams from actual engines several years before the results were taken by the instrument. The graphs shown on fig. 19 indicate these theoretical figures, and the graphs shown on fig. 20 are those produced by the information obtained with the Mirrlees, Bickerton & Day Cyclic Variation Recorder.

The novelty of the device lies in the use of the periphery of the flywheel of the prime mover as the recording drum, and the application to the flywheel of a delicate recording substance such as wax.

Having plotted a correct speed curve from data given by the trial, the angular deviation from true uniformity of rotation is obtained either (1) fairly accurately by direct calculation from the speed curve, or (2) very accurately by plotting another graph from the speed curve showing the changes in angular position of the flywheel relative to an imaginary wheel rotating uniformly.

The apparatus is inexpensive and of such a character that it can be readily manufactured and easily operated by any careful person with engineering experience. The data obtained can readily be transposed into scaled graphs by a skilled draughtsman.

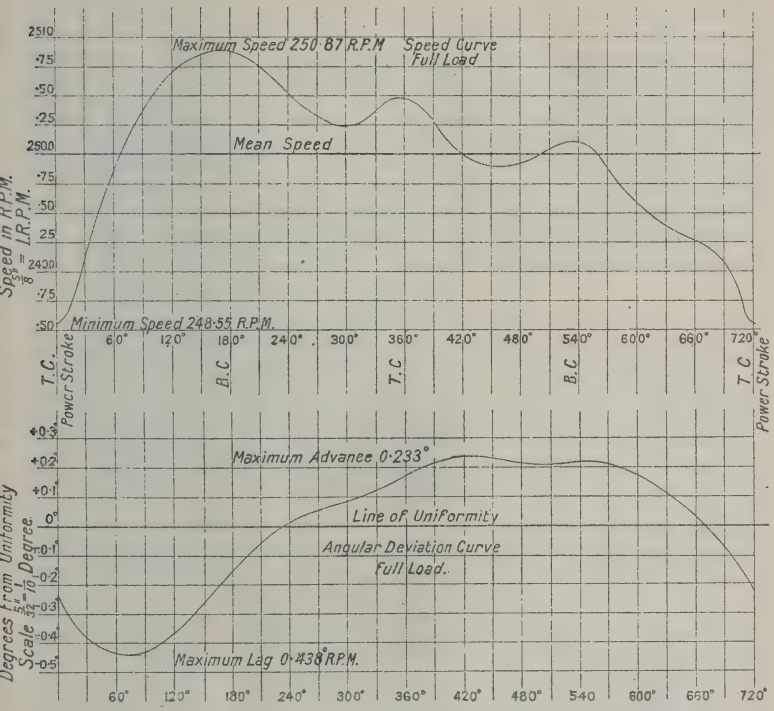

FIG. 20.

Scale.— $\frac{5}{32}$ in. (i.e., one square) = 30° of angular movement.

The amount of current used for operating the electric motor is very small, as its duty is to merely maintain at a constant speed the disc carrying the pointer, and to overcome the slight resistance offered by the pointer scratching the marks (one per revolution of the motor) on the surface of the wax.

The method adopted for securing the wax to the wheel is as follows :—The wheel is thoroughly polished and carefully rubbed down, whilst running, with turpentine ; the wax, which is pure beeswax, is carefully heated to a liquid state in a glue kettle and then plastered on to the surface of the wheel. The use of the glue kettle was found necessary, as if the wax were overheated during the process of warming it would not adhere to the surface, the overheating apparently reducing its resilience and causing it to become 'short.'

The thickness of wax deposited on the wheel should be about $\frac{3}{16}$ in. and turned down till it is about $\frac{1}{16}$ in. thick. It can be readily removed afterwards with a scraper, but it was found undesirable to use the same wax over and over again, as a certain amount of greasy matter (probably oil vapour condensed on the wax) mingled with it and destroyed its nature ; so that in carrying out experiments it is desirable to use fresh wax each time.

SEMI-DIESEL ENGINES.

A semi-Diesel engine is a prime mover actuated by the gases resulting from the combustion of a hydrocarbon oil. A charge of oil is injected in the form of a spray into a combustion space open to the cylinder of the engine at or about the time of maximum compression in the cylinder. The heat derived from an uncooled portion of the combustion chamber, together with the heat generated by the compression of air to a moderate temperature, ignites the charge. The combustion of the charge takes place at, or approximately at, constant volume.

The semi-Diesel engine is the simplest form of oil engine, especially if of the two-stroke cycle type, and can be arranged to work satisfactorily with practically the same range of fuel oil as the Diesel engine.

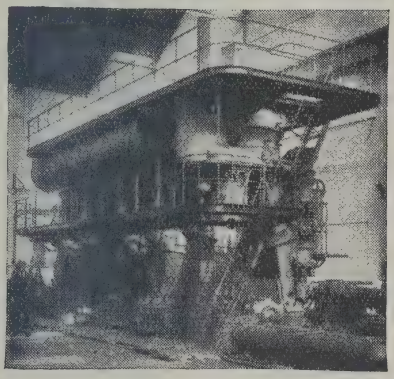
Moderate compression pressures of 150 to 200 lbs. per sq. in. are adopted, consequently the working pressures are low and a comparatively light and inexpensive engine is obtained. The majority of engines operate on the two-stroke cycle and have solid injection of the fuel.

The weight of the engines varies from about 1¼ to 2¼ cwts. per h.p., and the price at the makers' works is from about 12*l.* to 18*l.* per b.h.p. depending on the size.

Blackstone Crude Oil Engines.

In the Blackstone Company's crude oil engine a hot-bulb is used for ignition; air alone is compressed—as in the Diesel—though not to so high a pressure as to cause spontaneous ignition.

In these engines Scotch shale and other crude oils such as Texas, Borneo, and Russian, also petroleum residue, may be used efficiently without the aid of an abnormally high compression; ordinary refined petroleum may also be used. The compression of the charge is comparatively low, viz. 150 lbs. per sq. in. The fuel is injected into the cylinder at or near the end of the compression stroke by air compressed to a pressure of about 400 lbs. per sq. in. A very high compression is necessary to raise air to a sufficiently high temperature to ignite crude oils, therefore with a compression of only 150 lbs. some additional means had to be provided to ignite the charge. Ignition is effected by the employment of a dual spraying device, consisting of a main jet adapted to deliver its charge into the combustion chamber, and an auxiliary one, delivering a smaller charge into a bulb-shaped ignition chamber, heated at starting by a lamp and afterwards kept incandescent by the combustion of the fuel. This ignition chamber communicates with the combustion chamber by a port so arranged that the flame produced in the ignition chamber impinges upon and ignites the main fuel spray in the combustion chamber. The oil is delivered from a tank to the spraying device by a governor-controlled pump, and first reaches the auxiliary or igniter spray, all oil in excess of the quantity required for this overflowing into the main spray. This method ensures a charge of oil being injected into the igniter at every cycle, thus keeping it hot irrespective of the engine running light or loaded. The air compressor for the sprays is attached to the side of the cylinder and is worked by an eccentric on the crankshaft.



A great object kept in view in the design of this engine has been to prolong the initial pressure of the explosion in the cylinder. The pressure line on the indicator diagram is parallel to the atmospheric line for some distance along the working stroke, thus resembling those obtained from a steam engine working with a good cut-off. Means are provided by which the injection of the charge is sufficiently prolonged to keep the pressure in the cylinder at its maximum during the first portion of the working stroke. To effect this, an oil reservoir is provided in conjunction with the main spraying valve into which the surplus oil from the igniter spray flows. This chamber is so formed that it is not immediately emptied when the spraying valve is opened, but a further supply of fuel is forced into the combustion chamber as the working stroke proceeds, thus maintaining the combustion and the pressure for a portion of the stroke.

The effect produced by the prolonged injection of the fuel is to give increased mean effective pressure without high initial pressure. Both the auxiliary and the main spraying valves are actuated through suitable levers from a single push rod worked by a cam on the lay shaft, and means are provided whereby the movement of both valves can be adjusted.

Strong points in favour of crude and residual oils are freedom from danger and uselessness for any other purpose than that for which they are intended. Crude Texas is almost uninflammable, in fact a bucketful thrown on to a fire of shavings and sticks will act almost as if it were water instead of oil. In view of the danger attaching to the use of petrol in and about farm buildings and the higher fire insurance premium demanded where used, this consideration is of special value.

The engines are of very massive design. In the larger sizes the cylinder jackets and bedplate are cast in one piece, the base extending along the whole length of the cylinder with facings for attachment of the camshaft bearings and compressor. The governor is of the enclosed spring-loaded centrifugal type; it is placed in front of the engine and driven directly from the crankshaft, so avoiding the jump caused by the action of the exhaust cam. Speed is controlled by the governor varying the stroke of the fuel oil pump by inserting or withdrawing a wedge-shaped piece between the ends of the pump actuating lever and pump plunger; the actuating lever is connected with a dashpot to prevent 'dancing.' The camshaft bearings are ring lubricated; for the main bearings, piston, etc., forced lubrication is employed.

VICKERS-PETTER SEMI-DIESEL ENGINES.

The Vickers-Petter semi-Diesel engine is one of the most important manufactured in Great Britain, and is constructed for larger output than any similar design built in this country. It is built in sizes up to 450 h.p. in six cylinders, and is adapted either for marine or stationary work.

Messrs. Petters Ltd. of Yeovil, and Vickers-Petter of Ipswich, specialise entirely in two-stroke valveless oil engines, which have been developed by them in the direction of greater simplicity and fuel economy. The 2½ b.h.p. to 8 b.h.p. sizes are vertical, with electric ignition, and start at once on petrol, automatically changing to kerosene, after running a minute or two. Engines from 10 b.h.p. to 450 b.h.p. are vertical and are of the semi-Diesel type, using either paraffin, crude or residual oils. Vegetable oils, especially palm oil, have also been used with great success. The fuel consumption of the larger engines at full load compares favourably with that obtained with Diesel engines, taking into account the lower working pressure and greater simplicity, which can be seen on reference fo fig. 21.

Large numbers of these engines have been supplied for factories and for electric lighting and power stations. The multi-cylinder engines are especially suitable for the latter work owing to their great uniformity in rotation, and a number of engines have been supplied for driving alternators running in parallel with other machines.

The admission of air to the cylinder and the period of exhaust are controlled by the piston, which overruns ports at the lower end of the cylinder. Consequently no valves are required on the cylinder, and the air inlet valve on the crank case is only subjected to a few pounds pressure, the air from the crank case being transferred to the cylinder when the piston is at the bottom of its stroke. The fuel pump delivers oil direct to the cylinder through a pulveriser when the piston is at the top of its stroke, that is, at the period of maximum compression. The air blast for the fuel injection, which is usual on Diesel and on some makes of semi-Diesel engines, has been eliminated on the Petter engine, and by dispensing with the air compressor and operating gear this engine is greatly simplified. A separate fuel pump is provided for each cylinder.

Accessibility is a marked feature of this engine, and it will be seen that the cylinders are entirely independent from one another.

The fuel injection system embraces a patent shaft governor, which varies the length of the fuel pump stroke and at the same time automatically controls the moment of injection of the fuel in relation to the load on the engine. The patent light running gear secures complete combustion on light loads by means of a supplementary fuel injection timed in advance of the normal injection. Consequently the lamp is never required after the engine has been started and the use of water injection into the cylinder is eliminated.

Messrs. Vickers-Petters Ltd. have specialised in quick starting arrangements of which two alternative methods are employed by them.

1. The safety rapid starting burner (patent) using paraffin fuel, which enables the engine to be started within one minute from cold. Cleanliness, efficiency, and safety are ensured by the use of this burner.

2. Electric starting, by means of an electrically heated wire element. The engine can be started instantly from cold without external heating. The patent electric torch is only exposed to the heat of combustion for a few minutes, and being then withdrawn is not liable to get burnt out.

The single-feed lubricator. This is a new patent spray lubricator, by means of which the cylinder as well as the large and small connecting rod bearings are lubricated from one jet through which the lubricating oil is introduced mixed with air in the form of a spray. This invention reduces the lubricating oil consumption in this engine by one-half.

The leading dimensions of the engine illustrated are :

Cylinder bore 12 ins., stroke of piston 14 ins., rated h.p. 70, flywheel diameter 66 ins., flywheel width 10 ins., approximate weight 7 tons.

The results of some tests of an engine of this type are here given :—

Details.	Full Load.	Half Load.	Quarter Load.
Brake horse-power	71	36·8	18
Revolutions per minute	227	229	231
Total fuel used, pints	62	18	14
Hours run	2	1	1
Fuel per hour, pints	31	18	14
Fuel per b.h.p. hour, pints	0·437	0·49	0·778
Fuel used	Crude Texas	Crude Texas	Crude Texas
Specific gravity of fuel	0·9	0·9	0·9

The Vickers-Petter direct-reversing marine oil engine is similar in design to the above, and the reliability of the engines makes them especially applicable for ship propulsion. In comparison with other internal combustion engines, they have the advantages of lower fuel consumption and the absence of water injection in the cylinders, thus the amount of fuel to be carried on the ship can be reduced and there is no need to provide fresh-water tanks for the water drip. The engines work equally well on any crude or crude residual or refined petroleum obtainable throughout the world. In comparing fuel consumptions with those of the Diesel type, brake horse-powers and not indicated horse-powers should be considered, as the mechanical

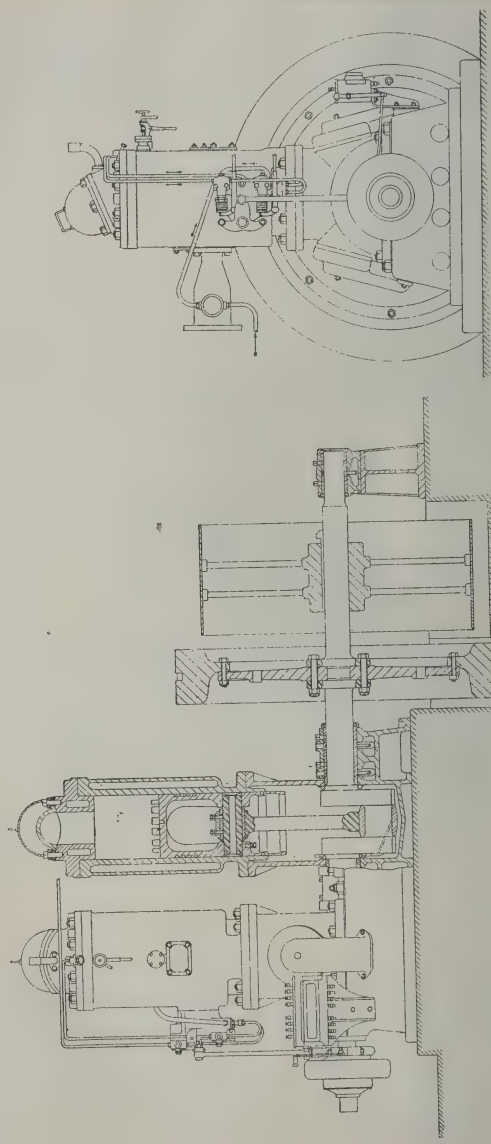

FIG. 21.—Sectional Arrangement of a Vickers-Petter Semi-Diesel Engine.

efficiency is less in the Diesel type. The direct reversing system is remarkably simple and certain; its action is positive and the whole operation from full speed 'ahead' to full speed 'astern' can be accomplished in less than half-a-minute.

One of the best of the recent improvements in semi-Diesel engines is the patented method whereby the Vickers-Petter engine will run light or at reduced speeds indefinitely without misfiring or cooling down.

Marshall Crude Oil Engines.

Messrs. Marshall Sons & Co., Gainsborough, make crude oil engines of the semi-Diesel type, both horizontal and vertical, in sizes from 8 to 300 b.h.p. They supply a number of the horizontal engines on portable carriages for agricultural and other work.

The engines operate on the two-stroke cycle and have an impulse every revolution. The governor is mounted on the crankshaft and controls the throw of the eccentric operating the fuel pump plunger; thus the amount of fuel injected into the cylinder is always proportional to the load on the engine.

Marshalls' engines have a wide range of speed variation, and do not cool down when running quite light. Also they will take overloads without trouble and no water injection is required in the cylinder. Separate cylinder liners are fitted on all engines.

Campbell Crude Oil Engines.

Vertical engines of the two-stroke cycle are made by the Campbell Gas Engine Co., Halifax, in sizes from 5 to 320 b.h.p. for land and marine purposes. They are supplied with single, two, and four cylinders.

The engines are of the usual valveless type, and have ports in the cylinder so that the air inlet and exhaust periods are controlled by the piston. All of the parts are substantially constructed and the engines are easily started; the smallest sizes by hand and sizes above 22 b.h.p. by means of air compressed at 120 to 150 lbs. pressure.

Lubrication, as well as other important details, has received careful attention on the engines and the large number in use indicate the success of the engines. They work on gas oil, solar oil, kerosene, and the lighter crude and residual oils.

Beardmore Oil Engines.

Engines in powers from 10 to 600 b.h.p. are made by William Beardmore & Co. Ltd., Coatbridge. The engines are of the vertical design working on the two-stroke cycle and are supplied in from one to six cylinders for both land and marine purposes.

The crank-case of the engine is used as a pump, the air drawn in through the covers is compressed during the downward stroke of the piston and admitted to the cylinder when the piston is nearly at the bottom of its stroke. The exhaust ports are already uncovered and the shape of the piston top deflects the air to assist in scavenging the cylinder. The air in the cylinder is compressed during the upward stroke of the piston and fuel is injected by means of a pump through an atomiser into the combustion chamber when the piston is nearly at the top of its stroke.

A number of these engines are in use for electric lighting and power purposes and for driving various kinds of industrial machinery, but the majority have been installed in yachts, barges, and coasting vessels of all descriptions.

The weight of the engines varies from about 1¾ to 2½ cwts. per horse-power for land work and from about 1½ to 2 cwts. per horse-power for marine propulsion.

Allen Oil Engines.

Crude oil engines are made by W. H. Allen, Sons & Co. Ltd., Bedford, in single, two and four cylinder sizes ranging in power from 10 to 320 b.h.p. Particulars of the engines, giving cylinder

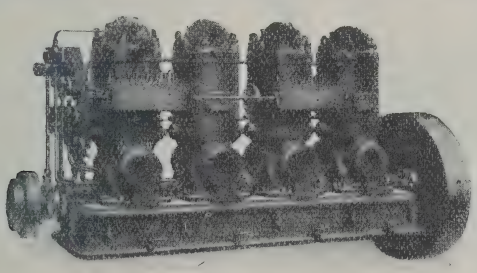

Fig. 22. The Allen Crude Oil Engine.

dimensions, are shown below. The rating and speeds are moderate and the engines are capable of running continuously at full power.

The engines work on the two-stroke cycle and have an impulse every revolution, the governor being arranged to control the amount of fuel oil injected in proportion to the load. They can be started in a few minutes by preliminary heating of the vaporiser with a blow lamp, which is used at starting only. They will run at any load for an indefinite period without the starting lamp or any other additional device; also no adjustment is required for light running, and the engine will run under no-load without misfiring.

320	250	4	16¾ × 17½	66	14	95	66	232	415	460

A noteworthy feature is that the engines will work satisfactorily when running at reduced speeds, down to as low as half the normal speed. Regular running is obtained and the exceptional economy of these engines is still maintained.

The engines will work on almost any good quality crude or residual oil of specific gravity up to ·95, and the fuel consumption is only ·5 pint per b.h.p. per hour at full load. At ¾-load the consumption per b.h.p. is slightly increased and at ½-load the increase is not more than 20 per cent Thus each engine has a large economical range of power.

Peter Brotherhood Oil Engines.

Single-cylinder horizontal oil engines in sizes from 16 to 120 b.h.p. are manufactured by Peter Brotherhood, Peterborough. The engines operate on the four-stroke cycle.

An illustration of one of these engines is shown in fig. 23, from which the substantial design

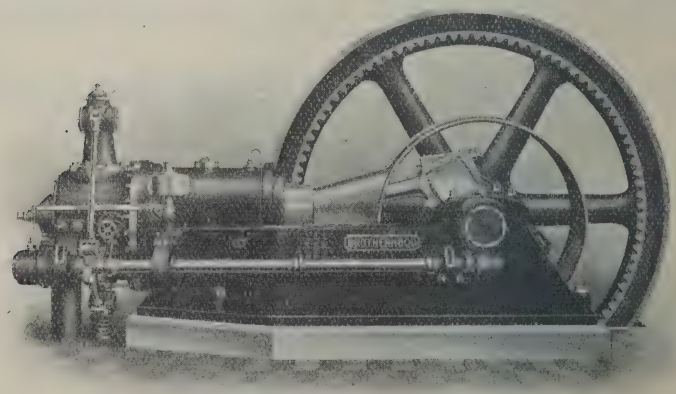

Fig. 23—Peter Brotherhood Oil Engine.

can be seen. The bed is well supported on the foundation and the thrust of the connecting rod is taken by it. The cylinder liner is removable and the combustion chamber is bolted to the bed.

Ignition is automatic, after the preliminary heating of the vaporiser by the starting lamp. The atomiser is of an extremely efficient design. It contains a needle valve, loaded with a suitable spring, and this is lifted at each stroke of the fuel pump. The stroke of the fuel pump plunger is controlled by the governor automatically in proportion to the load.

Robey Oil Engines.

Semi-Diesel engines for land and marine work are made by Robey & Co., Lincoln, in various sizes from 6 to 200 b.h.p. They are of the vertical two-stroke cycle type and are extremely simple.

The fuel is injected into the combustion chamber through a special form of sprayer, which gives good atomisation. The governor is of the centrifugal type mounted direct on the crank-shaft and controls the amount of fuel injected in proportion to the load.

Robey engines will run on the usual kinds of refined, crude, or residual oil, and they have worked satisfactorily on tar oil.

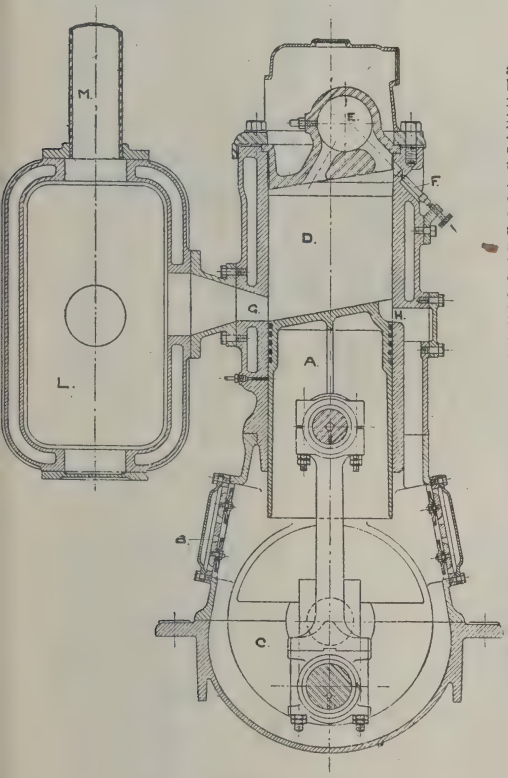

Fig. 24.—The Bolinder Engine.

Bolinder Engines.

The Bolinder engine (fig. 24), although essentially of the hot-bulb type, contains several features which distinguish it from other motors of this class. It is a high standardised production, and is now made in sizes up to 500 b.h.p. in four cylinders. As in most other motors of this design, the air is drawn in the crank chamber on the compression stroke of the piston, this air being compressed to a relatively low pressure in the crank chamber by the piston on its outward stroke. Just before the piston reaches the end of its stroke the exhaust ports are uncovered in the cylinder, allowing the exit of the exhaust gases, which are finally completely driven out through the exhaust pipe by the admission of the compressed air from the crank chamber through further ports in the cylinder wall uncovered by the piston as it continues on its downward stroke. On the upward stroke the piston compresses the air thus taken into the cylinder, and on reaching the top of its stroke the fuel is sprayed into the hot-bulb, thus causing combustion, vaporisation, and expansion within the cylinder. The bulb is kept hot by the heat due to the combustion, and the compression is usually about 125 to 150 lbs. per square inch. It is, of course, necessary to heat up the bulb by a blow-lamp before starting, but once the engine is running it is not necessary to keep the lamp burning, even when operating on light load.

Engines of 90 b.h.p. and above dispense with water injection into the cylinder, and are fitted with small two-stage air compressors driven from the main crankshaft. Compressed air is forced into the bulb at the same time as the fuel. If required the engine can be run at about three-quarters power with the air compressor disconnected and without overheating. On the smaller sizes, water injection is retained, as it is possible to obtain a higher power for given cylinder dimensions.

THE STILL (I.C. + STEAM) ENGINE.

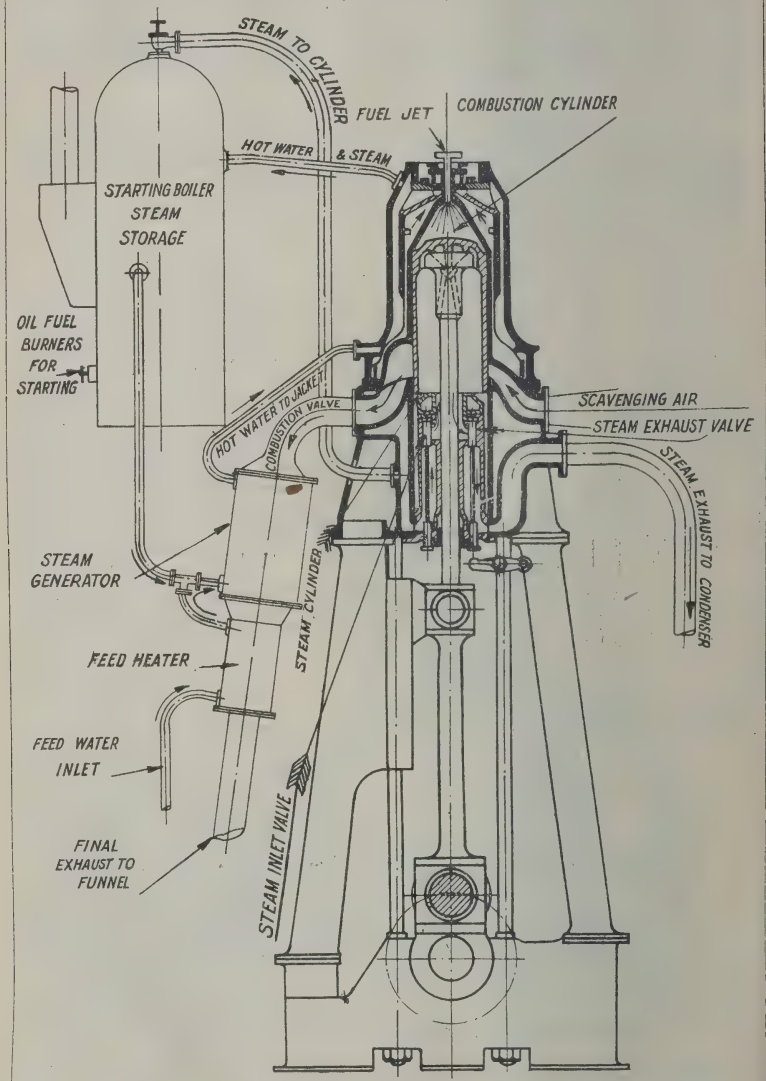

FIG. 25.

For marine work, the Bolinder engine is made directly reversible, the principle being, broadly, the injection of fuel to cause an explosion, after the engine has slowed down nearly to the point of stopping, whilst the piston is on the upward stroke, so that reversal of motion follows. This is carried out by a special device regulating the action of the fuel pump.

The Bolinder motor is manufactured in Stockholm, but is handled in Great Britain by Messrs. James Pollock, Sons & Co. Ltd.

Other Makes of Semi-Diesel Engines.

Semi-Diesel engines of the horizontal four-stroke cycle type are manufactured by Tangyes, Ltd., Birmingham; Fielding & Platt, Gloucester; and Bates & Scholes, Ltd., Denton, Manchester. Engines of the vertical design operating on the two-stroke cycle are also made by Plenty & Son, Newbury; the Aster Engineering Co., Wembley; John Kirkaldy, Ltd., Burnt Mill; Norris, Henty & Gardners Ltd.; the Keighley Gas & Oil Engine Co., Keighley; Widdop & Co., Keighley; and Clayton & Shuttleworth, Lincoln.

Still (I.C. + Steam) Engines.

An engine of high thermal efficiency has been developed by the Still Engine Co. and is manufactured by several licencees. The main working cylinder uses liquid or gaseous fuel, and in the same cylinder, on the opposite side of the piston, steam is employed. The steam is produced by the recoverable heat from the internal combustion side, which passes through the walls of the cylinder as well as into the exhaust gases.

Heat, wasted in other internal combustion engines, is usefully employed in the Still engine to increase the power of the engine and reduce the consumption of fuel per horse-power developed.

As will be seen from fig. 25, the jacket and cooling water form part of the circulating system of a steam generator, which may be an integral part of the engine. The cylinder liner is specially constructed and is about one-third of the usual thickness; it is ribbed externally to add to its conducting surface. The quantity of steam capable of being generated from the rejected heat of an internal combustion engine depends upon the efficiency of the combustion cycle and on the load. At full load the quantity may be about 7 lbs. per b.h.p. of the engine.

In the indicator diagram (fig. 26) taken from the under, or steam, side of the piston, the

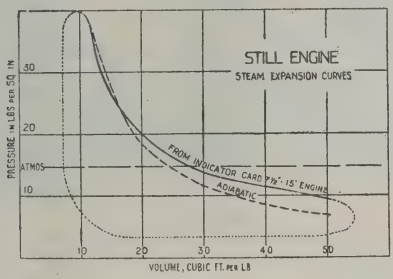

Fig. 26.

adiabatic expansion line as plotted shows there is no loss from condensation. Heat is taken from the piston and cylinder walls and the steam exhausts at a slight superheat.

An experimental engine tested by Professor Vernon Boys generated 3·28 lbs. of steam from the jacket alone, and from the jacket and exhaust together 6 lbs. of steam per b.h.p. hour. The average m.e.p. from the combustion stroke was 90 lbs. per sq. in. The steam evaporated by the heat rejected gave 14 lbs. m.e.p. per sq. in. on every return stroke of the piston. Thus, the four-stroke cycle engine had a total m.e.p. of 118 lbs. per cycle.

The possibilities of this design are very great; by admitting additional steam generated by fuel under the boiler, the total m.e.p. can be increased considerably. This enables the engine to take big overloads, and by the use of steam easy starting and manœuvring are obtained.

The thermal efficiency of the Still engine compared with other prime movers is shown in the following table:—

Marine steam engine, superheated	16% to 17%
Parsons steam turbines	15 „ 20
Gas engines	22 „ 30
Petrol engines	23 „ 27
Semi-Diesel engines	27 „ 30
Still gas engine	31
Still petrol engine	33
Diesel engines	30 „ 36
Still oil engines	38 „ 44

HIGH-COMPRESSION OIL ENGINES.

The high-compression oil engine is the outcome of experiments to simplify and reduce the cost of Diesel engines. Many attempts have been made to produce engines capable of burning cheap heavy oils with an economy approaching that of the Diesel, but in which the high-pressure air blast is avoided without sacrificing the capability of the engines to start immediately from cold.

Among the first of the successful engines was the Vickers, which has been largely developed for propelling submarines. Several other makes of high-compression engines are now on the market, and the elimination of the air compressor has produced a marked improvement as regards simplicity compared with Diesel engines.

What is known as 'solid injection' is adopted for spraying the fuel into the cylinder, the oil being raised to a high pressure by the fuel pump momentarily at the period of injection, or permanently in a small receiver and admitted to the cylinder by timing the opening of the fuel admission valve.

The weight and price per horse-power are lower on these engines than Diesel engines, but up to the present the economy is not quite so good.

Vickers Oil Engines.

High-compression oil engines for land or marine purposes are manufactured by Vickers, Ltd., Barrow-in-Furness, in sizes from 500 b.h.p. upwards. The engines are of the vertical, multi-cylinder, four-stroke cycle type.

The mechanical fuel injection system on these engines has been used for the last eight years and no air blast is required for the fuel. The engines will start from cold without preliminary heating of any part. A sufficiently fine spray into the cylinder is obtained, forcing the oil at a high pressure through minute holes in a special nozzle below the fuel-injection needle valve.

A fuel pump may be fitted for each cylinder, or two pumps can be used for all the cylinders, and delivers the oil at a pressure of from 2,000 to 4,000 lbs. per sq. in. into a pulsator tube from which it passes through a special strainer to the needle valve in the cylinder head. The pressure depends upon the speed and power at which the engine is running. Control of the power is obtained by varying the time and the amount of opening of the fuel valve, and by adjusting the pump to the desired pressure.

Engines of a total horse-power of nearly 500,000 have been built, and the makers claim the following advantages over Diesel engines:—

High-pressure air for fuel injection eliminated.
Increased safety in working and lower compression pressure.
Reduction of space, weight, and cost.
Elimination of cooling effect of air blast on piston and cylinder head.

The six-cylinder 1,250 b.h.p. engine has cylinders 24·5-in. diam. by 39-in. stroke, and the normal speed is 118 r.p.m. The fuel consumption is stated to be as low as 0·38 lb. per b.h.p. per hour.

Crossley Oil Engines.

Crossley Bros., of Openshaw, Manchester, make high-compression oil engines in sizes from 8 to 130 b.h.p. single cylinder, and up to 260 b.h.p. double cylinder. The engines are of the horizontal four-stroke cycle type.

RUSTON

OIL AIRLESS Cold Starting ATOMISER ENGINE

B 2301

Uses Low-Grade Fuel Oils
(e.g., Furnace Oil of ·95 Spec. Gravity).

Low Consumption Guaranteed
(·42 lbs. per B.H.P. hour).

No Lamp. No skilled attendant needed.

Made in sizes from 15 to 340 B.H.P. by

Ruston & Hornsby Ltd.
LINCOLN ENGLAND.

F. 1691

All of the engines start up from cold without pre-heating, and will work on crude, refined, or residual oils. The patent fuel pump and governor gear are particularly interesting, as the commencement of the fuel injection is constant at all loads. Governing is effected by reducing the amount of the charge delivered by the fuel oil pump at reduced engine loads; the full consumption is thus, as far as possible, proportioned to the power output. Messrs. Crossley state that in a recent test the consumption of (crude) oil for b.h.p. hour at full load was 0·42 lb., and at about half load rose to only 0·43 lb. with their governing arrangement; and that consumptions as low as ·40 lb. have been obtained. They point out that this performance compares favourably with that of the more costly Diesel type of engine.

These engines can be supplied as convertible engines to work with either fuel oil or producer gas, whichever may be the cheaper fuel at the time.

Ruston-Hornsby Oil Engines.

This engine of Messrs. Ruston & Hornsby, Ltd., fig. 28, is of the solid injection type. The makers have succeeded in dispensing with the high-pressure air blast for fuel injection

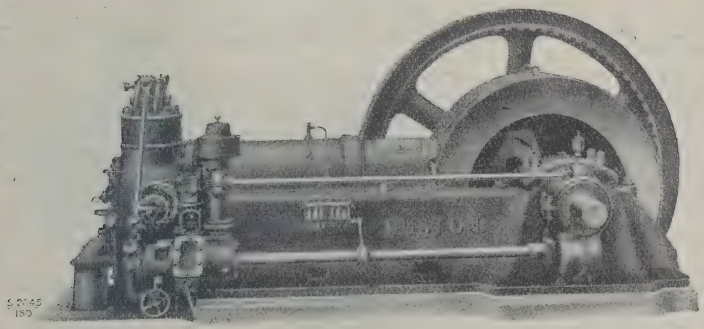

Fig. 28.—The Ruston-Hornsby Oil Engine.

altogether, a quick-acting fuel force-pump being employed to inject the fuel oil through a specially designed mechanical atomiser. The engine is of the high compression type and is started from cold without a lamp. It will use the same heavy oils as are used on a Diesel engine, and the principle is extended to engines of large power. The engines are built in single and multi-cylinder forms giving a range from 15 b.h.p. to over 340 b.h.p. An illustration of the 130 b.h.p. engine is given in fig. 28. The bedplate is in one piece carrying the liners and main bearings. A special feature is the valve gear, which is actuated by means of eccentric gear and one side shaft, thus reducing the number of working parts to a minimum, and giving a compact and silent running engine.

The action of the engine is as follows:—The piston on its outstroke takes in air, which, on the return stroke, is compressed in the combustion chamber, and nearly at the point of greatest compression, the oil fuel is injected by a pump, which forces the oil through a mechanical atomiser. The compression temperature is sufficient to ignite the charge. The power stroke follows, then the exhaust, after which the cycle is repeated. By adopting this cycle, on the one hand a high compression can be used with its attendant economy, without incurring pre-ignition, whilst, on the other hand, an air compressor and air receiver are avoided.

The oil-fuel pump is driven through a lever by a quick-acting cam on the layshaft, which is completely enclosed and runs in oil. A lever is provided by which the pump can be worked by hand, or thrown out of action altogether to stop the engine. The fuel pump and side shaft are carried by the bedplate, thus relieving the cylinder head.

The mechanical atomiser, which is fixed in the combustion head, consists of a duplex valve loaded by a powerful spring, which is lifted at each stroke of the oil-fuel pump. The valve has two seats of different diameters, the smaller of which closes the opening of the combustion chamber, and the larger a leak pipe to the oil tank. When the smaller valve lifts, the oil is forced through channels converging to a central outlet, which so split up the stream that it emerges on

either side of the nozzle in a cone-shaped cloud of oil particles. The movement of the valve is about $\frac{1}{10}$th inch, and is entirely automatic in action. There is no packing or oil-tight diaphragm, or any complication liable to get out of order, and the action, though delicate, is found in practice to be absolutely reliable.

The regulation of the speed is effected by the opening of a by-pass valve by the governor, the toe of the valve resting upon a lever carried upon a cam. The fulcrum of the lever is adjustable by a screw, so that although the lift of the valve is minute, there is always a means at hand for easily keeping it in perfect adjustment. The only attention required to the atomiser is cleaning out the oil passages after about every 300 hours' run. The consumption of oil, even the lowest grade of crude, residue, or fuel oils, is complete, while the economy is remarkable.

Tests which have been made show that a high thermal efficiency is obtained with the cheapest fuel oils on the market, the consumption ranging from ·40 to ·47 lb. per b.h.p. hour according to the size of the engine.

Campbell 'High-Compression' Crude Oil Engines.

The 'high-compression' crude oil engine made by the Campbell Gas Engine Co. Ltd., of Halifax, Yorks, works on the four-stroke cycle with a compression pressure of about 300 lbs. per sq. in.

Air only is taken into the cylinder and compressed by the piston. The fuel is injected at about the end of the compression stroke, so that pre-ignition is rendered practically impossible. The fuel is injected by a cam-operated ram pump through a mechanical atomiser which delivers the fuel into the combustion chamber in the form of an extremely fine spray or mist. The speed of the engine is governed by increasing or diminishing the stroke of the fuel pump and thus the quantity of fuel injected in each cycle; there is no by-pass on the fuel pump. This system provides a working impulse in every cycle at all loads, thus ensuring minimum speed fluctuation and approximate equalisation of the working stresses in consecutive cycles.

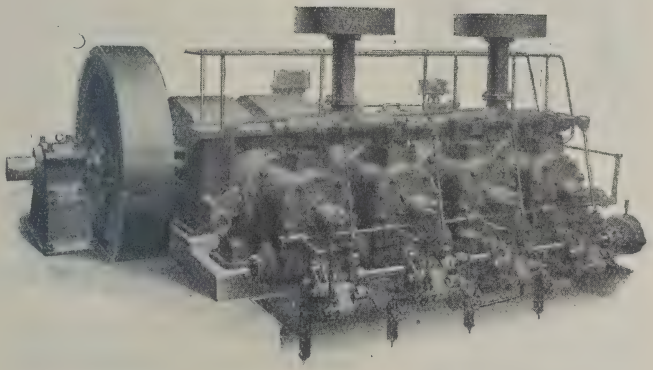
By a recent improvement the heating lamp can be dispensed with entirely and the engine started up immediately from cold. This system is the standard for all except small engines, but it can be applied to the latter if required.

In the Campbell high-compression engine water drip or injection to the cylinder is not required under any conditions, and no provision is made on the engine for using it.

It is claimed that any kind of crude or residual petroleum may be used, even if it contains asphalt or bitumen. Tar oil (distilled from coal, specific gravity 1·05) can also be used.

The Campbell Co. state that the consumption varies with the size of engine and heat value of the fuel. When using residual petroleum of about 18,000 B.Th.U. per lb., the consumption varies from ·55 lb. per b.h.p. per hour in an engine of 9 b.h.p. to about ·43 lb. in one of 100 b.h.p. A test was recently conducted on an engine of 35 maximum b.h.p. extending over a fortnight, running not less than 12 hours per day, including runs of 24 and of 30 consecutive hours, and finishing with a non-stop run for seven days and nights. This last run consisted of 72 hours consecutively at full load, 24 hours each at $\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$ load with a two hours' interval each day at loads varying from zero to maximum, and concluding with 24 hours at full load.

The fuel used during this trial was Mexican fuel oil of 0·96 sp. gr. containing about 3·2 per cent. of asphalt and having a viscosity of 1,500 sec. as tested in a No. 1 Redwood viscometer. The whole of the fuel used was weighed, and the consumption was found to be:—



At full load	·49 lb.	per b.h.p.	per hour
,, $\frac{3}{4}$,,	·485	,,	,,
,, $\frac{1}{2}$,,	·515		
,, $\frac{1}{4}$,,	·656	,,	,,

The test was carried out by independent engineers, and during the whole of the time no adjustment of any kind was made to any part of the engine.

The Campbell high-compression engine is built in a range of standard sizes from 9 to 100 max. b.h.p., single cylinder, 120 to 200 b.h.p. in two cylinders, and 200 to 400 b.h.p. in four cylinders. It is also built in the vertical type with two or four cylinders from 70 to 500 b.h.p. Higher powers can be had if required. The makers claim that this engine possesses all the advantages of the Diesel engine, while it is simpler in construction, easier to handle, and lower both in first cost and in running and maintenance.

CAMPBELL

HIGH COMPRESSION
CRUDE-OIL ENGINES

RUN ON ALL KINDS OF CRUDE OR RESIDUAL PETROLEUM or on TAR OIL.

Consumption, ·45 to ·55 lb. per B.H.P. Hour.

Start from **cold state** at a moment's notice
without use of heating lamp.

No lamp is used for starting. Water injection to cylinder is not used. Standard Sizes, 9 to 400 B.H.P.

LOW-COMPRESSION OIL ENGINES.

The early oil engines were all low-compression engines, and the desire to use the heavier grades of petroleum, which are cheaper than the more refined grades, caused the development of higher pressures, so that the increased temperature could completely vaporise the heavier fuels.

The low-compression oil engines still have, and will always continue to have, a wide application, owing to the low working pressures and small cost.

In the normal 'oil engine' a heavy kerosene is usually employed as fuel; Russian oil is, in general, rather preferred, though the ordinary American brands are also used with quite satisfactory results. A standardised oil described as R.V.O. (Russian vapourising oil) of specific gravity ·825 and flash point 86°F. (close test) is regarded as the normal fuel for these engines; other descriptions commonly used, however, include Rocklight, Russolene, Homelight, Gladiator, Phœbus, Silver Spray, Crown Diamond, Royal Daylight, White Rose, Tea Rose, and Bear Creek. Among the heavier fuels used are refined shale-oils as Broxburn and Scotch Lighthouse, and also the refined heavy oils of Burma, Assam, Roumania, etc.

The average composition of the petroleum oils used is 85½ per cent. carbon, 13½ per cent. hydrogen, and 1 per cent. oxygen, and the mean calorific value, by Berthelot calorimeter, is roundly 19,600 B.Th.U. per lb. When arranged to use either petrol, kerosene, or heavier oils, engines usually develop powers in the proportion of about 100 : 90 : 80, respectively.

It should be carefully noted that the nominal power of internal combustion engines in general is for location at sea-level; when required to work at an altitude a deduction from the nominal power should be made of 3 per cent. for each 1,000 feet of height, due to the diminished density of the air (see table, page 1742).

In the ordinary oil engine the heavy kerosene fuel is vaporised in a heated chamber maintained at the necessary temperature either by heat derived from the successive explosions (hot-bulb vaporisers), or from the exhaust of the engine; or lastly, in a few cases, by means of a separate blow-lamp. In most cases a preliminary heating of the vaporiser by a blow-lamp is necessary for 10 to 15 minutes before the engine can be started. These engines are practically all of the single-acting four-stroke type, and compress a mixture of kerosene vapour and air into the combustion chamber.

Ignition of the charge is sometimes automatic, as in the Hornsby and Blackstone oil engines; high and low tension magneto ignition is also used, while in cases where lamp-heated vaporisers are adopted tube ignition is general. On account of the care and attention necessary where lamps are used, and also in some cases due to increased fire risks, makers are in general favouring one or other of the methods of lampless ignition.

Ruston-Hornsby Oil Engines.

This widely-known engine, invented by Mr. Akroyd Stuart 1886–1890, first successfully adopted the now largely used 'hot-bulb' in order to vaporise the oil fuel and automatically explode the charge at the proper instant. A sectional view is given in fig. 29 of a present design

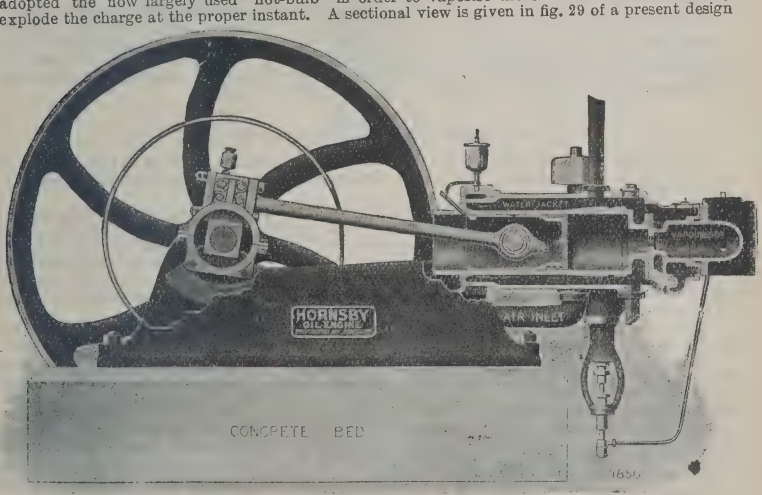

Fig. 29.—The Ruston-Hornsby Oil Engine.

by Messrs. Ruston & Hornsby, Ltd.; the hot-bulb is seen as an unjacketed, or partly jacketed, extension of the combustion chamber, the connection being by a narrow passage as shown; this hot-bulb receives a preliminary heating by a blow-lamp for 10 to 15 minutes and the engine is then turned by hand. On the suction stroke the piston draws a charge of air only into the combustion chamber and cylinder while at the same time a few drops of oil are injected by the fuel pump into the hot-bulb and there vaporised; on the compression stroke the air is packed into the combustion chamber and hot-bulb and mingles therein with the heavy petroleum vapour; the mixture is at first too rich to explode, but as the compression proceeds it becomes more and more dilute, and the capacities are so adjusted that just as the piston reaches the end of its stroke the heat of the walls of the hot-bulb automatically explodes the charge. The working stroke next follows and is succeeded by the exhaust; the cycle then recurs.

The temperature of the hot-bulb is maintained by the heat derived from the successive explosions and the ignition is entirely automatic. The engine is thus of the single-acting four-stroke type.

A test by Prof. W. Robinson in 1908, of a single-cylinder 32 b.h.p. Hornsby engine, using 'Russolene' as fuel, furnished the following results:—

Duration of trial	1 hour
Compression pressure, lbs. per sq. in.	85
Explosion pressure, lbs. per sq. in.	260
Revolutions per minute, mean	230·2
Brake horse-power	32
Total oil burned, lbs.	19·6
Lbs. oil per b.h.p. hour	0·613
Brake thermal efficiency, per cent.	22·6

Blackstone Kerosene Engines.

In the kerosene engines of Messrs. Blackstone of Stamford there is also a hot-bulb vaporiser in the form of an annular chamber, or jacket, surrounding an inner explosion chamber, this latter forming an extension of the cylinder head and being connected therewith by a short passage containing a mechanically-operated ignition timing valve which cuts off the explosion chamber at the end of the suction stroke, and reopens near the end of the compression stroke when the compressed charge is admitted to the explosion chamber and instantly fired by an automatic igniter of the internal hot-tube variety which is kept hot by the successive explosions. A preliminary heating of the vaporiser by blow-lamp is necessary, as usual, in order to start the engine. In these kerosene engines no force fuel pump is required, the piston suction causing a current of air to traverse a spraying nozzle and thus 'snift' the charge of kerosene spray into the vaporiser Any ordinary refined oil as Rocklight, Russolene, Royal Daylight, etc., may be used.

During occasional light load periods it is sometimes desirable to keep the blow-lamp in action in order to maintain the temperature of the vaporiser and prevent a smoky exhaust; this is a frequent necessity of kerosene engines at such times. Also, if long periods of full load service are required, a water spray is admitted to the cylinder during the suction stroke in engines not fitted with the above-mentioned timing valve to remove the 'pounding' or pre-ignition knocking otherwise liable to occur in a hot engine using a heavy petroleum fuel.

Blackstone Vertical Kerosene Engines.

This is a simple and compact four-stroke engine using ordinary kerosene as fuel, fitted with a vaporiser similar to that of the horizontal engines, and with water drip to prevent 'pounding' at heavy loads.

The enclosed crank chamber is provided with large inspection doors, through which big end adjustments can be made; the main bearings are ring-lubricated, while the crank-pin and piston are supplied by a sight-feed lubricator; the camshaft is also enclosed in an oil-containing casing, and is driven by skew gear from the crankshaft. Speed regulation is by a simple specially designed governor of the inertia type, which is claimed to act as effectively as the disc governor fitted to the larger Blackstone engines; the speed may be adjusted by hand while the engine is running.

This type of engine is also supplied in portable form, mounted on a massive four-wheeled girder carriage, and also in semi-portable form, both being provided with water-cooling apparatus.

There is no water pump, the pulsations of the exhaust being ingeniously utilised to cause the cooling water to circulate around the cylinder jacket. The device comprises a double-chambered valve-box to one compartment of which a branch from the exhaust pipe is attached; in this branch the water rises to the level of that in the cooling tank, but is prevented from returning by a non-return valve; the two compartments are connected through a second non-return valve, and from the second compartment the delivery pipe to the cylinder jacket proceeds; this delivery pipe is fitted with an air vessel.

When exhaust occurs the pressure in the first compartment impels the water into the second and then, via the delivery pipe, to the cylinder jacket; on completion of the exhaust stroke

a fresh charge of water flows by gravity from the cooling tank, through the non-return valve, to the first compartment. After passing through the jacket the hot water is delivered into a receiver surmounting a perforated cone through which it flows, becoming cooled by evaporation, and so returns to the supply tank.

CAMPBELL OIL ENGINES.

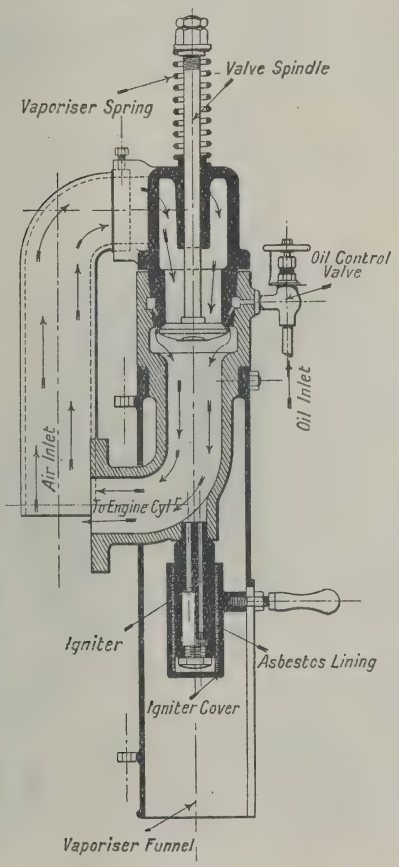

FIG. 30.—The Campbell Kerosene Engine.

In the kerosene engines of the Campbell Gas Engine Co. a very simple arrangement of vaporiser is adopted, as will be seen from fig. 30. The automatic inlet valve shown serves for admission of the whole charge of air to the cylinder ; the kerosene feed is through the seat of the inlet valve, and ignition is automatically effected by the thick-walled hot tube in the lower part of the apparatus. The kerosene is drawn into the vaporiser by the suction of the piston from the fuel tank which is formed in the engine bedplate. The feed pipe is connected to the oil control valve shown.

A preliminary heating of the vaporiser and ignition tube is necessary for 10 to 15 minutes before the engine can be started. Water spray is admitted to the cylinder when running at full load. The Campbell kerosene engines are very simple and satisfactory in service; they are built in sizes from 3 b.h.p. at 320 r.p.m. to 31 b.h.p. at 220 r.p.m.

National Oil Engines.

Oil engines of the horizontal four-stroke cycle type are made by the National Gas Engine Co., Ashton-under-Lyne, in sizes from 2½ to 47½ b.h.p.

The special feature of these engines is the vaporiser and ignition timing device, which secures effective vaporisation of the oil and the proper timing of the ignition at all loads. A lamp must be used for starting, and the vaporiser needs to be heated for about ten minutes to make it hot enough to start the engine.

The engines are supplied both stationary and portable, and are suitable for agricultural and industrial work.

Hamworthy Oil Engines.

Hamworthy oil engines are made in four sizes—2½, 5, 9, and 15 b.h.p.—and are manufactured on strictly repetition lines by the Hamworthy Engineering Co., Poole.

They are supplied as stationary, semi-portable, or portable engines, and are suitable for any purpose requiring power.

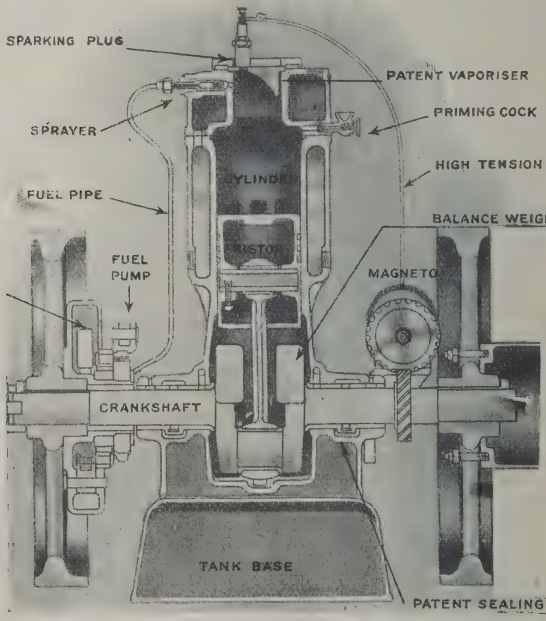

Fig. 31.—The Hamworthy Oil Engine.

Fig. 31 shows the extreme simplicity of these engines; they are stated to be most economical, the full load fuel consumption being only 0·5 to 0·6 pint per b.h.p. hour.

Magneto ignition is fitted and the engines can be started up immediately by one turn of the crankshaft on petrol, then changed over to paraffin fuel.

Robson Oil Engines.

Horizontal oil engines of the four-stroke cycle type from 9 to 75 b.h.p. are manufactured by John Robson Ltd., Shipley.

The engines are suitable for using paraffin and light crude oils. A separate cylinder liner is fitted and the bed is well supported on the foundation, the bed and cylinder jacket being in one casting.

The combustion chamber is a separate casting bolted to the bed, and the valves are arranged vertically, so that they are easily accessible. The governor is of the centrifugal type and regulates the amount of fuel injected into the combustion chamber.

Petter Oil Engines.

Engines of the two-stroke vertical type have been manufactured by Messrs. Petters, Ltd., of Yeovil, for many years, and the company have supplied over 20,000 oil engines. The small sizes are the well-known 'Petter Junior' engines, suitable for farm, estate, and factory machinery, electric lighting, pumping, and other purposes.

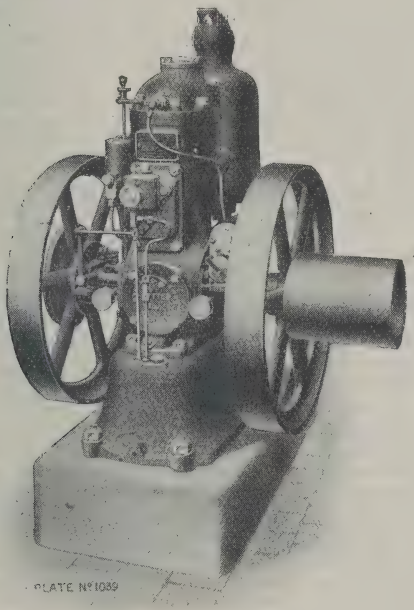

Fig. 32.—The Petter Junior Oil Engine.

The Petter Junior engines are made in three sizes: 2, 5, and 8 b.h.p.; and in three patterns: stationary, for fixing on concrete (as illustrated), semi-portable on wood skids, and portable on four-wheeled carriage.

These engines work on paraffin and have magneto ignition. They are started on a small quantity of petrol, and change over automatically to paraffin after working for a few minutes. By means of the patent fuel injector, the paraffin is vaporised and burnt with the same completeness as in a petrol engine, and at half the cost of fuel.

Other Makers of Oil Engines.

Engines of the horizontal four-stroke type are also made by Crossley Bros., Ltd., Manchester; Fielding & Platt, Gloucester; Tangyes Ltd., Birmingham; and Davey Paxman & Co., Colchester.

Vertical engines are made by Gardner & Sons, Patricroft; Griffin Engineering Co., Bath; the Parsons Motor Co., Southampton; J. I. Thornycroft & Co., Basingstoke; and the New Pelapone Co., Leeds.

INTERNAL-COMBUSTION TURBINES.

Many inventors have devoted attention to the excessively difficult problem of the internal-combustion turbine, and some success has now been attained. From the theoretical aspect, the operation of a jet of gas acting directly on the rotor of a turbine is attractively simple, but when an attempt is made to realise the idea in practice serious difficulties of construction are encountered, in consequence of the inadequate properties of the materials available. The chief difficulty arises from the action of the intensely high temperatures on the metal employed. In the case of the steam turbine with the use of superheated steam an extreme temperature of 400°C. is involved, but the metal work of the gas turbine is exposed to heated gases which may range from 1,500°C. to 2,000°C. The solution of the problem, therefore, depends largely on the question of the provision of suitable materials, especially for the turbine blades. One of the earliest inventors was John Barber, who, in 1791, constructed a machine in which an ignited mixture of gas and air issued in a continuous stream of flame and impinged upon the vanes of a turbine wheel, thus causing rotation; water was injected into the explosive mixture to reduce the high temperature and increase the mass of gas impinging on the vanes. This machine operated on the combustion at constant pressure method, but was not practically successful.

Recently the late M. Réné Armengaud succeeded in obtaining an output of 300 b.h.p. from a large constant-pressure internal combustion turbine by reducing the flame temperature at efflux to about 750°F. by large additions of steam; this machine may thus be equally fairly described as a highly superheated steam turbine. Petrol was used as fuel, the consumption amounting to roundly 3 lbs. per b.h.p. hour, which is about five times as great as in a petrol gas engine of good design.

M. Karovodine has also constructed a turbine in which explosions from atmospheric pressure are caused to occur in rapid succession and utilised to drive a small impulse turbine; this machine was very small, developing only 1·6 b.h.p. at 10,000 revolutions per minute, and the fuel consumption was very high. Mr. Holzwarth has also built a turbine designed for an output of 1,000 b.h.p., but it is said that so far only about 160 b.h.p. has actually been obtained with it. Designs involving the direct impact of flame on turbine vanes appear to present almost insurmountable practical difficulties. Sir Dugald Clerk, F.R.S., has suggested that in the not distant future very large internal combustion power units may become commercially possible by combining a device of the ingenious Humphrey internal combustion pump type with an efficient reaction turbine; it is certainly conceivable that such a combination may prove successful in large stationary land installations. Dr. Clerk points out that the machine would be of great simplicity in details as neither pistons, connecting-rods, nor crankshafts would be necessary.

An important work upon the gas turbine appeared in 1913 by Herr Holzwarth (English Trans. by A. P. Chalkley, B.Sc.: Griffin & Co.), in which the present position, both in theory and practice, is clearly set out. The fundamental unit of the Holzwarth turbine comprises a combustion chamber supplied by a suitable pump with a mixture of gas, or vapour, and air, through mechanically operated inlet valves. The mixture is delivered at a small pressure and ignited by H.T. magneto. The resulting gases at high temperature and pressure then discharge themselves through a spring-controlled flap valve termed the 'nozzle' valve, and issuing from a nozzle impinge on the vanes of a rotor. On passing these vanes, the gases next enter an exhaust, wherein a partial vacuum is maintained by a suitable exhauster. Shortly after ignition the nozzle valve is slowly closed mechanically, sufficient time being permitted, however, to allow a gust of scavenging air to pass through by which the combustion chamber is cleared in readiness for the next working charge, and the nozzle and vanes of the rotor are cooled.

The action is thus intermittent, and the design involves three valves together with charging and exhausting pumps. In the actual turbine several such units are arranged symmetrically around a turbine wheel, or rotor, whose rotation is maintained by the successive impulses thereby imparted to its vanes. Experiments are being continued by Herr Holzwarth and his colleague Mr. E. Junghaus.

A combined steam and gas turbine appears to be the most promising lines upon which the problem should be tackled, and some experimenters see great prospects of success in this direction.

Lloyd's Rules for Marine Internal-Combustion Engines.

The following rules for the survey of internal combustion engines for marine purposes have been drawn up by Lloyd's Register of British and Foreign Shipping:—

General.

Section 1.—In vessels propelled by internal combustion engines the rules as regards machinery will be the same as those relating to steam-engines so far as regards the testing of material used in their construction and the fitting of sea connections, discharge pipes, shafting, stern tubes, and propellers.

Construction.

Section 2.—1. The following points should be observed in connection with the design of the engines:—

2. The shaft bearings, connecting-rod brasses, the valve gear, the inlet and exhaust valves must be easily accessible.

3. The reversing gear and clutch must be strongly constructed, and easily accessible for examination and adjustment.

4. In engines of above 60 b.h.p. which are not reversible, and which are manœuvred by a clutch, a governor or other arrangement must be fitted to prevent racing of the engine when declutched.

5. Efficient positive means of lubrication—preferably sight feed—must be fitted to each part requiring continuous lubrication.

6. When the engines are of the closed-in type they must be so fitted that the contained lubricating oil can be drained when necessary, and in wood vessels an easily drained metal or metal-lined tray must be fitted to prevent leakage of either fuel oil or of lubricating oil from saturating the woodwork.

7. Carburettors, where petrol is used, and vaporisers, where paraffin is used, should be so designed that when the engine is stopped the fuel supply is automatically shut off. If an overflow is provided in the carburettor or vaporiser, a gauze-covered tray with means of draining it must be fitted to prevent the fuel from flowing into the bilges.

Strong metallic gauze diaphragms should be fitted either between the carburettor (or vaporiser) and cylinders or at the air inlets.

8. If the ignition is electric, either by magneto or by coil and accumulator, all electric leads must be well insulated and suitably protected from mechanical injury. The leads should be kept remote from petrol pipes, and should not be placed where they may be brought into contact with oil.

The commutator must be enclosed, and the sparking coils must not be placed where they can be exposed to explosive vapours.

9. No exposed spark gap should be fitted.

10. In paraffin and heavy-oil engines, where lamps are used for ignition or for vaporising, these lamps should be fixed by some suitable bracket, and the flame enclosed when in use.

11. The circulating pump sea suction is to have a cock or valve on the vessel's skin placed on the turn of the bilge in an easily accessible position, and the circulating pipe is to be provided with an efficient strainer inside the vessel. The discharge overboard is to be fitted with a cock or valve on the vessel's skin if it is situated under or near the load line of the vessel.

12. A bilge pump worked by the engines or an independent power-driven bilge pump is to be fitted to draw from each part of the vessel. In open launches this bilge pump may be omitted, provided suitable hand pumps are fitted.

13. The cylinders are to be tested by hydraulic pressure to twice the working pressure to which they will be subjected, the water-jackets of the cylinders to 50 lbs. per sq. in., and the exhaust pipes and silencer to 100 lbs. per sq. in.

14. The exhaust pipes and silencer should be efficiently water-cooled or lagged to prevent damage by heat, and if the exhaust is led overboard near the water-line, means must be arranged to prevent water from being syphoned back to the engine.

15. The machinery must be tried under full working conditions, the report stating the approximate speed of vessel, the number of revolutions of the engines at full power, both ahead and astern, and the lowest number of revolutions of the engines which can be maintained for manœuvring purposes.

Rules for Determining Sizes of Shafts.

Section 3.—The crank, intermediate and other shafts, if of ordinary mild steel, are to be of not less diameters than as given in the following table. When special steel is used, the sizes are to be submitted for consideration.

1. For petrol or paraffin engines for smooth water services :—

$$\text{Diameter of crank shaft in inches} = C\sqrt[3]{d^2 s},$$

here d = diameter of cylinder in inches,

s = stroke of piston in inches.

Four-stroke Cycle.	Two-stroke Cycle.	Bearing between each Crank.	Two Cranks between the Bearings.
For 1, 2, 3, or 4 cylinders	1 or 2 cylinders	$C = \cdot34$	$C = \cdot38$
,, 6 ,,	3 ,,	$C = \cdot36$	$C = \cdot40$
,, 8 ,,	4 ,,	$C = \cdot38$	$C = \cdot425$
,, 12 ,,	6 ,,	$C = \cdot44$	$C = \cdot49$

For open sea service add ·02 to C.

Diameter of intermediate and screw shafts in inches

$$= C \sqrt[3]{d^2 s} (N+3),$$

where d = diameter of cylinder in inches,
s = stroke of piston in inches,
N = number of cylinders.

For smooth water services—	For open sea services—
C = ·155 for intermediate shafts.	C = ·165
C = ·170 for screw shafts fitted with continuous liners.	C = ·180
C = ·180 for screw shafts fitted with separate liners or with no liners.	C = ·190

In engines of two-stroke cycle N is to be taken as twice the number of cylinders.

2. When ordinary deep-thrust collars are used, the diameter of the shaft between the collars is to be at least $\frac{21}{20}$ of that of the intermediate shaft.

3. In the cases of Diesel and other engines in which very high initial pressures are employed particulars should be submitted for special consideration.

Fuel Tanks and Connections.

Section 4.—1. Separate fuel tanks are to be tested with all fittings to a head of at least 15 ft. of water. If pressure feed tanks are employed, they are to be tested to twice the working pressure which will come on them, but at least to a head of 15 ft. of water. If the tanks are made of iron or steel, they should be galvanised.

2. Strong and readily removable metallic gauze diaphragms should be fitted at all openings on petrol tanks.

3. Paraffin or heavy oil tanks, not used under pressure, are to be fitted with air pipes leading above deck. Pressure-feed tanks and tanks containing petrol should be provided with escape valves discharging into pipes leading to the atmosphere above deck. The upper ends of all air pipes are to be turned down, and pipes above 1 in. diameter are to be provided with gauze diaphragms at the end.

4. No glass gauges are to be fitted to fuel tanks containing either petrol, paraffin, or heavy oil.

5. Filling pipes are to be carried through the deck so that the gas displaced from the tanks has free escape to the atmosphere.

6. Separate fuel tanks should be provided with metal-lined trays to prevent any possible leakage from them flowing into the bilges or saturating woodwork. Arrangements are to be provided for emptying the tanks and draining the trays beneath them. For petrol tanks the trays must have drains leading overboard where possible, or they should be gauze-covered trays with means for draining them.

7. All fuel pipes are to be of annealed seamless copper with flexible bends. Their joints are to be conical, metal to metal. A cock or valve is to be fitted at each end of the pipe conveying the fuel from the tank to the carburettor or vaporiser. The fuel pipes should be led in positions where they are protected from mechanical injury and can be exposed to view throughout their whole length.

8. The engine-room and the compartment in which the fuel tanks are situated are to be efficiently ventilated.

9. An approved fire-extinguishing apparatus must be supplied.

Periodical Surveys.

Section 5.—1. The machinery is to be submitted to survey annually. At these surveys the cylinders, pistons, connecting-rods, crank and other shafts, inlet and exhaust valves and gear, clutches, reversing gear, propeller, sea connections, and pumps are to be examined. The electric ignition is to be examined and the electric leads tested. The fuel tanks and all connections are to be examined and, if deemed necessary by the surveyor, to be tested to the same pressure as required when new. If practicable, the engines should be tested under working conditions.

2. The screw shaft is to be examined annually and drawn at intervals of not more than three years in the cases of shafts fitted with continuous liners, and not more than two years in the cases of other shafts. (On the application of owners, the Committee will be prepared to give consideration to the circumstances of any special case.)

High Compression Oil Engines.

Rules for the Construction and Survey of Diesel engines and their auxiliaries have been adopted by the General Committee of Lloyd's Register, and can be obtained on application to Registrary, 71 Fenchurch Street, London, E.C. 3.

SECTION XXX

PART IV

HOT-AIR ENGINES.

In these the working air receives its heat from an external furnace by conduction through the walls of a metal containing vessel ; such engines may thus be described as ' External Combustion Engines ' to distinguish them from ' Internal Combustion Engines ' wherein the air is heated by chemical combustion occurring throughout its mass. In the Stirling engine the diagram consists of two isotherms and two constant volume lines (fig. 33). The contained air is (1) compressed isothermally at (abs.) temperature T_1 from v_1 to v_2 ; (2) heated at constant volume v_2 to pressure p_3 and temperature T_3 ; (3) expanded isothermally at temperature T_3 behind the working piston from pressure p_3 and volume v_2 to pressure p_4 and volume v_1 ; and (4) cooled at constant volume v_1 from temperature T_3 to temperature T_1, the pressure corre-

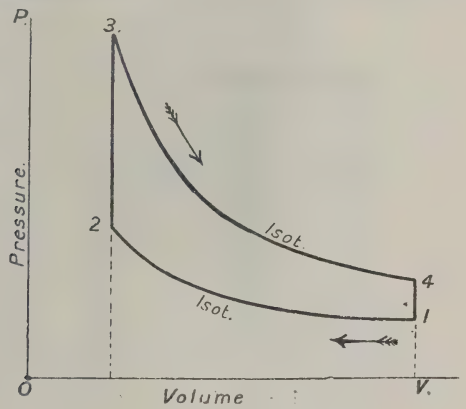

FIG. 33.

spondingly falling from p_4 to p_1. The useful work done is represented by the area 1, 2, 3, 4. If r denote the expansion ratio v_1/v_2 we have :—

$$\text{Heat supplied} = k_v (T_3 - T_1) + c\, T_3 \,.\, \text{Log}_e\, r.$$
$$\text{Heat rejected} = k_v (T_3 - T_1) + c\, T_1 \,.\, \text{Log}_e\, r.$$

The useful work is the difference of these, viz. :—

$$(T_3 - T_1) \,.\, c \,.\, \text{Log}_e\, r\,.$$

And the thermal efficiency is accordingly :—

$$\frac{(T_3 - T_1) \,.\, c \,.\, \text{Log}_e\, r\,.}{k_v (T_3 - T_1) + c\, T_3\, \text{Log}_e\, r\,.} \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

This has a value much less than that of the Carnot engine working between T_1 and T_3, viz. $\frac{T_3 - T_1}{T_3}$, on account of the term $k_v (T_3 - T_1)$ in the denominator. The Rev. R. Stirling, in 1827, introduced the regenerator or 'heat-filter' for storing the heat $k_v (T_3 - T_1)$ given out during the period

4, 1, fig. 33, and restoring it to the air during the period 2, 3; by this device the term $k_v(T_3-T_1)$ disappears from the denominator and, if perfectly realised, the efficiency would then become equal to that of the perfect Carnot engine, viz. $\frac{T_3-T_1}{T_3}$. The first Stirling engine (made in 1830) is shown diagrammatically in fig. 34. A is a light, bulky displacer filled with brickdust, and fitting easily in its cylinder. The lower portion of the air chamber, B, is situated immediately over the furnace C, the upper portion being kept always cool by a system of cold-water circulating pipes W. In the annular space EE, surrounding the cylinder within which A works, is a series of very thin metal plates separated by spaces of about ·02 in. width only; this is the regenerator. Its upper end is constantly at about the temperature T_1, and lower end at the temperature T_3; H is the working cylinder, and K its piston.

In the configuration shown, the displacer is at the top of its stroke, while K is at the bottom of its stroke; the contained air is thus at minimum volume and maximum temperature, and the

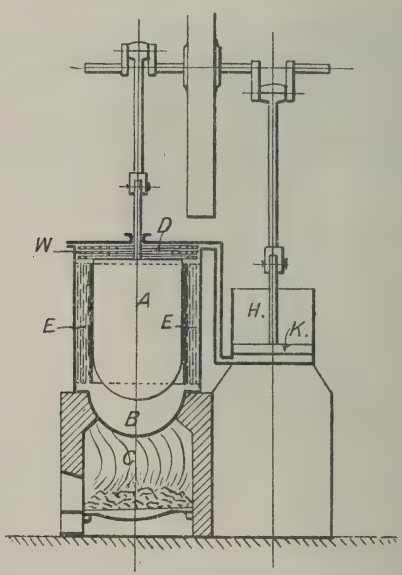

FIG. 34.—The Stirling Engine.

corresponding point on the diagram fig. 33 is 3. The piston next moves out on its working stroke, the pressure falling with expansion and heat being supplied to the working air from the furnace. At the end of the out-stroke of K, A is at the bottom of its stroke and has thus passed the working air from B, through the regenerator EE to the cooled end W of the air chamber; its temperature is now T_1, and pressure accordingly low. The air in passing from B to W through EE gives up to the plates the heat $k_v(T_3-T_1)$ in the ideal case, and this heat is restored again to the air on its return passage through EE from W to B; by this device the economy was much improved.

It will be noted that there are no valves; the working piston is always in communication with the air chamber, and the air in the working cylinder is always at low temperature. By closing the working cylinder H at the top, and connecting it to a second air chamber and displacer the engine becomes double acting. Though theoretically interesting, the hot-air engine proved so impracticable in any but the smallest powers that it is now quite obsolete. The practical difficulties of rapidly heating a large volume of air; failure of the bottom of the air vessel B; and the great weight and bulk of these engines have combined to effect their disuse. The actual thermal efficiency realised in practice is only from 7 per cent. to 10 per cent.; the mechanical

efficiency is also, in general, low. In the following short table some trial results are given for reference :—

Air Engine.	Date.	Cyl. Bore. Ins.	Stroke. Ins.	Revs. per Min.	Horse Power.		Mechl. Eff. Per Cent.	Lbs. Fuel per Hour.	
					Indic.	Brake.		per I.H.P.	per B.H.P.
Buckett	1883	24·0	16·0	61	20·2	14·4	71	1·8	2·5
Benier	1887	13·4	13·8	117	5·8	4·0	69	3·1	3·6
Bailey	1883	14·6	6·9	106	2·4	1·3	55	4·2	7·6
Rider	1898	6·7	9·5	128	0·66	0·23	35	—	—
Ericsson	1898	8·0	3·9	101	0·23	0·06	27	—	—

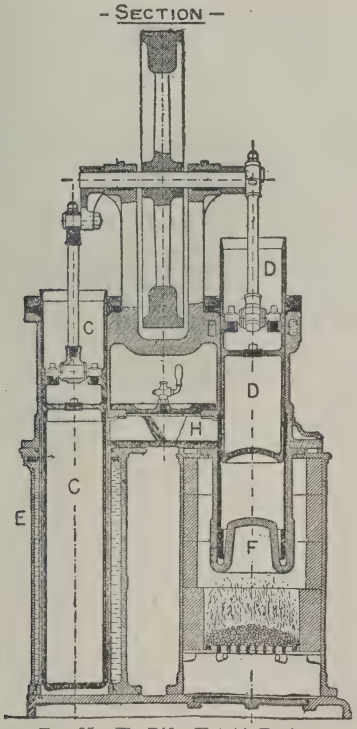

FIG. 35.—The Rider Hot-Air Engine.

Owing to their ease in working and absolute safety, small hot-air engines are still usefully employed in certain situations as, e.g. for driving fog signals on lightships and lighthouses, and for domestic purposes, as pumping, sawing, driving small tools, etc., in cases where only small power is needed.

The 'Robinson' is a small hot-air engine of the Stirling type, made in five sizes from $\frac{1}{4}$ to $\frac{3}{8}$ b.h.p., by A. E. Robinson & Co., Beswick, Manchester, and handled by Messrs. Norris, Henty & Gardners, of 115 Queen Victoria Street, London, E.C.4.

Another much used air engine is the 'Rider,' made by Messrs. Hayward, Tyler & Co. Ltd., 99 Queen Victoria Street, London, E.C., in three sizes, of ¼, ½, and 1 b.h.p., respectively. It includes all the features of the early Stirling engine except that the working cylinder is in communication with the hot end of the air chamber, and not the cold end as in all Stirling's designs.

In this engine (fig. 35) there are two vertical cylinders, each of which contains a piston or plunger, their strokes and diameters, however, not being equal, that in the power cylinder, in which the air is heated, being the larger. One of these (that to the left hand), lettered C, is the displacer, while that on the right, D, is the power piston. The crankshaft carries a flywheel in the middle of its length and cranks at each end attached to C and D by connecting-rods, as shown.

The cranks are so placed that when C is at the bottom, D is slightly above the middle of its stroke. A fire, F, is maintained below the power cylinder, while the displacer cylinder is cooled by a water jacket. The cylinders C and D are constantly in communication through the passage H, in which is contained a regenerator consisting of a number of thin wrought-iron plates placed very close together, whose function has already been explained (*supra*).

The bottom of the power cylinder is maintained at a high temperature by the fire below it; when the power piston D is at the bottom of its stroke the air beneath it, being highly heated, is at pressure and the piston accordingly moves upwards as D is of larger diameter than C. The accompanying descent of C transfers air from the cool displacer cylinder through the regenerator in H—where it becomes warmed up—and delivers it by way of a pendent liner in the power cylinder below the rising working piston D when it becomes heated, thus increasing in pressure, and assists in driving D to the top of its stroke.

When this point is reached, the displacer plunger C is at half-stroke upwards, and the subsequent descent of D transfers air from the power cylinder, via the regenerator, to the cooled displacer cylinder, the temperature and pressure consequently falling, and heat being stored up in the regenerator to be absorbed during the next power stroke.

Efficiency of Hot-Air Engines.

In the best hot-air engines a consumption of 1·8 lb. of gas coke has yielded 1 indicated horse-power, or 2·54 lbs. of coke per b.h.p., the h.p. being calculated after deducting the work required to compress the air. The absolute efficiency is therefore only about 7·9 per cent. referred to b.h.p. In the smaller sizes of hot air engine the consumption of fuel is usually very much higher than this, and is often 20 lbs. or more per b.h.p. hour.

SECTION XXX

PART V

AERO AND MOTOR CAR ENGINES—MOTOR CARS.

AERO ENGINES.

Engines for aircraft are either air-cooled or water-cooled, and operate on the four-stroke cycle. Vertical, diagonal, radial, and rotary types are used. The majority of engines are now water-cooled, but air cooling has certain advantages in low weight per h.p. and compactness when used with radial or rotary engines, so will always be in demand, especially for short journeys and low powers.

Vertical type engines have cylinders arranged vertically over the crankshaft. Six or eight cylinders are used, with a corresponding number of throws in the crankshaft. The engines are mainly water-cooled.

Diagonal or Vee type engines have cylinders mounted in two rows inclined at an angle of from 45 to 90 degrees, two cylinders acting on each crankshaft throw. The number of cylinders is eight or twelve, and they are invariably water-cooled in the larger sizes.

A modification of this type is sometimes called the fan or broad-arrow type; this has two rows of diagonal with one row of vertical cylinders in between. The high-powered engines are of this design, and are water-cooled.

Radial type engines have cylinders spaced radially around a rotating crankshaft. An odd number of cylinders, usually seven or nine, are used to secure an even turning moment. Both water-cooled and air-cooled engines are made.

Rotary type engines are similar in general appearance to the radial engine, but the cylinders and crankcase rotate around a fixed crankshaft; the cylinders are air-cooled. The first successful engine of this type was the Gnome.

In September 1910, Mr. F. W. Lanchester published the following figures relating to the Antoinette, Renault, and Gnome aero engines, and, for the purposes of comparison, corresponding results for the standard 22 h.p. and 38 h.p. Daimler-Knight car engines :—

Item.	Antoinette.	Renault.	Gnome.	Daimler-Knight.	Daimler-Knight.
Nominal horse-power	50	55	50	22	38
Actual b.h.p.	54·3	58·8	46	39	57·3
At revolutions per min.	1,200	1,800	1,000	1,400	1,200
Bore in inches	4·35	3·44	4·35	3·8	4·9
Stroke in inches	4·15	4·75	4·73	5·14	5·14
No. of cylinders	8	8	7	4	4
Brake mean effective pressure, lbs. per sq. in.	72·5	73·6	74·3	94·5	97
Engine weight, as defined, lbs.	292·4	375	167	360	520
Weight in lbs. per b.h.p.	5·38	6·4	3·63	9·2	9·1
Allow extra for radiator	—	—	—	1·0	1·0
Lbs. of petrol per b.h.p. hour	·94	·96	·89	·67	·54

The weight is defined as that of the engine in running order, including all accessories, with radiator and contained water (if fitted), but excluding silencer, flywheel (if any), and petrol and oil tanks. The low mean pressure and large petrol consumption of the aero engines will

be noted; well-designed car engines of from 30 to 60 h.p. require only about ·65 lb. of petrol per b.h.p. hour; the average of the three aero engines above gives ·91, an excess of 40 per cent. The consumption of lubricating oil is, in general, also abnormally large in aero engines. The primary consideration has so far been weight reduction in this class of engine.

Particulars of some British aero engines were given by Lord Weir in a paper read before the N.E. Coast Institute of Engineers and Shipbuilders, July 1919, and representative air-cooled and water-cooled were tabulated as follows :—

Ref. No.	Type.	Method of Cooling.	No. of Cylinder.	Bore m/m.	Stroke m/m.	Compression Ratio —to 1.	Piston Speed ft. per minute.
1	Bentley, Rotary 2 . . .	Air .	9	140·00	180·00	5·26	1,536·0
2	A.B.C., Fixed Radial, 'Dragon-fly'	Air .	9	139·7	165·09	4·42	1,787·5
3	Straight Six, Siddeley, 'Puma'.	Water	6	145·00	190·00	5·00	1,558·0
4	2 rows of 4 V. at 90 deg. Sunbeam, 'Arab'	Water	8	120·00	130·00	5·3	1,707·0
5	2 rows of 6 V. at 60 deg. Rolls-Royce, 'Eagle' 8	Water	12	114·29	165·09	5·3	1,950·0
6	2 rows of 6 V. at 60 deg. Galloway, 'Atlantic'	Water	12	145·00	190·00	5·4	1,872·0

The advance made by British manufacturers will be appreciated by a comparison of the two tables. Low weight per h.p. is now obtained, and the economy in petrol and lubricating oil is noteworthy; also the m.e.p. is approaching the theoretical maximum. Even compared with 1914, when the average engine developed about 100 h.p. and weighed approximately 3·75 lb. per h.p., remarkable progress has been made.

In stating the power of aero engines, the h.p. developed at ground level is given, but the machine operates under quite different conditions when up in the air. Taking the usual approximate rule of allowing 3 per cent. loss of power for every 1,000 feet altitude, the reduction in the h.p. of an engine is considerable when flying at 15,000 feet or over.

To prevent this loss, or to reduce it, some engines have been designed for the rarefied air conditions and have smaller clearance volume and forced induction. The full development of their power at ground level is prevented, as if no alteration is made the power and pressures at ground level will always be higher and may damage the engine.

On some engines a blower is provided to force more air into the cylinders at high altitudes and the pressure of the exhaust is employed. The exhaust turbine has now reached a high state of efficiency, and has been developed by Rateau for this supercharging of aero engines.

Supercharging permits of the realisation of a constant pressure of the cylinder charge at the end of the suction stroke, and makes it possible to obtain constant power under any atmospheric conditions. At first it was the practice to supply a small extra charge at the end of the suction

stroke, but now it is possible for a turbine or blower to supply the whole of the charge to the cylinders.

The altitude laboratory of the American Bureau of Standards is specially equipped for testing engines under various atmospheric conditions, and fig. 36 shows the results of altitude, as well

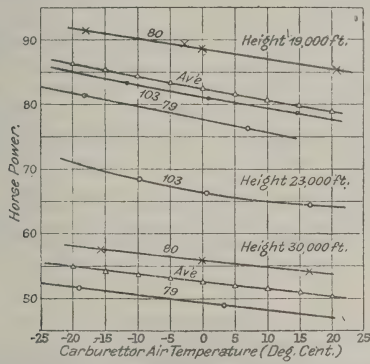

FIG. 36.—H.P. Temperature Curves at various altitudes: Hispano-Suiza Engine, 8 cylinder, 150 h.p.

as of varying air temperatures, upon the power of a Hispano-Suiza 150 b.h.p. engine. Three designs of carburettor were used, i.e., Claudel hand-adjusted 5·3 to 1, Claudel hand-adjusted 6·2 to 1, and Tice inherent-adjusted 5·3 to 1. The second gave the best results.

Carburation.

With radial and rotary engines, it is usual to fit a single simple carburettor without float chamber, the petrol flow being hand-adjusted to suit engine speed and atmospheric conditions.

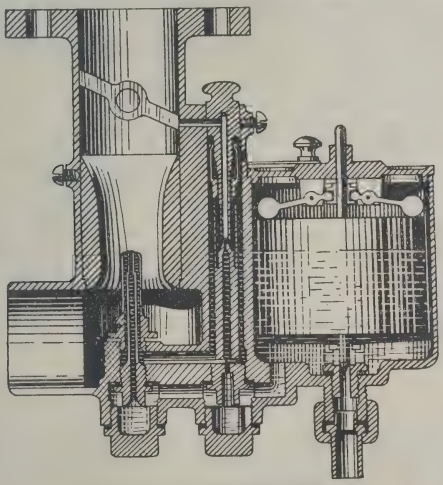

FIG. 37.—The Zenith Carburettor

With stationary engines two or four carburettors are fitted according to the size of the engine. Representative types are the Zenith and Claudel-Hobson, which are fitted with float-chambers, and designed to give a practically constant mixture under the usual variations of load and speed. These carburettors require to be carefully adjusted to each engine so as to give the same results, the operation of adjusting being known as 'synchronising.'

Aero engine carburettors must operate under variable circumstances. As the machine rises the density of the atmosphere decreases, and the quantity of petrol required per cubic foot of free air becomes less. The desired reduction in petrol flow is now carried out by hand adjustment, either by throttling the supply to the jet or, in the case of carburettors with float chambers, by reducing the pressure difference between the float chamber and the jet.

One of the best-known carburettors is the Zenith, fig. 37. The arrangement of the induction piping is a most important factor in getting good carburation; sudden changes in the speed of the charge, and sharp bends, cause a considerable loss. Also there must be no dip in the pipes. The usual methods of heating are by water circulation, by exhaust gases, and by hot air taken into the carburettor.

The purpose of the choke tube is to obtain the correct velocity of air around the jets in order to get the best mixture at all speeds. The main jet has most influence at high speeds, and the compensator, which corrects the irregularities of the main jet, has the greatest influence at low speeds. Besides these parts there is in the Zenith carburettor a special device to regulate slow running.

Water-cooling.

Water-cooling for aircraft has followed motor-car practice in general principles, but there has been great diversity of opinion as to radiator design. There was a tendency to utilise brass film, which is still predominant in car construction, owing to its low cost, but the fact that the water path is in long vertical channels which, under field-service conditions, are liable to become blocked, its liability to develop leakages, and the difficulty of repair, led to its complete elimination.

The tube honeycomb type has become standardised. Here again there was diversity, and after the trial of round, square, and hexagonal tubes, the survival of the fittest resulted in the selection of a round tube with hexagonally bulged ends. This gives maximum cooling surface with minimum solid frontal area, and therefore minimum head resistance.

Opinions of designers have also varied greatly as to the best position of the radiator. The 'nose' position, in which the radiator is placed immediately behind the propeller, has most adherents, but excellent results have also been obtained where the radiator is placed, (*a*) in two halves on the sides of the fusilage, or (*b*) below the fusilage.

In the latter case it is provided with a lifting gear, so that it can be drawn up into the fusilage for the purpose referred to below.

The Germans have also tried extensively a radiator inserted in the top plane centre section, but lately have abandoned this method.

The quantity of water carried is very small, and it is circulated somewhat rapidly by a pump so that the heat is dissipated quickly.

Radiator Shutters.

In machines designed for flying at very high altitudes, it is necessary to provide a variable cooling device to obviate the danger of the radiator freezing when high speeds are obtained in diving. For this purpose either the device referred to above, or more frequently a Venetian-blind type of shutter, which can be closed to prevent the air having access to the radiator, is provided.

It is controlled by the pilot, who also has a radiator thermometer enabling him to keep a watch on the radiator temperature.

Aero Engine Production.

According to the report of the Ministry of Munitions the total horse-power of aero engines manufactured between August 1914 and the end of 1918 amounted to 7,094,000, and more than half of this was turned out in the last year. The output in 1918 was 4,143,000 h.p. The horse-power of internal combustion engines for aeroplanes, motor vehicles, and tanks used during the war came to the huge total of 10,000,000 h.p.

Engines for British Aircraft Competitions, 1920.

In connection with the British Aircraft Competitions for prizes amounting to 64,000*l.*, the following list of engines for use by competitors has been approved by the Air Council. It will be left to the discretion of the judges to decide whether any new engine not included in this list fulfils the conditions of the competition.

Gnome Engines.

The first successful rotary engine was the Gnome. Thus, in the 'Aerial Derby' of 1913, of eleven machines which started, six had Gnome engines, two Anzani, two Le Rhône, and one Austrian-Daimler; no British engine appeared in this contest. The 50 h.p. Gnome engine has seven cylinders symmetrically arranged as shown in fig. 38; the 100 h.p. type has nine cylinders.

The Gnome rotary engine is air-cooled, dispenses with a flywheel, is very light for its power, and by its large angular momentum prevents 'fluttering' of the propeller and irregular running.

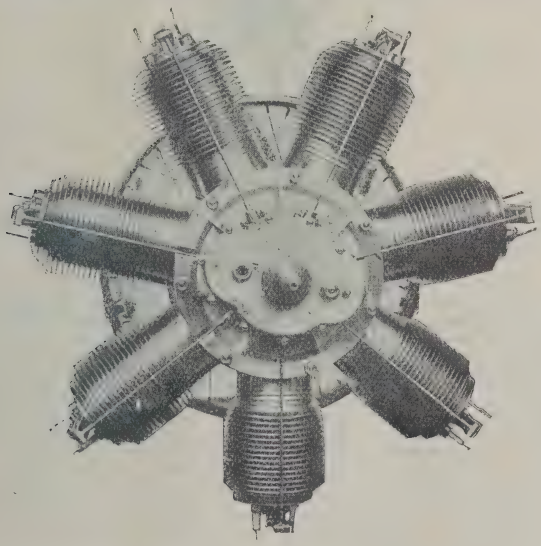

Fig. 38.—The 50 h.p. 'Gnome' engine.

In the 50 h.p. seven-cylinder type the cylinders are placed at equal angular intervals and, together with the crank-chamber, rotate around a fixed crankshaft. The seven connecting rods are all in the same plane and operate on one crank-pin; one of the rods is in one piece with the 'big-end,' which includes two large rings of L section having each six holes drilled in them at angular distances apart of 51⅓ degrees (fig. 39); these holes severally receive the six pins connecting up the big ends of the remaining six connecting rods to the crank-pin. One rod is necessarily rigidly connected to this large double-ring cage in order to define its position. The cage is fitted with two ball races through which the actions of the several rods are communicated

to the crank-pin. The angularity of the six shorter rods slightly exceeds that of the seventh rigid rod, but the difference does not appreciably affect the running of the engine; the rods are of steel, of H section, with milled surfaces.

The cylinders are machined from solid steel ingots, the finished thickness of the cylinder walls being but 1½mm. (·059 in.); the necessary strength is furnished by the fins left on the outer surface; these, as shown in fig. 38, increase in diameter towards the combustion chamber ends of the cylinders. The cylinder tops are removable and contain the exhaust valves; the bore is 4·35 ins. and stroke 4·73 ins.

The crank chamber is cylindrical in form, and of nickel steel; no aluminium whatever is used; the crank chamber is borne on the fixed crankshaft by a pair of ball bearings housed in the end plates; one end plate bears a cylindrical extension about 5 ins. diameter, to which the propeller boss is attached by means of two keys. Through the hollow fixed crankshaft the working

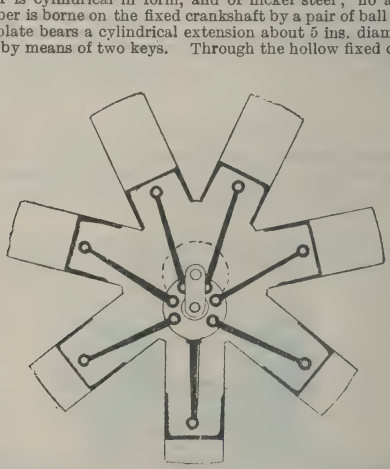

FIG. 39.—Diagrammatic sketch of the 'Gnome' engine, illustrating the method of coupling up the connecting rods to the single crank. It will be noticed that one connecting rod is rigid with the common big end.

charge of petrol vapour and air is introduced into the crank chamber; the hollow shaft also permits two copper lubricating pipes to be led into the centre of the engine. The carburettor is of a simple single-jet type without float chamber, the supply of petrol being hand regulated by the driver through a screw-down needle valve. Engine speed is regulated by a disc throttle valve placed at the junction of the carburettor and crankshaft. The inlet valves are of the spring-controlled automatic type formerly used in car engines, but now entirely superseded by the mechanically operated design. The automatic valve is here adopted partly to save weight and partly because it may then be located in the centre of the piston crown. Both inlet and exhaust valves are counterbalanced against the centrifugal actions arising from the cylinder rotation. The engine operates on the four-stroke single-acting system. As already mentioned, the exhaust valves are placed in the cylinder heads and the exhaust is discharged from them directly into the atmosphere. The pistons are of steel, very thin and light, and are fitted sometimes with three spring rings, sometimes with one broad one only. The spring rings are compound, and consist each of a thin L-shaped gunmetal ring with a stiff steel Ramsbottom spring ring behind it; the gunmetal rings are very thin and are considered to act somewhat in the manner of a cup-leather in preserving gas-tightness.

Dr. Watson has pointed out that in engines of this type, if the working impulses are required to occur at equal angular intervals during the working of the engine, then there must be an *odd* number of cylinders. Ignition is by high-tension magneto, the armature being so geared as to run at 1¾ times the revolution rate of the engine cylinders.

Lubrication has presented considerable difficulties with this type of engine, and in order to obtain satisfactory running the amount of lubricating oil used has frequently been abnormally great. Castor oil is used, and in one test the consumption *per hour* amounted to 1½ gallon. The surplus oil is whirled from the engine and discharged, with the exhaust gases, into the atmosphere from the cylinder heads.

110 H.P. Le Rhône Engines.

The Gnome and Le Rhône Co. also manufacture this engine, which has 9 cylinders, 112 mm. dia. by 170 mm. stroke, and operates on the four-stroke cycle. The weight of the engine, with oil pump and magneto, is 330 lbs. The engine is of the rotary air-cooled type, and gives a total of 127 h.p. when running at 1,200 r.p.m., which is reduced to a useful power, deducting windage, of 113 h.p.

Consumptions of ·765 pint petrol per h.p. per hour, and 12 pints of lubricating oil per hour are obtained.

To balance the rotating masses and to eliminate dead centres, the number of cylinders is an odd number, and the valve gear is arranged to fire them alternately. The Le Rhône differs from the Gnome engine, as inlet valves are fitted to the cylinder heads instead of the piston uncovering ports at the bottom of the cylinder, and induction pipes are led to each of the valves in the heads from the crankcase.

Zeitlin Engines.

Rotary four-stroke cycle Zeitlin engines having a designed b.h.p. of 220 at 12,000 ft. are being developed by the Zeitlin Engine Co., and have a cylinder diameter of 135 mm. A noteworthy feature in this engine is the variation in length of the stroke during each cycle, the working

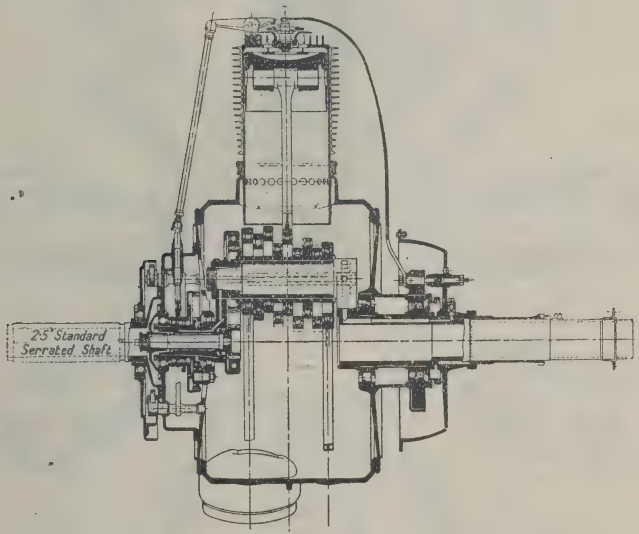

Fig. 40.—The Zeitlin Engine.

stroke is 188 mm., the exhaust and compression strokes are 203·5 mm., and the suction stroke is 226 mm.

The extra length of the exhaust stroke brings the piston almost up to the cylinder head and thoroughly scavenges the cylinder through the mechanically operated valve in the head. The still longer suction stroke draws in a supply of air through the exhaust valve, and at the bottom of the stroke uncovers ports; the mixture from the crankcase then passes into the cylinder. The following stroke compresses the charge to the desired pressure and upon the charge being fired the working cycle is repeated.

The piston, in addition to its ordinary reciprocating motion through 181 mm., performs a

harmonic motion through the range of 22·5 mm. This result is achieved by coupling the connecting-rod on to an eccentric bush of 15·907 mm. throw, surrounding the crank pin, and by driving this bush round the crank pin as axis, in the same direction as the engine and at one-half the engine speed. The crank throw is 101·75 mm.

The weight of air drawn into the cylinder at 12,000 ft. altitude, together with that obtained from the crank case with the mixture, is sufficient to permit the engine to develop its full rated power at that altitude. At lesser altitudes the weight of air drawn in past the exhaust valve during the suction stroke is in excess of actual requirements, and the exhaust valve is opened again during a portion of the compression stroke to expel the excess air from the cylinder before it has time to mix thoroughly with the explosive vapour. The length of time during which the exhaust valve is left open is regulated to suit the altitude, and the engine can be made to give the same power at all altitudes from the ground up to 12,000 ft.

COSMOS ENGINES.

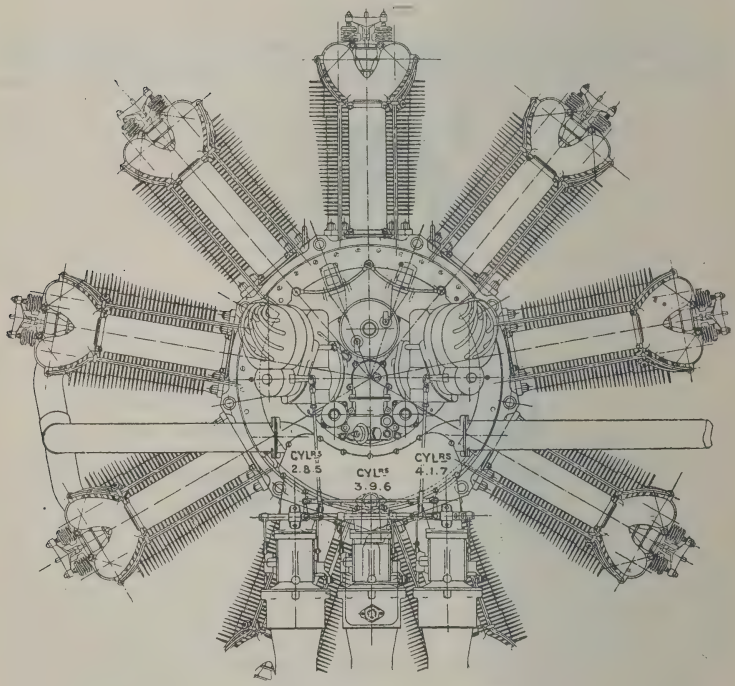

FIG. 41.—The Cosmos Jupiter Engine. Rear View.

The nine-cylinder Jupiter engine, fig. 41, is of the air-cooled radial type, and is made by the Bristol Aeroplane Co., Ltd. The cylinder dimensions are 5¾ ins. by 7½ ins. and 450 b.h.p. is developed at 1,850 r.p.m. The weight of the engine including carburettors, magnetos, etc., is 636 lbs., which gives a record low weight of 1·413 lb. per h.p.

The air-screw is direct driven, but the engines can also be supplied fitted with epicyclic gear reduction to drive the air-screw at 1,200 r.p.m. Accessibility is a special feature of this engine,

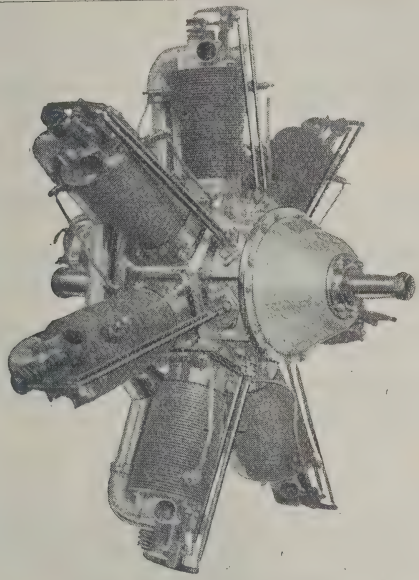

FIG. 42.—The A.B.C. Engine.

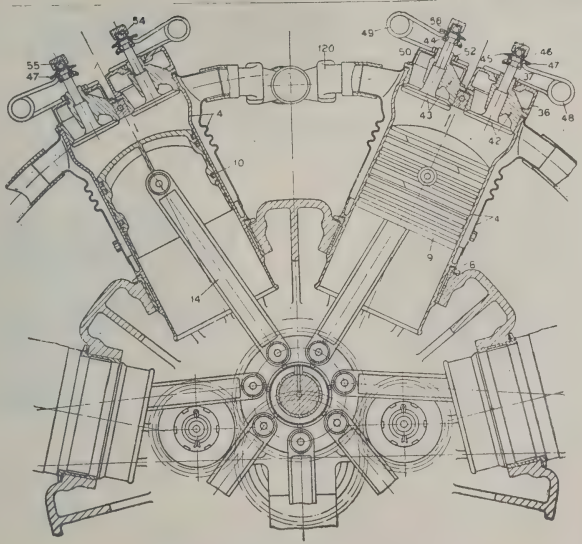

FIG. 43.—The Salmson Engine, 2 M7 Type.

all parts can be readily removed for inspection. The crankcase is an aluminium casting in two parts, held together by long bolts, and these bolts also hold the engine to the fusilage. The steel cylinders are turned from solid billets and bolted to crankcase. The carburettors are fitted, each feeding three cylinders, and ignition is by two Thomson-Bennett magnetos.

100 h.p. three-cylinder air-cooled radial engines are also made. These engines run at 1,600 r.p.m. and have steel cylinders 5¾ ins. by 6¼ ins., with aluminium heads.

A.B.C. Engines.

Air-cooled radial engines developing 50, 160, and 340 b.h.p. respectively, are made by Waltons Motors, Ltd. The 50 b.h.p. engine has five cylinders, and develops its normal power when running at 1,800 r.p.m. The total weight of this engine is 150 lbs.

The 160 b.h.p. engine (fig. 42) has seven steel cylinders with copper-coated fins, and runs at normal speed of 1,650 r.p.m. The cylinder dimensions are 4⅜ ins. by 6¼ ins, and the head is fitted with over-head valves, two exhaust and one inlet. The weight of the engine including airscrew boss is 350 lbs.

Two A.B.C. 48 mm. carburettors are fitted and the petrol consumption is ·56 pint per b.h.p. hour. Six pints of lubrication oil are consumed per hour and distributed by two rotary plunger pumps.

The nine-cylinder radial engine has cylinder dimensions of 5½ ins. diameter by 6½ ins. stroke and develops 340 b.h.p. when running at 1,650 r.p.m. The total weight of this engine is 600 lbs. giving a weight of 1·765 lbs. per b.h.p.

Salmson Engines.

The Dudbridge Iron Works make the Salmson water-cooled radial engines in powers up to 300 b.h.p., in nine cylinders, and each has two admission and two exhaust valves. The usual method of coupling the connecting rod to the crank pin in radial engines is by means of a master rod (see fig. 39, p. 1710) to which the other rods are attached, but in the Salmson engine the connection to the crank pin is shown in fig. 43. It will be seen that the ends are supported on pins carried by a cage engaging with an epicyclic train, which maintains the correct relationship to the cylinders.

The inlet and exhaust valves, as well as the method of holding the cylinder, are shown, and it will be noticed that the valves are held to their seats by a novel design of spring. The mixture is supplied by two Zenith carburettors fitted with the Salmson design of choke tube; ignition is by the ordinary high tension magneto.

Rolls-Royce Engines.

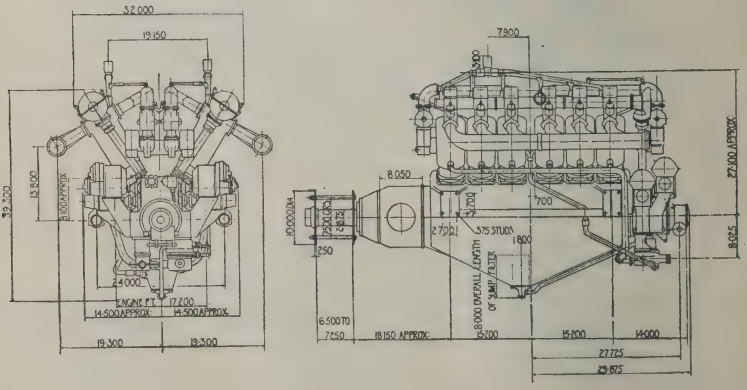

Fig. 44.—The Rolls-Royce Engine.

Aero Engine Supremacy

Current Expressions of Opinion.

An outstanding feature of the past year is the sweeping success of the 450 h.p.

NAPIER

aero engine. It has indisputably *proved* itself to be the best in the world. The following are a few recent opinions—opinions voiced on 1921 achievements:

'There is no finer engine for commercial work in the world.'
Evening News, 1.8.21.

'The premier aero engine in the world to-day.'
Daily Telegraph, 5.1.22.

'Absolutely and admittedly at the top of the tree.'
Tatler, 4.1.22.

D. NAPIER & SON. LTD.
14, New Burlington Street, W.1.
Works: ACTON, LONDON, W.3.

F, 1714

The *Proved* Best.

NAPIER

40/50 h.p. Six Cylinder Motor Carriages.

'No other car has ever put up so fine a performance.'
Bystander, 16.11.21

The 40/50 h.p. Six Cylinder Napier is Hall-marked by the Royal Automobile Club.

Its success does not rest on unofficial statements—it is officially *proved* by the recent trial over the Alps under the observation of the Royal Automobile Club—a trial which no other British manufacturer has had the courage to undertake.

2118 miles were covered, including over **70,000 ft.** of Alpine climbing. **Petrol consumption** was **18·7 miles per gallon. Speed** on **Brooklands 72·38 miles per hour.**

No water or **oil** was added during the progress of the trial, and **no work**—beyond greasing and oiling—was done to the car.

Let us send you full particulars.

Dunlop Tyres are the standard fitment on the 40/50 h.p. Napier

We, the Napier Company, guarantee that this trial was carried out with a standard chassis.

D. NAPIER & SON, Ltd.
14 New Burlington Street, W. 1
Works : ACTON, LONDON, W.3.

Rolls-Royce engines are famous as the first to cross the Atlantic, and to fly to Australia, in 1919. An aeroplane fitted with two Rolls-Royce 360 h.p. engines covered the 1,880 miles across the Atlantic in 15 hours 57 mins. Another machine, using the same size engines, flew the whole distance of 10,925 miles to Australia in 27 days, 20 hours, 20 mins. During the war, Rolls-Royce engines, totalling over 1,000,000 h.p., were in the possession of the Royal Air Force.

The 360 h.p. size is standardised for commercial purposes and the price of the engine is about 5*l*. per h.p.

The engine is of the water-cooled 12-cylinder diagonal type as shown in fig. 44, and runs at 1,650 r.p.m. Epicyclic reduction gear is used for driving the air-screw at about 1,200 r.p.m. The cylinders are of steel, arranged at 60°, and are 4½ ins. diameter by 6½ ins. stroke. A fuel consumption of approximately 0·47 pt. per b.h.p. is obtained, and 8 pints of lubricating oil are required per hour. With reduction gear the weight is 900 lbs. and without this gear the weight is reduced to 836 lbs.

The American 'Liberty' engines were designed mainly on the lines of Rolls-Royce aero engine.

Sunbeam Engines.

The Sunbeam Motor Car Co. have standardised 8 sizes of aero engines. The 100 h.p. engine is of the 6-cylinder vertical type, having two valves per cylinder. The dimensions are 120 mm. by 130 mm. and the normal revolutions are 1,200 r.p.m., at which speed 110 h.p. is developed.

The first engine was made in the record period of five weeks from the time the drawings were issued, and passed through 120 hours' testing under various conditions required by the Admiralty. It was then transferred in a non-rigid airship without any modifications and has since run for nearly 200 hours without any adjustment whatever. Two pressure feed carburettors are fitted, and the petrol consumption is ·54 pints per h.p. per hour. The average lubricating oil required is 6·5 pints per hour, and this is supplied to the main engine bearings at 45 lbs. per sq. in. When dry the engine weighs 399 lbs.

Eight-cylinder diagonal type engines with cylinder dimensions of 120 mm. by 130 mm. and developing 200 h.p. at 2,000 r.p.m. are also made. Another engine of the same type is the Sunbeam twelve-cylinder 300 h.p. engine which has cylinders 110 mm. diameter by 135 mm. stroke on the master rod side and 142 mm. stroke on link rod side.

The largest aero engine is the Sunbeam 800 h.p. 12-cylinder engine, of the Vee type, and these engines have cylinders 180 mm. diameter by 210 mm. stroke running at 1,400 r.p.m. There are 3 inlet and 3 exhaust valves of the overhead type in each cylinder, and both hand and electric starters are fitted.

Napier Engines.

The Napier 450 h.p. aero engine is of the diagonal fan type, having three rows of four-cylinders each, one vertical and two at 60 degrees. The cylinder dimensions are 5½ ins. by 5½ ins., and the normal power is developed at 2,000 r.p.m. The cylinders are steel forgings machined all over and have water-jackets of steel. The head is of aluminium, detachable, and contains inlet and exhaust passages, valves and valve mechanism.

Two inlet and two exhaust valves are fitted to each cylinder. The pistons are of aluminium alloy and have two packing and two scraper rings. The master connecting rod is coupled to the pistons of the vertical cylinders, and has lugs on either side, to which are attached the short auxiliary rods for the pistons of the right and left-hand cylinders. The fuel consumption is ·48 lb. per b.h.p. hour and lubricating oil consumption ·02 lb. per b.h.p. per hour. The weight of the engine is 850 lbs. and the gross weight in running order with fuel and oil for six hours is 2,670 lbs.

The Napier patent air petrol starter is provided by means of which explosive mixture is pumped into the cylinders and ignited by a hand-starting magneto operated through the special distributer rotors of engine magnetos. The starter comprises a hand-operated air pump, petrol vaporiser, air distributing cock and simple mechanism for opening the valves on each block of cylinders by hand.

Galloway Engines.

Six-cylinder engines developing 200 h.p. when running at 1,400 r.p.m. are made by the Galloway Engineering Co. (fig. 45). The cylinders are arranged in two blocks of three each, consisting of aluminium casting comprising cylinder barrels, combustion chambers and valve guides. The cylinder dimensions are 145 mm. by 190 mm.

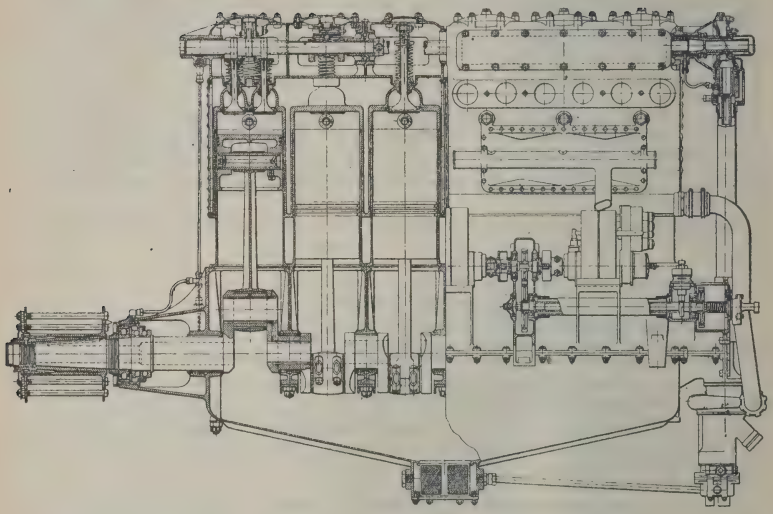

FIG. 45.—The Galloway Engine.

Forced lubrication at 20 lbs. pressure is supplied to the principal bearings and the oil consumption is ·029 pint per b.h.p. hour. The petrol consumption is ·58 pint per b.h.p. hour. Two Zenith carburettors are mounted on the right-hand side of engine and the two magnetos are of the Fellows type, with two independent sparking plugs in each combustion chamber.

The largest engine made by this Company develops 550 b.h.p. and is of the twelve-cylinder fan type.

ARMSTRONG SIDDELEY ENGINES.

The Puma engine is made by Armstrong Siddeley Motors, Ltd., Coventry, and is of the six-cylinder vertical type, developing 230 b.h.p. at 1,500 r.p.m. The cylinder dimensions are 145 mm. by 190 mm. The liners are shrunk and screwed into the aluminium alloy cylinder heads, and the cylinder jackets are cast in two blocks of three.

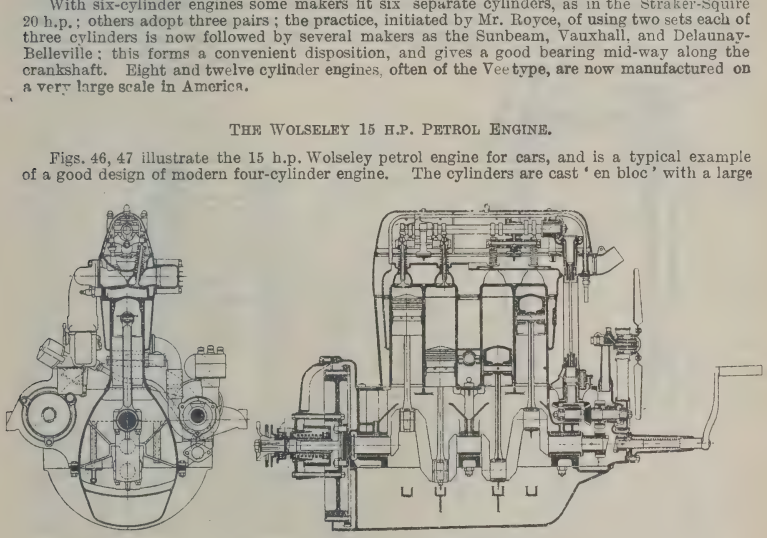
One inlet and two exhaust valves of tungsten steel are fitted to each cylinder. The exhaust valves are worked direct from the overhead counter shaft and the inlet valve is operated from this by a rocking lever. Lubrication is forced, and the aluminium alloy pistons are fitted with scraper rings to prevent the oil getting past the piston. Ignition is by two independent systems with separate magnetos or with one magneto and one high tension electric system. The petrol consumption is ·55 and lubricating oil consumption is ·03 pint per h.p. hour. The compression ratio is 4·9 to 1, and total weight 630 lbs.

OTHER MAKERS OF AERO ENGINES.

Other aero engines of the vertical type are Beardmore 120 b.h.p. six-cylinder, 130 mm. by 175 mm., and the Beardmore 160 b.h.p., six-cylinder engine, 142 mm. by 175 mm., running at 1,350 r.p.m. In addition vertical aero engines are made by the Green Engine Co., and a large number have been fitted to airships.

Aero engines of the diagonal type are the Wolseley and R.A.F. engines. This type of engine has also reached a high state of development in the Renault and Hispano-Suiza designs.

Rotary engines of other makes are the Clerget made by Gwynnes, Ltd., and the Bentley, which is an improved design of the Clerget. Large numbers of both have been fitted to aeroplanes.



MOTOR CAR ENGINES.

The four-stroke single-acting inverted vertical type of engine is mainly used for motor cars, and the 'en bloc' type of cylinder, i.e. with the four cylinders all in one casting, has been largely adopted. This practice results in a short, neat, compact engine of simple external appearance, and lends itself well to the thermo-syphon system of cooling now so largely used.

With six-cylinder engines some makers fit six separate cylinders, as in the Straker-Squire 20 h.p.; others adopt three pairs; the practice, initiated by Mr. Royce, of using two sets each of three cylinders is now followed by several makers as the Sunbeam, Vauxhall, and Delaunay-Belleville: this forms a convenient disposition, and gives a good bearing mid-way along the crankshaft. Eight and twelve cylinder engines, often of the Vee type, are now manufactured on a very large scale in America.

The Wolseley 15 h.p. Petrol Engine.

Figs. 46, 47 illustrate the 15 h.p. Wolseley petrol engine for cars, and is a typical example of a good design of modern four-cylinder engine. The cylinders are cast 'en bloc' with a large

Figs. 46, 47.—15 h.p. Wolseley Engine.

water space between Nos. 2 and 3; the crankshaft is carried in three substantial bearings; cooling is of the thermo-syphon type, and the ignition is effected by high-tension magneto. The engines are also made in 24 and 30 h.p. sizes, with six cylinders.

The Daimler Engine.

The Daimler-Knight sliding valve engine.—In this engine, which operates on the four-stroke single-acting method as usual, the poppet valves are replaced by cylindrical sliding valves. These engines run very quietly, and it is impossible to get the valve setting wrong after manufacture.

The piston is enveloped by two open-ended shells which are in turn contained within the cylinder casting.

These shells are reciprocated in a vertical direction by short links or connecting rods mounted on a miniature crankshaft running parallel with the main crankshaft. Cut in these shells are narrow ports extending a considerable way round the shell, which are covered or uncovered by the sliding of the shells over one another and in the cylinder. At certain periods, dependent upon the position of the piston, the ports in the sleeves and in the cylinder casting register with one another, thereby allowing fresh mixture to enter the cylinder or exhaust gases to escape, as the case may be.

The sizes of this engine for the 1921 season are 6-cylinder 30 h.p. 90 × 130 mm. and 6-cylinder 45 h.p. 110 × 130 mm. The crankshaft is of substantial construction, hollow, with bearings lined with white metal. These bearings are hung from the top plate of the crank case, and allow the bottom portion of the case to be withdrawn without disturbing the bearings, the bottom portion serving merely as an oil well.

Mounted parallel with the crankshaft is the layshaft, which for simplicity of construction is formed in two parts. This shaft runs in three plain bronze bearings which can be pushed through into position in the crank case with the shaft *in situ* after the crank case has been erected.

On the layshaft are two spiral gear wheels cut from the solid shaft. The forward one operates, by means of a small shaft running across the crank chamber between two cylinders, the magneto on the one side and the water-pump on the other. The rear one drives the low-tension contact breaker or distributer, according to what system of accumulator ignition is fitted as reserve. This shaft also drives off one of the crank pins a small pump supplying air pressure to the fuel tank at about 4 lbs. pressure.

Surrounding the piston U (figs. 48 and 49) are two shells—B the inner one and A the outer one—both shells and the piston being in turn surrounded by the cylinder, which has a detachable

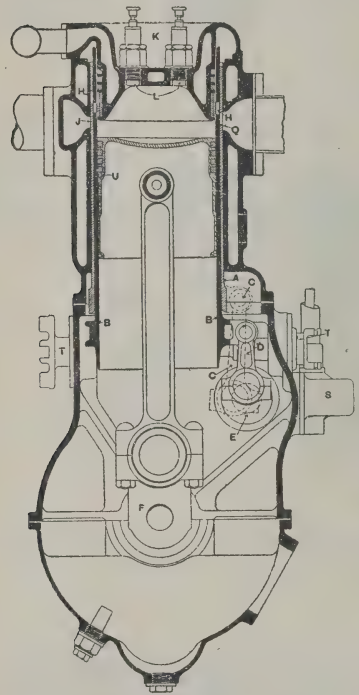


FIG. 48.—Cross-section of engine.

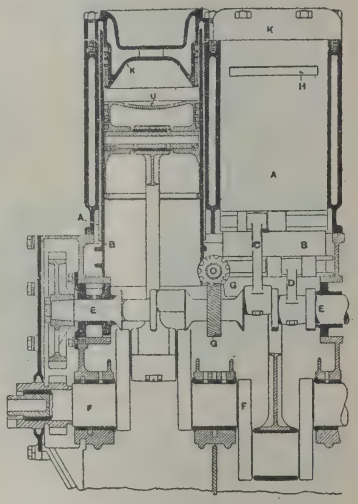

FIG. 49.—Longitudinal section of engine.

A, outer valve shell; B, inner valve shell; C, operating lever for A; D, operating lever for B; E, layshaft; F, crankshaft; G, helical gears; H, valve opening; K, cylinder head; L, sparking plug holes; O, cross-shaft driving pump and magneto; U, piston.

head K of peculiar design. This head projects down into the cylinder, and is provided with a number of piston rings, which form a gas-tight joint between the combustion chamber and the shell B. The ports in these shells are shown at H, J, and Q, being the ports in the cylinder casting, to the flanges of which the inlet and exhaust piping is bolted. E is the layshaft carrying the small connecting rods C and D which operate the shells A and B respectively. The motion given the shells is obviously a reciprocating one, as the levers C and D are carried on crank pins on the shaft E, which is driven in the same direction and at half the speed of the crankshaft by means of a silent chain off the crankshaft and enclosed in a cover in the front of the engine.

The Napier Engine.

The 40 h.p. Napier engine (fig. 50), which has six cylinders, 4 ins. by 5 ins., is of noteworthy design as it is modelled on the lines of aero engines. The cylinders and upper part of the crank-case are of cast aluminium, and steel liners are fitted in the cylinders. Aluminium alloy pistons are used and their weight is reduced to a minimum.

Overhead valves of non-corrodible steel are mounted in the detachable head, which, when removed, carries with it the whole of the valve mechanism. Two sparking-plugs are fitted to each cylinder and there are two systems of ignition. One is the usual high tension magneto and the other obtains current from the starting battery ; both systems operate independently.

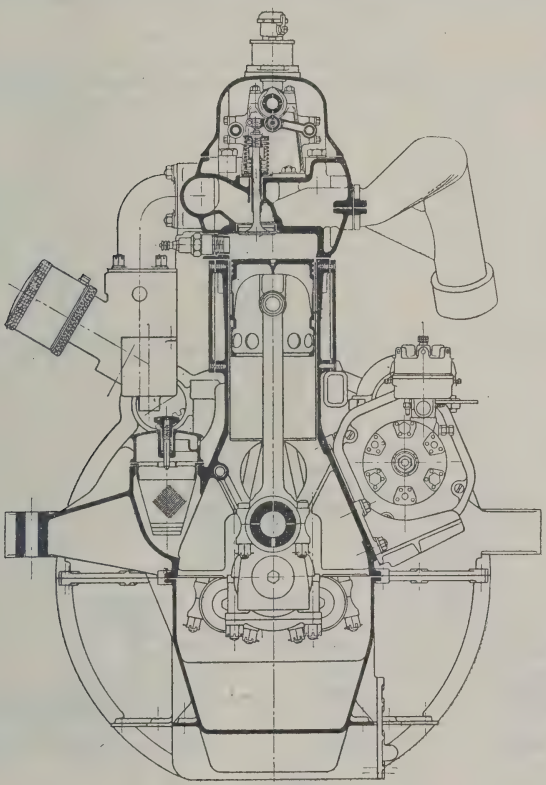

Fig. 50.—The Napier Engine.

The Napier S.U. carburettor supplies the mixture, and the jet is regulated by hand, as well as controlled by the automatic depression needle. Thus an initial mixture can be provided to suit varying atmospheric conditions, whilst the proportions of air and gas are regulated automatically.

In addition to obtaining a high volumetric efficiency, hence a high power output per cylinder, an advantage of the overhead valves is the short length of engine, which gives a short and stiff crankshaft. This helps to eliminate whipping tendencies, and increases the resistance to torsional stress.

The Dorman Engine.

The Dorman 12 h.p. four cylinder, 69 mm. by 120 mm. engine is another example of the improvement effected by overhead valves. This has valves worked by push-rods operated from two timing shafts located in the top of the crankcase, and the gear is very compact and accessible. An aluminium casting forms the cylinder jackets and crankcase, and separate cast-iron cylinder liners are fitted.

When the cast-iron detachable head is removed it brings away with it all the valves, springs and tappet levers; no adjustment is upset. Lubrication has received special attention, even the valve gear is automatically lubricated, and the design has reached a high state of perfection.

Dormans specialise in the manufacture of motor car and motor vehicle engines of the following sizes, and have been awarded the W.D. subvention certificate.

Brief Particulars of Dorman Engines.

Type.	Bore mm.	Stroke mm.	Cubic Capacity.	Brake Horse Power Guaranteed.		
				Petrol.	Paraffin.	Speed. r.p.m.
4 M.V.	69	100	1,490	10	—	1,000

The Tylor Engine.

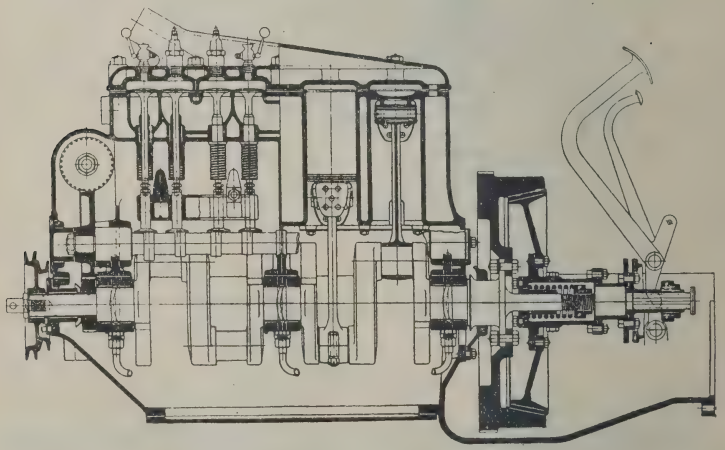

Fig. 51.—The Tylor Engine.

45 b.h.p. Tylor engines, 5 in. bore by 6 in. stroke, are fitted to the motor vehicles manufactured by the Associated Equipment Co. The normal speed is 1,000 r.p.m. and the engine is an approved subsidy model.

The cylinders are cast in two pairs with side pockets for the valves, and the induction passages are cored through the cylinders to enable the carburettor to be fitted on the other side. The three main bearings and the big end bearings are of gunmetal lined with white metal, and oil is forced to these, as well as to the camshaft bearings, by a pump. Ignition is by high-tension magneto with separate induction coil.

An illustration of 14·9 h.p., 76 mm. by 127 mm., engine as fitted to the Argus Sanderson car is shown in fig. 51. The four cylinders are cast 'en bloc,' and the upper part of the crank case is in the same casting. The cylinder head is separate and easily removable.

The engine is well balanced and the makers state that even at 2,000 r.p.m. very little vibration occurs. Thermo-syphon cooling is adopted, and the induction and exhaust manifold is a single casting bolted to the cylinders. A 'hot spot' is provided in the induction portion to ensure complete vaporisation of the incoming charge before it enters the cylinder.

The White and Poppe Engine.

White and Poppe, Coventry, specialise in the manufacture of engines for motor cars and vehicles. The engines are of the four-cylinder design, ranging in power up to 40 b.h.p.; the smallest cylinder is 60 mm. by 90 mm. and the largest 127 mm. by 180 mm.

They can be supplied for using paraffin fuel; their special carburettor ensures a non-smoky exhaust, and prevents any sooting-up of the valves.

The Aster Engine.

An attractive four-cylinder engine intended for light cars is made by the Aster Engineering Co. and develops 10 b.h.p. The cylinder dimensions are 65 mm. by 100 mm. and they are cast in one with the crank case and water-jacket.

Overhead valves are fitted in the detachable cylinder head and the operating gear is quite enclosed and automatically lubricated by taking the oil mist from the crank case into the cover. Thermo-syphon cooling is adopted, a horizontal Zenith carburettor is fitted, and ignition is by means of high-tension magneto.

Air-cooled Engines.

Air-cooled engines are fitted to a number of light cars; they are of the stationary type and weigh much less than water-cooled engines. They keep cool even after long runs, and display a high standard of reliability and economy.

The air-cooled engines have decided advantages in the winter, there is no risk of damage by frost, and the elimination of radiator, pump, and piping is of importance.

Horizontal opposed engines of this type, developing 10 b.h.p., are fitted to the Palladium, G.N., and A.B.C. cars. The Speedy car has an 8 b.h.p. J.A.P. air-cooled engine. A 10 b.h.p. three-cylinder radial engine of the inverted Y type is fitted to the Cosmos Engineering Co.'s car. The cylinders have a bore and stroke of 80 mm. with separate heads of aluminium alloy and cast-in steel valve seats. The Enfield-Allday 10 h.p. motor car is fitted with an air-cooled engine of the five-cylinder radial type. The cylinders are 68 mm. in diameter and have aluminium alloy pistons with four thin and deep packing rings. Concentric valves in the form of sleeves, working one inside the other on to taper valve seatings, are arranged for operation by overhead rocking levers actuated by tension rods from a camshaft in front of the engine. The cylinders are cooled by the fan-shaped flywheel, and the efficiency of cooling does not depend upon the motion of the car.

Air-cooled engines are largely used on motor-bicycles; one of the best-known is the two-cylinder Vee engine made by J. A. Prestwich & Co. This engine operates on the four-stroke cycle and develops 8 b.h.p. at 2,000 r.p.m. Another well-known engine is the Douglas.

Trend of Motor Car Engine Design.

An interesting comparison of engine changes since 1913 was made by M. Charles Favoux after the last Paris Exhibition, and is as follows:—

Details.	1919.	1913.
	Per cent.	Per cent.
Four-cylinder chassis	75	89
Six " "	20	10
Eight " "	3	1
Single valve-shaft engines	57	42
Overhead valves engines	28	22
Spiral-gear timing	80	3
Teeth on bias (not helical)	18	92
Chain timing drive	2	3
Cylinders 'en bloc'	52	21
Electric starter and lighting set	92	4

* Fractions of a cubic inch or cubic centimetre will be reckoned as 0·0 if below 0·5, and as 1·0 if 0·5 or over. † Minimum weight, includes driver.

NOTE.—1 cubic inch = 16·38706 cubic cent. 1 cubic cent. = 0·0610237 cubic inch.

Cranks and Crankshafts.

Crankshafts are usually of the hardest steel that can be satisfactorily worked. The grades used vary from steels having an elastic limit of about 28 tons per sq. in. and ultimate strength of 35 tons per sq. in. to an elastic limit of 90 tons per sq. in. and an ultimate strength of over 100 tons per sq. in. Nickel, vanadium, and chrome steels are largely used. The following table illustrates practice :—

TABLE OF SOME SUITABLE STEELS FOR MOTOR CARS.

Part of Car.	Tensile Tests. Elastic Limit, Tons per Sq. In.	Ratio of Elastic to Maximum per Cent.	Maximum Strength Tons per Sq. In.	Elongation, per Cent.	Material.
Crankshafts	48·5	86·5	56·0	22	Chrome Nickel
" "	48·0	85·7	56·0	19	Chrome Vanadium
Connecting Rods (stamping)	30·0	62·5	48·0	26	5 per Cent. Nickel
Gear Shafts (*a*)	98·0	89	110·0	13	Chrome Nickel
" " (*b*)	88·0	78·5	112·0	2·5	
Live Axles	57·0	77	73·8	18	Chrome Nickel
	48·0	65·7	73·0	14	
Piston Gudgeon Pins	29·0	85·2	34·0	31	Flather & Co.'s Ubas Annealed Case-hardening Steel

Most of these steels are more susceptible to variation during their hardening and tempering processes than is ordinary carbon steel, and unless handled with knowledge and skill are liable to give very disappointing results. As an illustration of the importance of careful and accurate heat treatment, take the test of gear shaft steel (*b*) in the above table.

To give the results specified in the table, this steel is heated in a muffle to 750° C. with all air carefully excluded or consumed by burning with coal gas. At 750° C. it is quenched in oil and tempered by reheating in the muffle to 330° C. for 15 minutes and plunged into oil until cool. The same steel heated to 740° C. and tempered at 400° C. gives the following tensile test :—

Elastic Stress, Tons per Sq. In.	Ratio of Elastic to maximum per cent.	Maximum Stress, Tons per Sq. In.	Elongation, per cent.
78	87·6	89	10

For case-hardening steels the best results are obtained by allowing the pieces to get quite cool before unpacking them from the carbonising boxes, then reheat and quench until cool.

With four-throw crankshafts having three bearings the shaft diameter must be slightly greater than when five bearings are fitted in order to provide the necessary stiffness ; crankshaft design in motor-car engines has regard to stiffness as the primary consideration. In the four-cylinder 14 h.p. de Dion, and 12 h.p. Delage engines, the crankshaft is carried in *two* bearings only ; the cylinders are ' en bloc,' and kept as close together as possible ; this is the extreme case. The three-bearing four-throw crankshaft is adopted by many first-class builders and may be regarded as entirely satisfactory in practice.

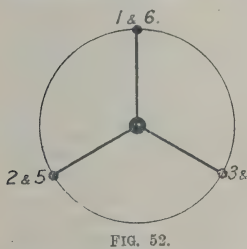

FIG. 52.

Disposition of Cranks.—From considerations of balance, in two-cylinder engines the crank-throws are nearly always at 180°. This, however, involves the disadvantage that two working strokes occur in one revolution, the succeeding revolution being idle ; the turning moment is thus very un-uniform.

With the very light pistons and connecting-rods now used it becomes possible to place the crank-throws together (i.e. at 0°) ; this is done in the 2-cylinder 9 h.p. de Dion engine and one or two others ; there is then a working impulse in every revolution of the shaft.

In four-cylinder engines the crank-throws are always placed all in one plane, the two centre throws being together and at 180° to the two outer throws. With this arrangement two orders of firing are possible, viz. 1 2 4 3 and 1 3 4 2 ; both are used, but 1 3 4 2 appears to be the sequence preferred. With this arrangement of crank-throws a practically perfect balance is obtained. In four-cylinder engines the crankshaft diameter is about one-third of the cylinder bore in five-bearing designs, to half the bore in three-bearing arrangements.

In six-cylinder engines the usual arrangement of crank-throws is the ' two 3-cylinder engines reversed,' which gives an excellent balance. Thus (fig. 52) throws numbers 1 and 6 are together, as also are 2 and 5, and 3 and 4.

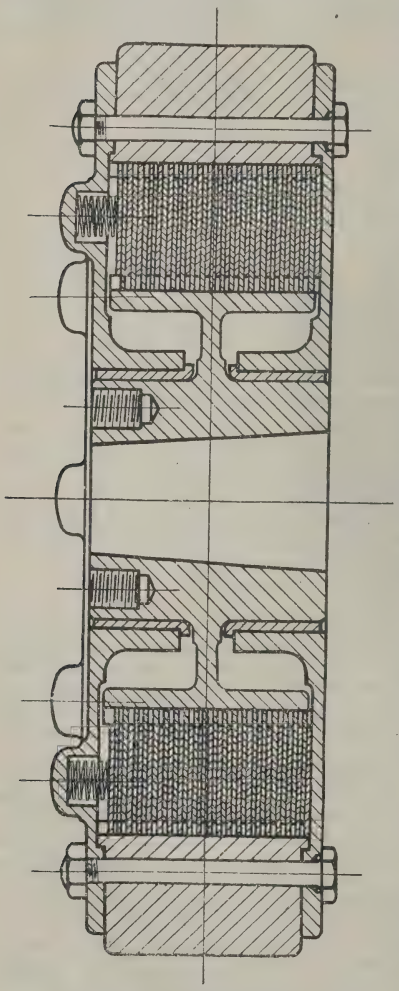

Fig. 53.—Lanchester Torsional Vibration Damper.

With this disposition, eight orders of firing are possible, four of which are ' mirror images ' of the other four ; these are :—

5	3	6	2	4	1		1	4	2	6	3	5
2	3	6	5	4	1		1	4	5	6	3	2
5	4	6	2	3	1		1	3	2	6	4	5
2	4	6	5	3	1		1	3	5	6	4	2

It is to be noted that 5 3 6 2 4 1 and its image 1 4 2 6 3 5 are the only two in which no two adjacent cylinders fire consecutively ; these are the orders usually adopted, as giving greatest freedom of exhaust.

Torsional Vibration of Crankshafts in Six-Cylinder Engines.

Torsional vibration of the crankshafts occurs at certain critical speeds on almost all six-cylinder high-speed engines. In cases which have come under observation periodic or torsional vibration has occurred at or about three-fourths the normal running speed of the engine, e.g. an engine rated at 1,200 r.p.m. vibration occurred at about 900 r.p.m. An engine rated at 385 r.p.m., vibration occurred about 290–5 r.p.m. ; whilst in the case of another engine having 200 r.p.m., vibration occurred between 150-160 r.p.m. The normal B.H.P. ratings of the examples referred to were respectively 150, 1,200, and 750 B.H.P.

One method of eliminating or reducing the effect has been to reduce the weight of reciprocating parts, in particular the piston, which, generally speaking, is now made of an aluminium-copper alloy.

Another method has been to considerably increase the diameter of the journals, crankpins, and crankwebs of the crankshaft.

A third method has been to increase only the diameter of the journals and crankpins of the three cylinders nearest the flywheel, or that end of the crankshaft from which the power developed is taken off.

A fourth method is to fit a Lanchester Torsional Vibration Damper, which permits of retaining a shaft of normal dimensions. This damper is usually fitted on the end of the crankshaft *furthest* from the flywheel, or that end from which the power developed is taken off. The apparatus, fig. 53, consists of a rotor (which is firmly secured to the end of a crankshaft) which has cut upon its circumference a number of axial slots.

Mounted externally upon this rotor are two diametrical side plates, and sandwiched between them is a small flywheel rim secured by suitable bolts. The side plates are bushed with bronze, and are housed upon the external diameter of the fixed rotor, so that the rim and side plates are free to move independently on the fixed rotor. On the internal diameter of the flywheel rim is also cut a number of axial slots, and in the annulus formed by the rim and the rotor are placed a number of thin, hard steel plates. These are provided with keys

or projections which fit loosely in the axial slots formed in the fixed rotor and the internal circumference of the small flywheel rim. These plates are so placed that they engage alternately in the slots formed, much in the same way as the plates are fitted in a multi-disc plate clutch.

The plates are pressed together by means of a number of springs, housed in one of the side plates, and the spaces between the plates are filled with thick engine oil.

The flywheel rim and side plates are driven solely by oil friction between the plates.

In all crankshafts an intermittent torsional stress is produced by the work done as each piston transmits its force to the shaft.

At certain speeds a reactionary effect is produced throughout the length of crankshaft, of such a severe character as to set up a severe and ofttimes intense vibration, which, if not eliminated, will ultimately fracture the shaft.

The function of the Lanchester Damper is to prevent or soften down this reaction, and it does so in the following manner:—

The small flywheel rim, which is driven by oil friction through the plates, is rotating normally at a uniform speed and as the torsion on the crankshaft increases at each impulse the shaft is, in a sense, wound up, say like a clock spring, and in its reactionary effect seeks to unwind or to return to its normal. The reversal of energy is transmitted to the floating flywheel rim, and in doing so deaccelerates gradually, owing to the rim being permitted to slip, and again gradually accelerates to uniform speed without producing any sudden changes, and thus prevents the torsional vibration occurring at certain critical speeds.

The effect of fitting this apparatus is most marked, and its value to engine builders cannot be too fully recognised.

Bearings.

Crankshaft and big-end bearings are usually white-metal lined; gudgeon bushes of bronze. Corresponding to a maximum explosion pressure of 300 lbs. per sq. in., the bearing pressure in lbs. per sq. in. of projected area is as follows:—

For 'big end' bearings:—800 to 1,100 lbs. per sq. in.; more usually the latter.

For 'gudgeon' bearings:—1,500 to 2,700 lbs. per sq. in.; average about 2,000 lbs. per sq. in.

Pistons.

Pistons are usually of medium hard, close-grained cast-iron, usually with three but occasionally four cast-iron spring rings; an additional oil-excluding or 'scraper' ring is often fitted near the piston bottom; in normal touring-car engines the length of piston averages 1·16 times its diameter. Pressed steel pistons are now being used in order to reduce the mass of the reciprocating parts as far as possible.

The Ricardo Piston.

This piston, fig. 54, is a 'slipper' type, and aims at securing increased power by the reduction of friction and weight. The contamination of the lubricating oil due to gas leaking past the rings, which takes place in the ordinary form of piston, is reduced by allowing the

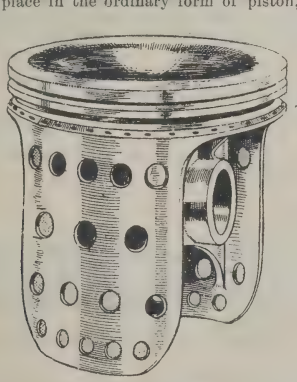

Fig. 54.

leaking gas to escape before reaching the piston skirt. Also the lower ring groove is bevelled and drilled to enable the ring to act as a scraper. The general advantages are as follows: (1) Gas pressure is transmitted direct from the crown of the piston to the centre of the gudgeon

pin bosses; (2) Thrust from the connecting rod is transmitted directly to the bearing surfaces; (3) Bearing surface is provided only where it is needed; (4) Gases that pass the piston-rings may escape freely into the crankcase; (5) No load is transmitted through the side walls, or past the piston-ring grooves; (6) The lower piston-ring acts as a scraper, so that oil that has worked up past the slippers can be returned through the small holes beneath.

Experiments made with the Ricardo piston showed a marked reduction in oil consumption, in one case this consumption falling from ·06 lb. per horse-power-hour, to ·035 lb. At the same time the fuel consumption dropped 4 per cent. and the brake horse-power was increased 4 per cent. approximately. The whole piston is extremely light. For cylinder bores ranging from 3½ ins. to 5 ins. diameter, the weight of the piston complete with gudgeon pin and piston-rings can be reduced to ·1 lb. per sq. in. of piston area.

Ratio of Stroke to Bore.

This has increased during recent years, especially in small-bore engines, and may be considered to range from 2·0 in engines of 6-15 h.p. (as, e.g., the Gregoire, Lion-Peugeot, Calthorpe, Le Gui, Delage and Jackson), to 1·0 in large car engines as instanced by the Lanchester, Maudslay, and Napier designs. An average value for the normal touring-car engine of 15 to 30 h.p. may be taken as 1·5.

Connecting Rods.

Connecting rods are in nearly all cases of stamped steel of H-section; the length of connecting rod varies but little from 2½ times the piston stroke.

Weight of Reciprocating Parts.

If m denote the weight of the piston and connecting rod, in lbs., and if r denote the ratio of stroke to bore, and d be the cylinder diameter in inches, then for cast-iron pistons :—

$$m = \cdot 08\, d^3\,(1 + \cdot 15r) + 1 \cdot 5 \qquad (30)$$

(*Burls.*)

For steel pistons the coefficient of d^3 may be reduced from ·08 to ·05; Eq. (30) well represents current practice.

Ignition.

Ignition is almost universally by high-tension magneto. Battery and coil ignition is occasionally fitted for starting and as a stand-by. In the Bosch Dual Ignition device the high-tension magneto and battery-coil ignitions are ingeniously combined, with one sparking plug only to each cylinder; with this one has :—

(A) A momentary ignition by trembling coil and battery; or permanently if desired.
(B) A permanent ignition by non-trembling coil and battery.
(C) A permanent ignition by high-tension magneto.
(D) An effective self-starting arrangement for four-cylinder engines.

As the magneto armature gives two firing sparks per revolution, it must be driven at a rate relatively to that of the crankshaft as follows :—

No. of cylinders	1	2	3	4	6
Ratio $\frac{\text{Armature speed}}{\text{Crankshaft speed}}$	½	½	¾	1	1½

Practically, however, in one-cylindered engines the magneto is driven at *half* the crankshaft speed, and in two-cylindered engines with cranks at 180°, the armature is driven at crankshaft speed, so that in each of these cases half the sparks are idle. In single-crank two-cylinder engines, however, as there is a working stroke in every revolution, the magneto is driven at half the crankshaft speed, and there are no idle sparks.

The advantages of the high-tension magneto as compared with the coil and battery are broadly :—

1. Weaker mixtures can be fired regularly.
2. Faster and quieter running of the engine can be obtained owing to the plain make-and-break device embodied in the magneto.

With an efficient coil, a Siemens 'G.W. 4' dry battery (see Index) would give permanent ignition in a two-cylinder engine for some 1,000 miles. For starting purposes only it should last for about two years.

Valves.

Excepting only the Daimler-Knight sliding valve engines, the poppet valve is almost universally employed in the petrol engines of automobiles. The valve axes are in general vertical and parallel to that of the cylinder; both inlets and exhausts are mechanically operated. Practice is about equally divided in the matter of valve location, some makers fitting them on the same and some on opposite sides of the cylinder; in a few instances, as e.g. the Maudslay, they are fitted in the cylinder head. Recently the old arrangement, common in the days of automatic inlets, of placing the inlet valve piston above the exhaust, and operating it by some form of overhead gear, is being revived; this gives a compact combustion chamber, and the ingoing fresh charges pass over the exhaust valve top and tend to keep it from becoming overheated.

Valves are usually of mild, or nickel, steel with coned seats having an angle of about 30°; the inlets and exhausts are very usually made exactly alike, so as to be interchangeable; the exhaust valve lift is sometimes from $\frac{1}{32}$ in. to $\frac{1}{16}$ in. larger than that of the inlet, and *vice versâ*.

In the table below, the diameter and lift of the inlet valves is shown for twenty-four touring-car engines of 1910 design; in each case the exhaust was of the same diameter as the inlet. The two columns on the right show the ratio of valve diameter (in throat) to cylinder bore, and of valve lift to valve diameter, respectively. The valve diameter in throat is denoted by δ and the lift by λ, fig. 55, p. 1728, both in inches. The ratio of valve diameter to bore varies from 0·345 to 0·563, the average proportion being 0·41; the average lift is, roundly, 0·2 of the valve diameter.

VALVE PROPORTIONS OF SOME TOURING-CAR ENGINES.

Examination of nearly 150 engines of good design in 1910–1911 showed a mean velocity V of gas through the throat of the inlet valve of 7,000 to 8,000 ft. per minute, as computed by aid of the formula :—

$$V = \left(\frac{d}{\delta}\right)^2 \sigma \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (31)$$

where σ is the piston speed in ft. per minute; n denoting the speed in revolutions per minute, and s the stroke in inches :—

$$\sigma = \frac{n\,s}{6} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (32)$$

In present practice σ is occasionally as high as 1,400 ft. per minute, under normal running conditions, but this is rare; 1,000 ft. per minute is, however, common, and 1,200 ft. is often attained. If in (31) we put $V = 7{,}000$ and $\sigma = 1{,}200$, then

$$\delta = 0{\cdot}414\, d \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$

which is a convenient rule for the practical proportioning of valves; the lift may be one-fifth of δ for ordinary touring engines. In recent designs V is only from 6,500 to 7,000 ft. per minute.

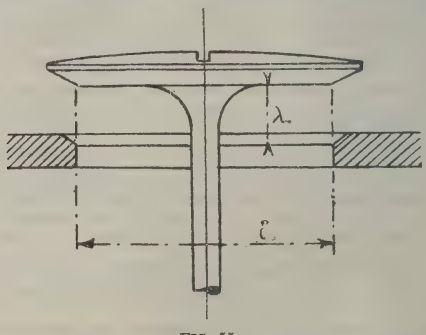

FIG. 55.

Valve setting.—As determined from an examination of forty touring-car engines in 1910, the average setting was :—

Inlets :—Open . . .	12° late.	Close	20° late.
Exhausts :—Open . .	45° early.	Close . . .	6° late.

In racing engines an 'overlapping' setting is sometimes adopted, i.e. the inlet opens before the exhaust has closed, so that for a few degrees of crankshaft revolution both valves are partly open. This is done to assist scavenging and is sometimes beneficial in such cases, but it is not a practice that tends to economy in running.

According to a bulletin on 'The Manufacture and Use of Alloys,' by Mr. Henry D. Hibbard, and issued by the United States Bureau of Mines, high-speed steel is being used for the exhaust valves of petrol motors and has given excellent results, owing to its heat-resisting quality.

Compression.

Compression.—If V denotes the volume of the combustion chamber, in cubic inches, then,

$$\text{Volume ratio of compression} = C = \frac{V + \frac{\pi}{4} d^2 s}{V} \quad . \quad . \quad . \quad . \quad . \quad (34)$$

whence,

$$V = \frac{\frac{\pi}{4} d^2 s}{C - 1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (35)$$

In petrol engine practice C varies quite irregularly over a range from about 3 to 5; in most cases, however, the value is between the narrower limits of $3\frac{1}{2}$ to $4\frac{1}{2}$. Recent examination of a large number of well-designed engines shows the average value of C to be about $4\frac{1}{4}$, corresponding to an absolute compression pressure of 100 lbs. per sq. in., or 85 lbs. per sq. in. above the atmosphere. The compression pressure realised is dependent on the engine speed, the 'volumetric efficiency' or proportion of actual charge received to full charge diminishing at high speeds. The limit of compression for touring-car engines is $C = 5\frac{1}{2}$, corresponding to a pressure (absolute) of about 135 lbs. per sq. in.; above this pre-ignition troubles usually arise.

Alcohol used in an engine with a raised compression can be made to give approximately 50 per cent. more power than when a compression suitable for petrol is used.

Efficiency.

Mechanical Efficiency.—The mechanical efficiency of a good four-cylinder four-cycle single-acting petrol engine at about 1,000 revs. per min. should depart but little from the value 0·85.

Brake Thermal Efficiency.—For engines of this type also, the brake thermal efficiency is between 0·20 and 0·25, the latter being exceptional; an average good performance is 0·22.

Of the whole heat of combustion of the petrol, roundly 22 per cent. appears as b.h.p.; 33 per cent. appears in the cooling water; and 45 per cent. is lost in the exhaust gases and by radiation. If P denote the number of pints of petrol used per b.h.p. hour, then :—

$$\text{Brake Thermal Efficiency} = \frac{2545}{16800\,P} \quad . \quad . \quad . \quad . \quad . \quad (36)$$

for ordinary petrols. A brake thermal efficiency of 22 per cent. thus corresponds to a petrol consumption of 0·69 pint per b.h.p. hour.

Power Rating.

Power Rating of Petrol Engines.—Many rating formulæ have been proposed; some of these are discussed in a report on Horse-Power Formulæ for Petrol Engines prepared by G. A. Burls, M.Inst.C.E., for the Society of Motor Manufacturers and Traders in 1908.

The R.A.C. Formula.—For taxation purposes the authorities have up to the present used the old Royal Automobile Club formula, viz. :—

$$\text{Power Rating} = 0{\cdot}4\,d^2N \quad . \quad . \quad . \quad . \quad . \quad . \quad (37)$$

where d is the cylinder bore, in inches, and N is the number of cylinders.

This rating is independent of the stroke of the engine and is thus unsuitable for actual power rating purposes. It implies a constant piston speed of 1,000 ft. per minute, and a constant value of 67½ lbs. per sq. in. for the 'brake mean effective pressure.'

The Joint Committee's Formula.—An investigation into the question of rating was made by a joint committee of the Royal Automobile Club, the Institute of Automobile Engineers, and the Society of Motor Manufacturers. This joint committee issued its report in February 1911, and recommends that the following be regarded as the *maximum* practicable b.h.p. per cylinder that can be obtained from carefully-designed and well-built touring-car engines of bore from 2½ ins. to 5 ins. on bench tests under onerous, but safe, conditions :—

$$\text{B.H.P. per cyl.} = 0{\cdot}45\,(d+s)\,(d-1{\cdot}18) \quad . \quad . \quad . \quad . \quad (38)$$

This formula implies (1) a brake mean effective pressure increasing with the cylinder bore and (2) a maximum practicable piston speed increasing with the stroke-bore ratio. In the table below, some ratings furnished by Eq. (38) are given for convenience of reference :—

JOINT HORSE-POWER FORMULA COMMITTEE'S RATINGS PER CYLINDER.

r = STROKE-BORE RATIO.

r =	d = ins.	s = ins.	Rating per Cyl.	r =	d = ins.	s = ins.	Rating per Cyl.
	2½	1⅞	2·6		2½	3⅜	3·7
0·75	3	2¼	4·3		3	4½	6·1
	4	3	8·9	1·5	3½	5¼	9·1
	5	3¾	15·0		4	6	12·7
					4½	6¾	16·8
	2½	2½	3·0		5	7½	21·4
	3	3	4·9				
1·0	3½	3½	7·3		2½	5	4·5
	4	4	10·2	2·0	3	6	7·4
	4½	4½	13·5		4	8	15·2
	5	5	17·2		5	10	25·8
	2½	3⅛	3·3		2½	6¼	5·2
	3	3¾	5·5	2·5	3	7½	8·6
1·25	3½	4⅜	8·2		4	10	17·8
	4	5	11·4		5	12½	29·6
	4½	5⅝	15·1				
	5	6¼	19·3				

The Brooklands A.C. Rating.—The Brooklands Automobile Racing Club in February 1912 adopted the volume displaced by the pistons as a rating basis, the formula being :—

$$\text{Brooklands Rating} = \frac{\pi}{4} d^2 s N \quad . \quad . \quad . \quad . \quad . \quad . \quad (39)$$

where N denotes the number of cylinders.

The table on page 1722 shows the mode of classification adopted.

Burls' Maximum Horse-power Formula.

Extremely high powers per cylinder are obtained from racing engines by the use of specially large valves, piping, and carburettors, and very high piston speeds arising from exceedingly light reciprocating parts. For such cases Burls, making a certain assumption, has suggested (*vide* Proc. Inst. A.E. 1910–1911) for rating purposes, the formula :—

$$\text{Max. B.H.P. per cyl. for racing engines} = 0{\cdot}5\ d\ (d - 1{\cdot}18) \sqrt{\frac{d^2 s}{m}} \quad . \quad . \quad (40)$$

where d and s are the bore and stroke in inches, and m is the mass of the piston and connecting-rod jointly, in lbs., as given by Eq. 30, page 1726.

The valve diameter of such engines is given by :—

$$\delta = 0{\cdot}29 d \sqrt[4]{\frac{d^2 s}{m}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (41)$$

and yields results giving, on the average, a value of δ of about $0{\cdot}52\ d$. Where it is considered that the value of δ is too high, the practice of fitting two inlet and two exhaust valves to each cylinder is resorted to.

Weight of Engines.

Weight of Petrol Engines.—The weight per b.h.p. is somewhat variable, as some makers employ an exceedingly high piston speed and thus obtain increased power. Including radiator, fan, pumps, carburettor, magneto, silencer, and flywheel, all complete and in running order, but without fuel or water, the weight per b.h.p. at *normal* power output varies from 16 to 24 lbs., and at *maximum* power output from 8 to 16 lbs.

Lubrication.

There are various systems of lubrication in vogue amongst automobile engine manufacturers ; generally speaking they may be classified under three headings :

Splash ; Gravity or indirect forced ; and Forced.

Splash, which was at one time almost universally used, is so well known that it needs no description.

Gravity lubrication is the term applied to systems in which oil is measured out by mechanical means into separate ducts or conduits, through which it flows by gravity to its appointed bearings. Frequently a pump is employed in this system which draws the oil from a reservoir or sump in the crank case and redelivers it to the upper reservoir from which it is distributed. This combination is sometimes erroneously termed forced lubrication.

Forced lubrication is that system in which a pump is employed to force oil direct into the bearing, and in its complete form lubricates not only the crankshaft but the connecting-rod end and piston gudgeon. The pump draws oil from a well or reservoir into which the surplus oil returns after circulating through the bearings, etc. One advantage which this system has over others is that no dashboard fittings are required, excepting a pressure gauge or some other form of pressure indicator.

Forced lubrication as a system embracing all the working parts of an ordinary reciprocating steam engine was patented and introduced by Messrs. Belliss & Morcom in 1890, being employed in their steam engines to lubricate crank journals, crank pin, and gudgeon pin bearings. It was adapted to automobile engines by the Lanchester Motor Co. in 1904, and at the present time it is used by many motor manufacturers. Recently, however, the combination of an oil pump delivering

from a pump into movable troughs placed below the big ends is becoming common ; the troughs are kept full to overflowing, and the engine is lubricated by the big-end splash. The troughs are connected with the throttle control in such manner as to be raised when the throttle is more fully opened, and *vice versâ* ; the oil supply is thus increased at increased engine speed. It is advantageous to cool the oil by passing it through an external reservoir before it re-enters the troughs.

(See also page 1539.)

Cooling.

Thirty to forty per cent. of the total heat generated in the cylinder of an internal combustion engine is lost through the water jacket.

Excessive cooling is detrimental to the economical working of the engine. Some experiments have shown the highest efficiency when the cooling water leaves the jacket at 180° F. to 200° F. It is probable that the latter figure is the average most efficient temperature. The efficiency of a motor-car radiator is materially increased by coating with black, and tests have demonstrated that a radiator may be coated with dull black varnish or lacquer up to as many as fourteen coats, its efficiency being increased slightly by each coat.

A radiator should have at least 40 square inches of effective cooling surface to 1 square inch of total combustion chamber surface of the motor cylinders if the water is circulated by a pump delivering about 2 gallons per minute. If the water is circulated by natural convection or 'Thermo-syphon' it is usual to allow more radiator surface per unit of heated surface of the cylinders, 45 : 1 being at least necessary.

It is usual to provide a fan to draw air through the radiator, but unless the radiator surface is insufficient the fan is not necessary above a speed of about twenty-five miles per hour.

If aluminium is used in parts of the radiator or circulation system exposed to the waters the use of crude glycerine as a preventive against freezing should be avoided.

The admixture of glycerine to the cooling water is rare ; the safer plan is to drain off the water if there is any risk of frost.

Thermo-syphon cooling is now very largely adopted and as now fitted is entirely satisfactory ; it seems probable that it will soon completely supersede pump circulation. It lends itself especially well to engines having the 'en bloc' arrangement of cylinders.

Boilerine Radiator Tablets.

These tablets, invented and manufactured only by Boilerine Limited, are for the purpose of obviating the fur which forms in radiators and water-jackets of motor-cars, cabs, lorries, or buses. There is nothing in the preparation detrimental to the joints or metal parts. Where scale is already in existence 50 tablets per gallon of water take the lime into solution, dissolving the particles, thus leaving the walls of the cylinder-jackets and radiator tubes perfectly clean.

Following this cleaning process all water put in the radiator should be 'Boilerined' to the extent of 2 tablets per gallon, up to 14 degrees of hardness, and one extra tablet for every 7 degrees beyond ; one tablet per gallon for rain water to prevent rust.

When water is poured into the radiator, it amounts to putting in a quantity of lime or chalk, or if soft water, a means of producing rust.

If this is done without 'Boilerine' tablets, the lime adheres to the walls of the cylinders and radiator tubes until efficiency is choked out of the cooling system.

Boilerine Limited have proved from tests that thirty hours heating of water at 190° F. gives nearly the same amount of deposit as half an hour's boiling, thus, surely, though unseen, the motor is, at the working temperatures, storing up in its cooling system this cause of trouble, consequently the flow of water is reduced, producing overheating, or allowing the impurities in the water to cause rust and corrosion, hence leakages.

These claims are confirmed by the reports given on tests of twelve and six months' duration, respectively, made by Messrs. Thomas Tilling, Ltd., and Messrs. W. H. Dorman & Co., Ltd., Stafford, copies of which can be had on application to Boilerine Limited.

Carburettors.

Carburettors.—The only wick carburettor now surviving is that of Lanchester. With this exception, the float-fed spray-nozzle type is practically universal. In many cases this does not far depart from the original Maybach model, but some makers employ double nozzles ; in other cases, as e.g. the Wolseley, three nozzles are used ; the first is very small and used only for slow running ; a further throttle opening cuts this first nozzle out of action and brings the second into operation ; this is of a size to give economical running at ordinary speeds. At full throttle the third jet comes into action jointly with the second ; this third jet is relatively large and increases the richness of the mixture, high power being the primary requisite at full throttle, and maximum economy then a secondary consideration.

The Daimler carburettor has seven jets in as many choke tubes, whose upper ends converge into the mixing chamber at different heights and are uncovered in succession by a sliding sleeve which functions automatically in response to the rise and fall of the negative pressure in the gas mixture pipe. One of the jets has an adjustable needle and serves as a 'pilot' jet for starting. The carburettor casing is jacketed to the water circulation, and the air is warmed by the exhaust pipe.

In the well-known Polyrhöe (many-jet) carburettor, an exceedingly large number of very fine jets is used; these are arranged along one edge of a rectangular air opening and are brought into action by a sliding throttle in accordance with the requirements of the engine, the proportion of air to petrol thus continuing the same at all degrees of opening.

In the White and Poppe carburettor, from which also excellent results are obtained, the petrol nozzle is gradually increased and the air supply simultaneously proportionately increased as the throttle is opened. A common practice to prevent over-richness of mixture at high speeds is to introduce between the carburettor and engine an automatic spring-controlled extra air valve which opens when the engine is speeded up and admits air into the induction pipe, thus diluting the mixture; the device is imperfect, but answers quite well in many ordinary cases.

The essential organs of the float-feed spray carburettor, now so widely employed, are shown in the accompanying sectional view, fig. 56.

The float chamber A contains a light brass or copper cylindrical float, B, which maintains the petrol supplied through the branch C at a constant level within the chamber by its action on the central needle valve D through the weighted levers E. The float chamber is in constant communication with the spray chamber F through the passage H; J is the spray nozzle, within which

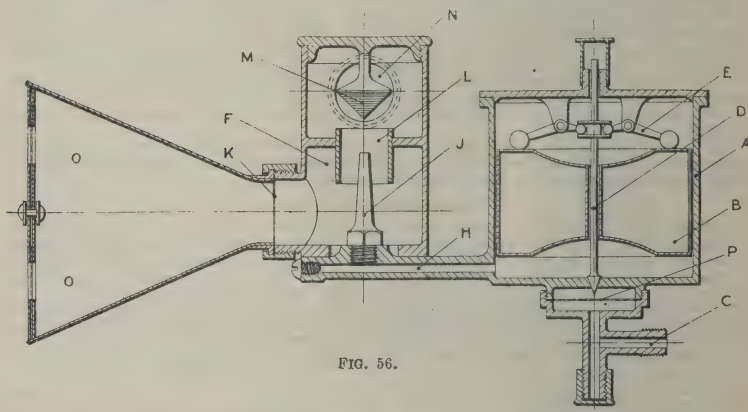

FIG. 56.

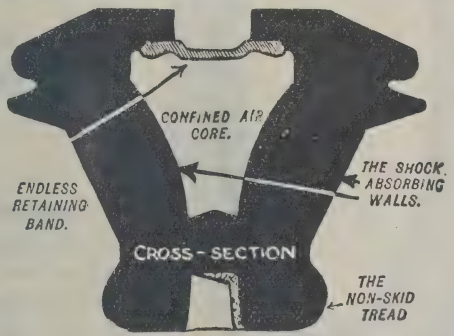
the petrol rises nearly to the top when there is no suction. During the suction stroke of the engine air enters through the funnel-shaped intake OO and gauze screen at K and passes into the 'choke tube' L surrounding the spray nozzle; in the choke tube its velocity is much increased, due to the contraction of area, and the pressure consequently falls below that of the atmosphere. The petrol accordingly issues from the nozzle in a fine stream, and mingling with the inrushing air is broken up into a cloud of spray; this 'atomisation' and the subsequent vaporisation are assisted by the mixture impinging on the serrated cone M depending from the cover of the chamber. The mixture thence passes to the engine by way of the inlet branch N.

P is a gauze strainer to intercept any solid particles in the petrol which might cause the needle valve D to leak, or obstruct the spraying nozzle J. The supply of air through the intake OO can be regulated by means of a perforated movable diaphragm as shown in the illustration. It will be observed that the buoyancy of the float is utilised to forcibly close the needle valve, and that when the float sinks the weighted outer ends at the small belt-cranked levers E permit it to rise. Fig. 56 shows an early and simple, though quite effective, form of carburettor; a multitude of variations of detail and minor refinements appear in the many designs which have been produced in recent years.



Paraffin Carburettors.

Paraffin carburettors which have been used on marine motors for a number of years past are now being adopted to a certain extent on motor cars and particularly on commercial motor vehicles. Although there are many types that have been employed the general principle is practically the same in every case, namely heating the mixture on its passage to the cylinder by means of the exhaust gases. The arrangement adopted is to pass the mixture through a vaporiser, around which the exhaust gases have to flow on their way to the silencer. In any case, however, the motor must always be started on petrol. Up to the present time paraffin carburettors have not been entirely successful for automobiles.

MACINTOSH N·A·P UNPUNCTURABLE TYRES

The Ideal Tyre for Industrial Motors.

Guaranteed in the United Kingdom for 10,000 miles or 12 months

Section of an N·A·P Tyre.

MACINTOSH N·A·P TYRES

Require no pump and cannot puncture or burst.
Require no study of air pressures, they are automatic.
Require no repair outfit.
Have no internal casing.
Do not require a spare wheel.
Absorb and swallow up road inequalities.
Are perfect non-skids.
Require no vulcanizing plant.
Give the maximum resistance to the abrasive action of the road.
Have the most durable tread that it is possible to manufacture.

See Editorial Notice in this Work, page 1736.

CHAS. MACINTOSH & CO. Ltd.

Cambridge Street, MANCHESTER

(Established 1824).

Telephone:
7147 Central Manchester.

Telegrams and Cables:
'Macintosh, Manchester.'

[SEE ALSO OVERLEAF]

The Macintosh TITAN TYRE

As supplied to the British, South African and other Governments, and in demand all over the world.

Manufactured by

Chas. Macintosh & Co. Ltd.

Cambridge Street, Manchester.

Codes—Bentley's, A B C (5th and 6th Edn.), Marconi.
Telephone—**7147** Central, Manchester.
Telegraphic Address—'Macintosh, Manchester.'

NOTE.—Chas. Macintosh & Co. Ltd., who were established in 1824 and were the original patentees of the Vulcanizing Process, make all sizes and classes of tyres—cord and fabric; straight side and beaded edge. *They strongly recommend their* 32 × 4½ *straight-side cord tyres for Ford* 1-*Ton Trucks.*

F. 1733

MOTOR CARS.

Many designs of motor cars are now on the market, but the general features have now become somewhat standardised in the most important makes. An example of good design of a 10 h.p. motor car is the Wolseley, illustrated in fig. 57, and the leading particulars of this and the other cars made by Wolseley Motors are given in the following table.

Maker's H.P.	R.A.C. Rating.	Weight of Chassis Empty.	Engine.				Wheel Base.	Track.	Body Space.	
			Bore.	Stroke.	No. of Cyls.	Normal Revs.			Dash to End of Frame.	Width of Frame.
10	10·5	9	in. $2\frac{9}{16}$ mm. 65	in. $3\frac{3}{4}$ mm. 95	4	1,700	ft. in. 8 3	ft. in. 3 10	ft. in. 5 5	in. 27
15	15·6	16	in. $3\frac{1}{4}$ mm. 80	in. $5\frac{1}{8}$ mm. 130	4	1,700	ft. in. 9 10	ft. in. 4 4	ft. in. 7 9	in. 34
20	23·5	—	in. $3\frac{1}{4}$ mm. 80	in. $5\frac{1}{8}$ mm. 130	6	1,400	ft. in. 11 5	ft. in. 4 6	ft. in. 8 8	in. 32

No. of Gears.	Drive.	Standard Axle Ratio.	Approximate Road Speed (M.P.H.) at Normal Engine Revs.					Approx. Road Wheel Dia.	Tyres, All Wheels.	Turning Circle.
			1st.	2nd.	3rd.	4th.	Reverse.			
3	Worm	$\frac{7}{38}$	$8\frac{1}{2}$	17	26	—	11	in. 28	710×90	ft. 34
3	Worm	$\frac{7}{38}$	10	20	34	—	$12\frac{1}{2}$	in. 32	815×105	ft. 36
4	Worm	$\frac{9}{37}$	8	$16\frac{1}{2}$	24	$32\frac{1}{2}$	8	in. 32	820×135	—

Cooling of the engine cylinders is by thermo-syphon and is assisted by a three-blade fan running on ball bearings mounted on a bracket carried up from the timing gear case. An eccentric adjustment is provided for the tension of the flat fan belt. On the other side of the engine is mounted a 'Blic' electric motor for starting the engine. The flywheel is cast iron and has bolted to it a mild steel gear ring in which the pinion on the motor engages when starting the engine.

The clutch is of the multi-disc type, completely enclosed, and running in oil. The back axle, which also carries a three-speed gear box, is driven through a universally-jointed shaft with a fabric type joint at the leading end and slipper box type at the back end. The final drive is by a worm wheel which surrounds the straight tooth differential.

The pedal and hand brake operate upon a single drum bolted to the hub, and are of the internal expanding cam-operated type. The design is quite novel. The two fulcrum pins are set at 90 degrees, and the webs of the shoes are made to pass one another. The braking surface of each of the four shoes covers about 80 degrees of the circumference and extends across the full width of the drum, so that each brake has the benefit of the full wearing surface on the drum. The torque member is a steel casting bolted to the front of the gearbox, and has a spherical end which fits into a link machined to fit the sphere which hangs from a tubular cross-member upon which it is free to swing. The car is propelled through the springs.

The gear change is of the quadrant type, the selector rods being hinged in line with the centre of the sphere on the torque member. The gears slide upon a castellated shaft which is

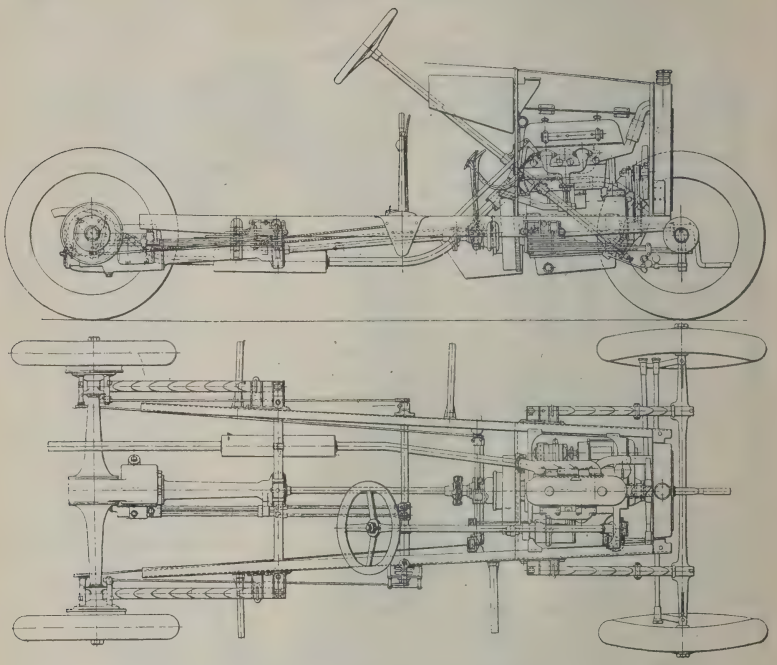


FIG. 57.—The Wolseley 10 h.p. Motor Car.

integral with the driving worm. All shafts and road wheels run on Timken roller bearings of ample dimensions. The springs are of the cantilever type directly bolted to the axles, and the pressed channel steel frame.

The panels and other sheet metal portions are pressed to shape, and there are various types of bodywork, as follows: For the 10-h.p. chassis, two-seater, three-seater and two-seater *coupé* bodies; for the 15-h.p. chassis, touring and saloon bodies; and for the 20-h.p. chassis, touring, landaulette, limousine, and four-seater *coupé* with folding head bodies.

MOTOR OMNIBUSES.

The greatly improved construction, reliability, low running cost, ability to instantly change route, and to at once expand the service when necessary, have all contributed to render the present-day 34-seated petrol motor omnibus a most formidable competitor of the 78-seated electric tramcar with its high initial and maintenance charges and fixed route. There is moreover very much less obstruction to other traffic with the newer independent carrying unit.

At the end of 1912 about 300 miles of streets were daily traversed by about 2,600 motor omnibuses in Greater London alone; of these about 2,450 were petrol driven, the remaining 150 (roundly) being operated by steam.

Along the main highways of Central London three motor omnibuses per minute, in each direction, is now usual; thus 6,120 passengers can be conveyed per hour past a given point in each direction with this normal frequency of service without interference with the other heavy traffic existing.

Where regular motor-bus services are run over ordinary roads of water-bound macadam, rapid deterioration of the surface occurs due to the formation of very numerous and large 'pot-holes'; such road surfaces are unsuited to this new fast and heavy traffic, and will be gradually replaced by stronger tar-treated crusts.

In the London district the average daily mileage per motor bus is from 100 to 120; the total running cost per mile from 7½*d.* to 8*d.*, and the average revenue from 10½*d.* to 11*d.* per mile.

In country services the daily mileage is often not more than 75 per bus, due to inferior and hilly roads, while the total running cost per mile is often from 9*d.* to 1*s.*

The following table (from E. Shrapnell Smith) shows the inclusive running cost per mile of London motor omnibuses during 1909, and also during 1912; it will be observed that a reduction of no less than 2·23*d.* per bus mile has been effected at the later date :—

TOTAL RUNNING COSTS PER MILE OF LONDON MOTOR OMNIBUSES.
(*From E. Shrapnell Smith.*)

Item.	Average of 1907-type Motor Buses Running during 1909.	Average of Petrol and Petrol-electric Motor Buses during 1912.
	Pence per Mile.	Pence per Mile.
Traffic expenses	2·65	2·43
Running and maintenance	3·28	2·44
Tyres	1·33	1·02
General expenses	0·79	0·62
Depreciation	1·00	0·50
Interest on capital	0·50	0·31
Totals	9·55	7·32

It is estimated that in the United Kingdom at the end of 1912 there were, roundly, 4,500 motor omnibuses, practically all being operated by petrol.

The various types of double-deck omnibus now used weigh from 3 to 4½ tons, when fully equipped for the road, and the weight of a full load of passengers (sixteen inside and eighteen outside), together with the driver and conductor, averages 2·5 tons, making the total weight of a fully loaded omnibus 5½ to 7 tons.

The load on the driving wheels with the omnibus fully loaded averages about 0·6 of the total weight; thus the maximum load on the driving wheels is about 3¾ tons, or 1·9 ton per wheel.

The average weight of an omnibus body is between 28 and 29 cwts.

COST OF WORKING MOTOR-BUSES.

The 1916 report of the working of the Manchester Corporation Tramways shows that the Corporation motor omnibuses ran 180,956 miles, and carried 1,416,760 passengers; the cost per mile run, including depreciation, was 9½*d.*, and the earnings nearly 9¾*d.*

The weights of some petrol omnibuses are tabulated below :—

	Weight of Chassis.			Complete Omnibus.		
	Tons	Cwts.	Qrs.	Tons	Cwts.	Qrs.
24 H.P. De Dion	2	2	2	3	11	2
30 H.P. Dennis	2	12	0	4	1	0
28 H P. Milnes Daimler	2	14	0	4	3	0
24 H.P. Scott Stirling	3	0	0	4	9	0
30 H.P. Straker Squire	2	14	2	4	3	2
30 H.P. Wolseley	2	13	0	3	18	0

The leading dimensions of the average omnibus are as follows :

Extreme length varies from 18 ft. 6 ins. to 22 ft. 6 ins. Extreme width varies from 6 ft. 3 ins. to 7 ft. 2 ins. (7 ft. 2 ins. being the maximum width allowed). Extreme height to hand rail of top deck, 11 ft. 6 ins. to 11 ft. 9 ins. The average wheel base is 12 ft. The average width of track is 6 ft. 2 ins.

Due to increased experience and consequent improvement in manufacture, the tyre-mileages attained by the London motor omnibuses are now very much larger than at first; makers of solid rubber tyres are usually willing to give a guarantee of 10,000 to 12,000 miles, but, as the short table hereunder shows, in favourable circumstances these distances are greatly exceeded :—

SOME EXCEPTIONAL TYRE-MILEAGES IN LONDON MOTOR-BUS SERVICES.

Name of Tyre.	Mileage Attained.	Notes.
Macintosh	79,885	Tyre removed from motor omnibus 30th June 1921
Dunlop	27,605	Used on a 'Metropolitan' steam bus
Dunlop	32,663	" " "
Continental	18,346	Average of 543 motor omnibus tyres
Hercules	27,000	Used on a 'motor omnibus'

It may be taken that an average all round of 20,000 miles may be assumed as the mileage life of the solid rubber tyres of motor omnibuses in London service.

Pneumatic Tyres.

Pneumatic tyres are, in general, manufactured in the following varieties :—Plain, Grooved or Ribbed, Rubber Studded, Steel Studded. The following table gives the most usual sizes together with the recommended air pressure to be used :—

USUAL SIZES AND PRESSURES FOR PNEUMATIC TYRES.

Wheel Diameter.		Tyre Diameter.		Maximum Load per Tyre, in Lbs.	Air Pressure, Lbs. per Sq. In.		Notes.
In mm.	In inches.	In mm.	In inches.		In Front Tyres.	In Back Tyres.	
650	25·6	65	2·56	450	60	70	Used on miniature cars.
750	29·5	65	2·56	450	60	70	
700	27·6	85	3·35	600	70	80	Used on normal motor cars
750	29·5	85	3·35	600	70	80	
760	29·9	90	3·54	900	70	80	
765	30·1	105	3·93	1,050	75	85	
800	31·5	85	3·35	600	70	80	
810	31·9	90	3·54	900	70	80	
810	31·9	100	3·94	1,000	75	85	
815	32·1	105	4·13	1,050	75	85	
820	32·3	120	4·73	1,300	80	85	
875	34·4	105	4·13	1,050	75	85	
880	34·6	120	4·73	1,300	80	85	
895	35·2	135	5·32	1,400	80	85	
915	36·0	105	4·13	1,050	75	85	
920	36·2	120	4·73	1,300	80	85	
935	36·8	135	5·32	1,400	80	85	
1,020	40·2	120	4·73	1,300	80	85	
—	30·0	—	3·0	—	65	75	Used on American motor cars.
—	30·0	—	3·5	—	70	80	
—	32·0	—	3·5	—	70	80	

The air pressures given in the foregoing table are for the maxima loads per tyre ; for lighter roads the chart, fig. 59, may be used.

THE MACINTOSH N.A.P. UNPUNCTURABLE TYRE.

(Chas. Macintosh & Co., Ltd., Manchester.)

This tyre, fig. 58, is so constructed that it possesses a large hermetically sealed core containing uncompressed air. It has a broad and flat base similar to that of the ordinary solid tyre, thick, strong, and abnormally flexible walls, and a narrow tread having a central row of triangular cavities about half an inch deep, which give definite non-skidding and side-slipping properties on slippery surfaces. This form of construction is such that it is claimed to need no

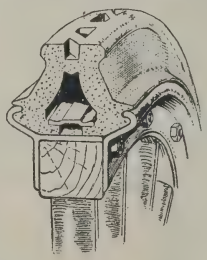

FIG. 58.

attention whatever during the whole life of the tyre, which is guaranteed to be a minimum of 10,000 miles or twelve months, whichever expires the sooner. Another important feature is that the walls are entirely of rubber and contain no fabric, with the result that exceptionally cool running is obtained. The Lancashire United Tramways, Ltd., are using it for all their medium-weight vehicles. This tyre seems to combine in a remarkably efficient manner the advantages both of the pneumatic and the solid variety.

CHART OF PRESSURES FOR PNEUMATIC TYRES.

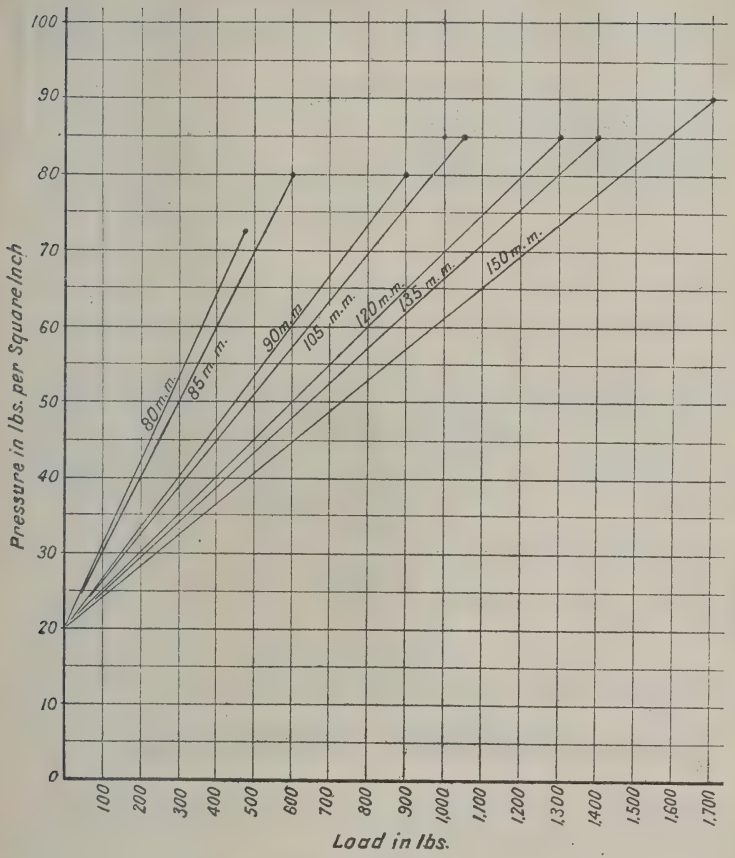

FIG. 59.

MISCELLANEOUS DATA.

Valve Springs.

The high revolution speed of the petrol engine necessitates the employment of stiff helical springs to ensure sufficiently quick closing of the valves notwithstanding the small mass of these. Let,

m = the mass of valve, tappet rod, roller, etc., all complete, in lbs.;
μ = the mass of the spring itself, in lbs.;
λ = the lift of the valve, in inches;
n = the number of revs. per minute of engine;
f = the *average* necessary compressive force in the spring, in lbs.
Then f may be found from the equation :—

$$f = 11{\cdot}5\ (2m + \mu)\ n^2\lambda \times 10^{-6} \quad . \quad . \qquad 3\ T\ 2$$

Helical Springs.

Helical springs, often, though incorrectly, referred to as 'spiral' springs, made of steel wire of round or square section, are most commonly used for the valves of internal combustion engines. Let,

D = the mean diameter of the coils, in inches;
δ = the diameter or side of square of wire, in inches;
F = the load on the spring, in lbs;
K = the compression of spring, in inches, under F.;
N = the number of complete working coils;
c = 8,000 for round steel; = 11,000 for square steel;
a = $1{\cdot}44 \times 10^6$ for round steel; = $1{\cdot}96 \times 10^6$ for square steel;

then,

$$\delta = \sqrt[3]{\frac{FD}{c}} \text{ ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (43)$$

and,

$$K = \frac{FND^3}{a\delta^4} \text{ ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (44)$$

For example, if $m = 1$ lb., $\lambda = \frac{7}{16}$ in., $n = 2{,}000$, and $\mu = \frac{1}{2}$ lb., we have from Eq. (42):—

$f = 50{\cdot}3$ lbs., average compressing force.

In petrol engines, the 'accumulation' of the valve springs, or ratio of the compressing forces with valve fully lifted and seated respectively, may be taken roundly at the value 3·0.

Hence, the maximum compressing force is about $1{\cdot}5f$ and the minimum $0{\cdot}5f$; thus in the example here taken, the maximum compressing force = 75·5 lbs.

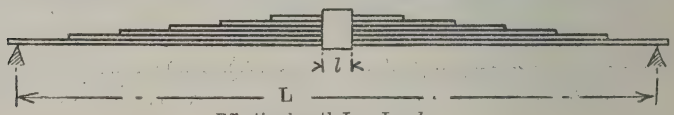
The total compression of the spring due to the maximum load of $1{\cdot}5f$ is easily found to be $1{\cdot}5\lambda$, or 0·65625 inch.

We may now find a suitable spring, knowing that F = 75·5 and K = 0·65625. The design of the engine leaves room for a value of D = 1·5, say; then, using round wire, we have from Eq. (43):—

$$\delta = 0{\cdot}242 \text{ in.}$$

the diameter of the spring wire.

While from Eq. (44) we next obtain:—



$$N = 12{\cdot}72$$

as the necessary number of working coils.

(See also page 931.)

Laminated Springs.

Let the spring contain n leaves each of breadth b inches and thickness t inches. Let L_1 be the effective length of the spring in inches as indicated in fig. 60.

Effective length $L_1 = L - l$

FIG. 60.

Let W be the load at the centre, in tons; and let K be the deflection of the centre due to the load W tons. Then for ordinary laminated steel springs:—

$$W = \frac{24\,nbt^2}{L_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (45)$$

and,

$$K = \frac{WL_1^3}{36{,}000\,nbt^3} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (46)$$

Joint Packings.

A preparation which has been recommended for use in packing the cylinder joints of internal combustion engines is made by mixing graphite and kerosene into a thick paste, which is applied to both sides of sheet asbestos. This may also be used in packing the joints of induction or exhaust pipes.

When the joint packing is exposed to water and high temperatures a better packing is made by soaking sheet asbestos in boiled linseed oil for six to twelve hours; the packing should then be allowed to dry for about twenty-four hours. The surface of the packing should be wiped or dusted with graphite before using.

Notes on Traction.

The force necessary to maintain the motion of a wheeled vehicle is dependent upon the nature and condition of the road surface, the diameter of the wheel, the width and material of the tyre, and the type of axle bearings.

On hard roads whose surface is not sensibly impressed narrow tyres may be used with advantage; directly a 'rut' is made, however, the tractive resistance greatly increases and wider tyres become desirable. The table hereunder gives some tractive force results obtained by various experimenters, with iron tyres and plain bearings:—

SOME EXPERIMENTAL RESULTS ON RESISTANCE TO TRACTION.

Resistance to Motion on Road.

The resistance to motion of any automobile may be found by permitting it to run freely down a measured length S feet of a known slope, and observing the velocity v feet per second acquired from rest. If h denote the vertical distance through which the vehicle descends, and R the resistance to motion on the level, estimated in lbs. per ton, then,

$$R = \frac{2240}{S}\left(h - \frac{v^2}{2g}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (47)$$

Horse-Power necessary to Propel Automobiles.

Let,
R = resistance on level, in lbs. per ton;
W = gross weight of automobile in tons;
V = velocity in miles per hour;
V_1 = velocity in miles per hour, relatively to the wind;
A = area in sq. ft. normal to action of wind;
P = actual horse-power necessary at road wheels;
e = efficiency of transmission from clutch to road wheels;
B.H.P. = Brake horse-power of engine;
Slope of gradient = 1 in m;

then,

$$P = \frac{WV}{375}\left(R + \frac{2240}{m}\right) + \frac{8{\cdot}5}{10^6} A V_1^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad (48)$$

and,

$$B.H.P. = \frac{P}{\epsilon} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (49)$$

R may be determined as in Eq. (47), or by direct pull. It is, however, generally sufficient for English service to take R as 70 lbs. per ton (see table, p. 1739). The second term in Eq. (48) represents the wind resistance horse-power; this is, in general, negligible at speeds below 20 miles per hour.

As a typical case, let it be required to estimate the b.h.p. of engine necessary to propel a car having a gross weight of 1 ton at 20 miles per hour up a 1 : 15 gradient on top gear. The car opposing an area of 30 square feet to a wind blowing in the opposite direction at 10 miles per hour. As in direct-driving top gear there is only one gear transmission from clutch to road wheels, we may take $\epsilon = 0{\cdot}85$.

We have therefore for this typical case :—

$$R = 70,\ W = 1,\ V = 20,\ V_1 = 20 + 10 = 30,\ A = 30,\ \epsilon = 0{\cdot}85, \text{ and } m = 15.$$

Hence from Eq. (48) :—

$$P = 11{\cdot}7 + 6{\cdot}9 = 18{\cdot}6.$$

And from Eq. (49) :—

$$B.H.P. = \frac{18{\cdot}6}{0{\cdot}85} = 21{\cdot}9.$$

Gear Ratios of Motor Cars.

Let n = number of revs. per minute of engine;
N = " " " of driving wheels;
D = diameter of driving wheels in feet;
V = desired speed of car in miles per hour;
G = total gear ratio from engine to driving wheels;

then,

$$G = \frac{n}{N}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (50)$$

and,

$$N = \frac{28\ V}{D}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (51)$$

so that,

$$G = \frac{n\ D}{28\ V} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (52)$$

For example, in the typical case above, if the driving wheels are 760 mm. in diameter we have $D = 2{\cdot}5$. Assume the normal engine speed to be 1,000 r.p.m., and the desired speed of the car 20 miles per hour. Then $n = 1{,}000$, and $V = 20$.

Thus from Eq. (51) :—

$$N = 224 \text{ revs. per minute.}$$

While Eq. (52) gives :—

$$G = 4{\cdot}46.$$

A very complete and valuable table giving the gear ratios of all the principal motor cars of the year 1913 appeared in 'The Autocar' of September 20, 1913. Not only are the gear ratios given, but also the number of cylinders, their bore and stroke, the cubic capacity, and the diameter of the driving wheels. It may be referred to with advantage in this connection.

SECTION XXX

PART VI

AEROPLANES — GENERAL DATA — THE ATMOSPHERE — WINGS OF MONOPLANES—AIR SCREWS—AEROPLANE PERFORMANCE — NOTABLE FLIGHTS — AIRSHIPS FOR COMMERCE—STANDARD DATA FOR AIRSHIP CALCULATIONS—OXYGEN APPARATUS—PARACHUTES.

(Revised and amplified by Major D. H. Kennedy, O.B.E., F.R.Aë.S.)

GENERAL DATA.

The Atmosphere.

That the temperature of the atmosphere diminishes as one ascends is obvious from the fact that the summits of high mountains are constantly snow-covered.

The rate of diminution is, naturally, somewhat variable, but for London averages about 3·5°F. per 1,000 feet of height. The mean annual temperature of London is roundly 50°F. Hence, as the average condition a temperature of 50°F. may be taken at the surface of the earth, and a fall of temperature of 3·5°F. per 1,000 feet of height.

At h feet, therefore, the average temperature is assumed as :—

$$t = 50 - 3{\cdot}5 \times \frac{h}{1000} \text{ °F.}$$

Or, using absolute temperatures :—

$$T = 510 - {\cdot}0035\ h \text{ °F. abs.}$$

Hence the characteristic Equation (1) becomes in this case :—

$$p\ v = c\ (510 - {\cdot}0035\ h) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (53)$$

If at height h feet the pressure be p, then at height $(h+dh)$ feet the pressure must be $(p+dp)$, dp including its sign ; the (negative) increment dp is due to the weight of a layer of air 1 square foot in horizontal section and dh feet high, and is therefore numerically equal to $\frac{dh}{v}$; hence :—

$$dp = -\frac{dh}{v},$$

From Eq. (53) this becomes :—

$$c\frac{dp}{p} = -\frac{dh}{510 - {\cdot}0035h}$$

hence,

$$c\int_{p_o}^{p}\frac{dp}{p} = -\int_{o}^{h}\frac{dh}{510 - {\cdot}0035h}$$

where p_o is the pressure at the earth's surface ; performing the integration, reducing, and taking $p_o = 14{\cdot}7$, we have for determining p, the pressure in lbs. per square inch at height h feet :—

$$\text{Log. } p = \overline{1}4{\cdot}654741 + 5{\cdot}36.\ \text{Log. } (510 - {\cdot}0035h) \quad . \quad . \quad . \quad . \quad . \quad (54)^*$$

From this equation the table on page 1742 has been prepared ; in addition, the table gives the absolute and ordinary average temperatures in °F. for heights up to 30,000 feet ; the pressures in lbs. per square inch and in inches of mercury ; the ratio of the pressure at height h to the pressure at the earth's surface, and the volume of 1 lb. of air, in cubic feet, at the several heights. It will be found useful in calculations relating to aeronautics.

25,000	422·5	−37·5	5·36	10·94	0·365	29·17
30,000	405	−55	4·27	8·72	0·291	35·08

The weight of 1 cubic foot of air in lbs. is of course the reciprocal of the figure in column 6, at any given height.

The effect of the fall in temperature with height is to cause the pressure to be slightly *less* than if the temperature were uniform throughout; thus at 9,000 feet, with uniform temperature of 50°F. throughout, the pressure is 21·54 inches of mercury, while with diminishing temperature (*vide* table) it is 21·32 inches. Actually the atmosphere is very rarely quiescent, and in the uniform condition here assumed; the results obtained are, however, useful for calculation. In particular, for a few hundreds of feet above the surface of the earth the air is usually in a condition of more or less complex turbulence with eddies, ascending heated currents, etc., due to the nature and configuration of the country beneath.

This table should be regarded as approximate only until further actual observations as to the temperatures and pressures at altitudes are available. The observed temperature on January 2, 1919, at an altitude of 30,500 ft., was −38°F.

Flight of Heavier-than-Air Machines.

The following elementary treatment of the subject furnishes results of some practical interest and exhibits clearly the *rationale* of mechanical flight:—

Wind Pressure on a Normally Moving Smooth Plane.

Let A = the area of the plane in square feet.
v = the velocity of the plane, relatively to the air, in feet per second.
G = the weight of the air, in lbs. per cubic foot.
g = 32·2.
P = the resulting pressure on the plane, in lbs.

Then in one second a mass (GAv) lbs. of air impinges on the plane and its momentum is

destroyed; the momentum is $(GAv)\times v$, and the momentum destroyed per second measures the force, in absolute units (i.e. poundals); hence we have :—

$$P = \frac{1}{g}(GAv)\,v \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (55)$$

Actually, however, owing to the air streams formed, and the action at the back of the moving plane, the case is not quite so simple, and it is found necessary to unite :—

$$P = f\,GA\,\frac{v^2}{g} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (56)$$

where f is a coefficient whose value is determined by experiment.

Very numerous experiments have at various times been made to determine f, with somewhat widely differing results according as the size, shape, and material of the plane have been varied. Recent experimental results of M. Eiffel and Dr. T. E. Stanton suggest that f may be taken, for large surfaces, at the value $\frac{5}{8}$ roundly, so that Eq. (56) becomes, putting 32·2 for g :—

$$P = \cdot 0194\times GA\,v^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (57)$$

Power Required to Drive the Plane.

If E be the horse-power necessary to drive the plane at v feet per second in opposition to a resistance of P lbs., we have :—

$$E = \frac{1}{550}Pv \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (58)$$

By aid of Eq. (57) this becomes :—

$$E = \frac{35\cdot 3}{10^6}GAv^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (59)$$

Thus the horse-power necessary varies :—

Directly as the heaviness of the air.
Directly as the area of the plane.
Directly as the cube of the relative speed of plane and air.

Case of a Smooth Plane inclined to the Direction of Motion.

Let the smooth plane be inclined at an angle $\phi°$ to the direction of its motion (assumed as horizontal).

As the plane is smooth, the resultant pressure R upon it must be normal to its surface. R may be resolved into a horizontal component H, which directly resists the progress of the plane, and a vertical component L which measures the upward thrust of the air, or 'lift of the plane.'

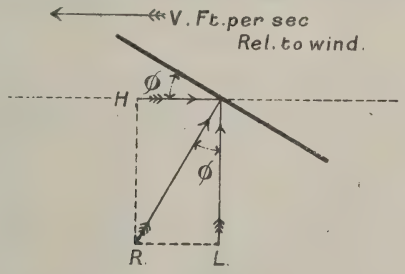

FIG. 61

From fig. 61 it is evident that :—

$$H = R\sin\phi \quad . \quad . \quad . \quad . \quad (60) \qquad L = R\cos\phi \quad . \quad . \quad . \quad . \quad . \quad (61)$$

Experiments on the normal pressure of air on inclined planes show that the complete relation connecting P, H, L, and ϕ is exceedingly complex. M. Eiffel finds that the value of $\frac{R}{P}$ is independent of v; that it increases with the area of the plane; and that for rectangular plates with the shorter dimension inclined, and for values of ϕ, in degrees, not exceeding 12 :—

$$\frac{R}{P} = \frac{3{\cdot}2 + 0{\cdot}5\ n}{100}\ \phi \text{ (app.)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (62)$$

where n is the proportion of span to chord of the plane, or its 'aspect ratio.'

In general the value of n is about 6; taking this value in Eq. (62) we get as an average case,

$$R = 0{\cdot}062\ \phi \text{ P. lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (63)$$

Hence from Eqs. (57), (60) and (61) :—

$$H = {\cdot}0012\ \phi \sin \phi\ GAv^2 = a\ GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad (64)$$

$$L = {\cdot}0012\ \phi \cos \phi\ GAv^2 = b\ GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad (65)$$

and as $E = \frac{1}{550} Hv$, we have,

$$E = \frac{2{\cdot}187}{10^6}\ \phi \sin \phi\ GAv^3 = c\ GAv^3 \quad . \quad . \quad . \quad . \quad (66)$$

whence, dividing Eq. (66) by Eq. (65) there results :—

$$E = \frac{1822{\cdot}5}{10^6} \tan \phi \times v\ L = k_0\ v\ L \quad . \quad . \quad . \quad . \quad . \quad (67)$$

which connects power, inclination, velocity, and lift.

In order to achieve horizontal flight the velocity of the plane relatively to the air, v, must be just so great as to make the lift, L, equal to the weight of the plane, W.

Substitute, then, in Eq. (65), W for L, and we obtain on transposition :—

$$v_{min} = \frac{1}{\sqrt{b}} \sqrt{\frac{W}{GA}} = k_1 \sqrt{\frac{W}{GA}} \text{ feet per sec.} \quad . \quad (68)$$

Thus the speed necessary for horizontal flight varies :—

Directly as the square root of the weight of the plane.
Directly as the square root of the volume of 1 lb. of the air in cu. ft. (Table, p. 1692, col. 6).
Inversely as the square root of the area of the plane.

The horse-power necessary to just maintain horizontal flight is from Eqs. (67) and (68), putting W for L :—

$$E_{min} = k_0\ k_1 \sqrt{\frac{W^3}{GA}} = k_2 \sqrt{\frac{W^3}{GA}} \quad . \quad . \quad . \quad . \quad . \quad (69)$$

Values of a, b, c, k_0, k_1 and k_2 from $\phi = 0°$ to $\phi = 12°$ are given in the following table.

ϕ in Degrees.	a. $\times 10^6$.	b.	c. $\times 10^6$.	k_0. $\times 10^6$.	k_1.	k_2. $\times 10^6$.
0	0	0	0	0	∞	0
1	21	·0012	·038	31·8	28·9	920
2	84	·0024	·1523	63·6	20·4	1,299
3	188	·0036	·3426	95·5	16·7	1,593
4	335	·0048	·6088	127·4	14·5	1,841
5	523	·0060	·9508	159·4	13·1	2,088
6	753	·0072	1·3684	191·6	11·8	2,265
7	1,024	·0083	1·8613	223·8	10·9	2,451
8	1,336	·0095	2·4291	256·1	10·3	2,627
9	1,689	·0107	3·0717	288·7	9·7	2,795
10	2,084	·0118	3·788	321·4	9·2	2,957
11	2,519	·0130	4·579	354·3	8·8	3,113
12	2,994	·0141	5·444	387·4	8·4	3,264

From Eq. (69) it is seen that the power necessary to maintain the plane in horizontal flight varies :—

Directly as the $\frac{3}{2}$ power of the weight.
Directly as the square root of the bulkiness of the air as given in table, page 1742, col. 6.
Inversely as the square root of the area.

As the bulkiness of the air increases with the altitude, it appears from Eq. (68) that both the velocity necessary for horizontal flight and also the horse-power must increase as the plane ascends.

If the horse-power developed, E, exceed E_{min} the difference is expended in causing the plane to ascend. In the absence of any vertical resistance, the rate of ascent will be :—

$$\text{Rate of ascent} = \frac{550}{W}(E - E_{min}) \text{ ft. per second} \quad . \quad . \quad . \quad . \quad (70)$$

When ϕ is small, sin ϕ and tan ϕ are each sensibly the same, and equal to $\frac{\phi}{57{\cdot}3}$, while cos ϕ is practically unity. Hence, as we are here considering values of ϕ not greater than 12°, we may with sufficient accuracy write :—

$$10^6 \times a = 21\ \phi^2. \qquad b = {\cdot}0012\ \phi.$$
$$10^6 \times c = {\cdot}038\ \phi^2. \qquad 10^6 \times k_0 = 31{\cdot}8\ \phi.$$

Accordingly Equations (64), (65), (66), and (67) respectively become :—

$$H = \frac{21}{10^6}\phi^2\, GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (71)$$

$$L = {\cdot}0012\ \phi\, GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (72)$$

$$E = \frac{{\cdot}038}{10^6}\phi^2\, GAv^3 \text{ horse-power} \quad . \quad . \quad . \quad . \quad . \quad . \quad (73)$$

and,

$$E = \frac{31{\cdot}8}{10^6}\phi\, v\, L \text{ horse-power} \quad . \quad . \quad . \quad . \quad . \quad . \quad (74)$$

From these equations it is seen that, within the range of inclination taken :—

The horizontal resistance, and the horse-power required, vary directly as the square of the angle of inclination of the plane, while the lift varies directly as the angle simply.

The velocity necessary for horizontal flight, v_{min}, diminishes as ϕ increases agreeably with the values of k_1 as given in table, page 1744 : but the necessary horse-power increases with increase of ϕ, as shown by the increasing values of k_2 (*vide* table p. 1744), in consequence of the rapid increase in H.

AEROPLANES.

Aeroplanes may be broadly classed as follows :—

Monoplanes, having a single main plane, developed from the early Antoinette and Blériot machines.

Biplanes, having two superposed main planes, developed from the Wright and Farman designs.

Triplanes, having three superposed main planes, first put into practical form by Mr. A. V. Roe.

There are no practical examples of more than three planes, but the development of large aeroplanes may necessitate some such arrangement.

In general, the biplane gives the best all-round results, being stronger than a monoplane of equal lift and speed, and offering less head resistance than a monoplane of equal strength.

The very small Blériot monoplane which, on July 25, 1909, crossed the Channel from Calais to Dover, covering 31 miles in 43 minutes, had a wing span of only 25 ft. 7 ins., a total length of 26 ft. 3 ins., and a gross weight including pilot and in flying order, of only 650 lbs.

The superficial area of the planes was about 150 square feet; sufficient petrol was carried for a two hours' flight, and the engine was a 3-cylinder air-cooled 20 h.p. 'Anzani,' driving a two-bladed propeller. The wing frames were of ash covered with water-proofed linen.

The engine was placed in front, below the planes, and the pilot sat above the engine. This machine was caused to ascend by depressing the after ends of the planes; horizontal steering was effected by a vertical rudder placed at the rear; the planes were normally inclined about 8° to the horizontal.

It will be seen that the upward pressure amounted to $\frac{650}{150}=4\frac{1}{3}$ lbs. per sq. foot of wing area in this case; from 3 to 6 lbs. per sq. foot is usual, though in races, with shortened planes, the figure is said to rise sometimes as high as 10 lbs. per sq. foot.

A distance of 31 miles in 43 minutes implies an average speed, relatively to the *earth*, of $63\frac{1}{3}$ feet per second. If the Anzani engine developed just 20 b.h.p., the effective horse-power with a propeller efficiency of 70 per cent. was 14.

It is of interest to apply the formulæ obtained to the foregoing case. Thus we have W=650, A=150; and as the flight was not at a great height, we may take $\frac{1}{G}=13$ (table, col. 6, p. 1742); also $\phi=8$. Hence, Eq. (68) gives:—

$$v_{min}=77 \text{ feet per sec.}$$

relatively to the *air*.

While, putting L=650, Eq. (74) gives:—

$$E_{min}=12\frac{3}{4} \text{ effective horse-power.}$$

Assuming the propeller efficiency as 70 per cent., the necessary brake horse-power of the engine must accordingly be, roundly, $18\frac{1}{2}$.

Remembering that the formulæ were deduced for the simple case of a smooth true plane these figures may be regarded as giving a helpful indication. Actually the wings are neither smooth (see table, p. 1748) nor are they true planes (see fig. 62, p. 1747); there is also the resistance offered by the air to the body, rudder, stays, etc., etc., of which no account has been taken in the above investigation.

The velocity of the wind is, in general, least near the earth's surface, and in flying round a closed circuit the effect of a wind from any quarter is, on the whole, to retard the aeroplane. Hence, in aerodrome speed trials (i.e. speed relatively to the *earth*) pilots usually fly very near the ground.

It appears from Eq. (69) that the horse-power necessary to maintain horizontal flight slowly increases with the altitude of the plane. Eqs. (68) and (69) show, in fact, that both the velocity and power for horizontal flight must increase in proportion to $\sqrt{\frac{1}{G}}$, that is, in proportion to the square root of the bulkiness of the air. For example, at an altitude of 20,000 feet we have from table, col. 6 (p. 1742), $\frac{1}{G}=24{\cdot}44$. Hence, in the case above taken, the necessary velocity at this height must be $77\times\sqrt{\frac{24{\cdot}44}{13}}=105{\cdot}5$ feet per second, while the effective horse-power must be $2\frac{3}{4}\times\sqrt{\frac{24{\cdot}44}{13}}=17{\cdot}5$. Thus both the velocity relatively to the air, and the power, must, in this case, be increased by 37 per cent. to sustain horizontal flight at an altitude of 20,000 feet, owing to the diminished density of the air.

For the first two or three thousand feet of ascent as $\frac{1}{G}$ alters but little (see table, p. 1742), there is, in the example taken, an excess of $17\frac{1}{2}-12\frac{3}{4}=4\frac{3}{4}$ horse-power available for causing ascent so that, neglecting all vertical resistances, the plane would rise during the first part of its flight at a maximum rate, agreeably with Eq. (70) of $\frac{4{\cdot}75\times550}{650}=4{\cdot}0$ feet per second, or 1,000 feet in 4·15 minutes.

This, again, is a result of the right order of magnitude; for example, the winning machine in the International Air Competition at Hendon on September 27, 1913, attained a height of 2,700 feet in 13·17 minutes, i.e., at the rate of 1,000 ft. in about 4·9 minutes.

The types of aeroplanes now in general use are :—

* Reconnaissance and Light Bombing. † Heavy Bombing.

Wings of Aeroplanes.

The main planes or wings of aeroplanes are commonly of rectangular form in plan, with a transverse length, or 'span,' about 6 times the fore-and-aft length, or 'chord' ; the ratio of transverse to fore-and-aft length is termed the 'aspect ratio' ; hence the 'aspect-ratio' has usually a value about 6.

The planes on either side of the fore-and-aft centre lines are set at an angle to the horizontal plane, known as the 'dihedral' or 'anhedral' angle, according to whether the planes are above or below the horizontal.

Experiments by Mr. Horatio Phillips in 1885 showed clearly that the best form of fore-and-aft

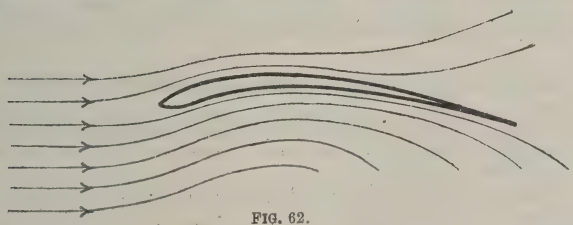

FIG. 62.

section for the wings is as indicated in fig. 62, the maximum height occurring at about one-third of the length measured from the front edge.

The approximate direction of the impinging air streams is as indicated ; the reduction of pressure on the *upper* surface actually contributes the larger portion of the lifting force.

The value of the 'aspect-ratio' is important ; if the wings be too long in a fore-and-aft direction diminished performance results ; at the Rheims aviation contest, by reducing the fore-and-aft length of the wings of his aeroplane by about one foot, M. Blériot, carrying the same weight as before, flew much faster with the same engine.

The ' Aerial Derby ' of 1913 was won by G. Hamel, who, by shortening his wings prior to the contest, averaged a speed of 76 miles per hour (relatively to the earth). It is obvious from Eq. (68) that a reduction in A causes an increase in v_{min}; the horse-power necessary must also be increased in the same proportion, however, as is shown from inspection of Eq. (69). The wing area is now frequently reduced for speed contests.

' Skin Friction ' of the Planes.

The experiments of Dr. Zahm of Washington led him to conclude that, in proportion to their densities, the frictional resistance of air is at least as great as that of water, and that this resistance is an important factor in the problem of high-speed flying. Some of Dr. Zahm's results are exhibited in table below. He states also that ' the frictional resistance of a plane or arched surface soaring at small angles on a horizontal course is equal to the *horizontal projection* of the surface multiplied by the average friction per square foot as given by table below.'

Experiments were made to determine the effect of the nature of the surface of the plane upon the frictional resistance; practically no difference was found with dry varnish, sticky varnish, wet surface, sheet zinc, glazed cambric, calendered or uncalendered paper, or drawing paper. With coarse buckram having sixteen meshes to the inch, the friction at 10 lbs. per second was, however, found to be from 10 to 15 per cent. greater than with the uncovered surface.

FRICTION OF AIR PER SQUARE FOOT OF PLANE FOR VARIOUS FORE-AND-AFT LENGTHS. (*Dr. Zahm.*)

Calculation of Frictional Resistance and Horse-Power.

In using the above table, it must be remembered that a material plane exposes *two* surfaces to the action of the air. For example, the frictional resistance of a material plane of 24 feet span, and with a fore-and-aft length (' chord ') of 4 feet, at a speed of 80 miles per hour relatively to the air is to be estimated as follows :—

From the table the friction per square foot for a fore-and-aft length of 4 feet at a relative speed of 80 m.p.h. is ·0474 lb.; and as there are $2 \times 24 \times 4 = 192$ square feet of total area exposed to the action of the air, the total frictional resistance of the material plane is $192 \times \cdot0474 = 9{\cdot}1$ lbs.

Eighty miles per hour $= 1{\cdot}47 \times 80 = 117{\cdot}6$ feet per second; hence the work necessary to overcome friction alone is $117{\cdot}6 \times 9{\cdot}1 = 1070{\cdot}2$ foot-lbs. per second; and thus $\frac{1070{\cdot}2}{550} = 1{\cdot}95$ horse-power must be expended to overcome this resistance. In the practical design of aeroplanes it is, of course, necessary to take account not only of the frictional resistance of the wings, but also that of the body, stays, and other parts of the machine exposed to the relative velocity of the air.

Control of Aeroplanes.

When in flight an aeroplane has freedom of motion in three dimensions about its own centre. Its motion in these dimensions is controlled by :—

The Rudder, a movable vertical surface, adjusted by the pilot's feet, controlling the direction of flight in a horizontal plane.

The Elevator, a movable horizontal surface adjusted by a lever in the pilot's hand, controlling the direction of flight in a vertical plane within the limits set by the lift of the main planes and the power developed by the engine.

The Ailerons, small movable planes attached to the outer ends of the main planes, arranged so as to increase or decrease the lift on either side of the aeroplane and adjusted by the same lever which controls the elevator. The ailerons enable the machine to be kept laterally horizontal, and to be tilted or 'banked' as required for any manœuvre in the air.

Stability.

Aeroplanes may be unstable, or inherently stable. The former require constant vigilance on the part of the pilot, or the incorporation of some mechanical device such as the Sperry Gyroscopic Stabiliser, which gives them 'automatic stability.' The latter possess a tendency to return to their normal flying position after any disturbance.

Inherent stability is obtained by correct proportioning of the main and auxiliary planes and their dihedral angles, and a proper balancing of the couples about the centre of the machine due to the lift and resistance of the planes, the mass of the machine, and the thrust of the propeller.

Unstable machines can be manœuvred more rapidly and accurately than can highly stable machines; they are therefore more suitable as fighting machines, whilst the latter have a wider application for commercial purposes.

Airscrews.

Airscrews for aircraft are now constructed entirely of wood; laminations of walnut and mahogany are glued and pegged together, and shaped to the correct pitch and blade section. Blades may be copper tipped, but more often are left bare. Two- and four-bladed airscrews are generally used.

The metal propellers fitted to some of the early Blériot monoplanes are now obsolete, but experiments continue to be made, and it is probable that a practicable form will be evolved, as in some cases metal is preferred to wood.

For the sake of efficiency, airscrews should be of large diameter, and should run at a low speed. In large engines, a reduction gear is usually incorporated so as to allow the engine to run at a higher speed than the propeller. With modern airscrews, an efficiency as high as 77 per cent. and over has been obtained.

Colonel Dorand has found that the diameter of the airscrew should be proportional to the weight supported per h.p. and to the square root of the total weight of the machine. Also, that the r.p.m. of the airscrew should be inversely proportional to the square of the weight supported per h.p. and to the square root of the total weight.

The loss in the efficiency of airscrews running at a high speed is serious, and has been found greater than any gearing loss; therefore, for engines running at high rotational speeds, it is necessary to fit reduction gearing to allow the airscrew to run at about 1,200 r.p.m. Tip speeds up to 800 ft. per second have been used, but it is better for the speed not greatly to exceed 600 ft.

An exhaustive treatise on aviation is that of Mons. G. Eiffel, entitled 'The Resistance of the Air and Aviation' (Eng. Trans. by J. C. Hunsaker, Constable & Co., 42*s.*); the subject is treated as completely as is at present possible, and the work may be studied with advantage by engineers interested in the design and construction of aircraft.

Resistance of Wood to Reversals of Stress.

The limiting resistance of spruce (used for aeroplane wing spars) to alternate tension and compression was proved by experiment to be above 1,600 lbs. per sq. inch, and below 1,970 lbs. per sq. inch. For spruce of this quality the safe range of stress under reversals of bending would be

approximately ± 1,800 lbs. per sq. inch, or one quarter of the ultimate stress, which was found to be 6,800 lbs. per sq. inch. In this respect spruce appears to be at a slight disadvantage compared with mild steel, in which the safe limit of stress under similar circumstances is generally about one-third of the ultimate stress. (*The National Physical Laboratory.*)

Resistance of Tension Members of a Structure to Lateral Vibrations.

In cases in which the tension members of a structure are attached to the pin joints of the frame by means of a screw connection unaccompanied by a universal joint, it has been found that the screws are liable to the development of fatigue cracks at the bottom of the threads, and to ultimate failure.

It has been found that if a universal joint be provided at both ends of a wire subjected to lateral vibrations, a load of one-third of the breaking load will in the case of high class material be borne for an unlimited number of vibrations, but that if only a single joint be used fracture takes place under one-sixth of the breaking load after a few hours. (*The National Physical Laboratory.*)

Rough Prediction of Aeroplane Performance.*

The curves (fig. 63) show how the speed of flight near the ground and at 10,000 ft. depends on the nominal power of the engine and the gross weight of the aeroplane. The ratio of horse-power to weight is used. Regarded as an empirical curve, however, it is found that the performances of the smallest and largest aeroplanes are equally well predicted. Like all generalisations it has its limitations, and a designer who has given special attention to one type will be able to give a closer prediction. On the other hand, any record of performance showing striking departure from the curve may be regarded with mistrust.

The curves illustrate the aerodynamic disadvantages of high speed. It is to be noted that a gross weight of 1,000 lbs. can be carried by an aeroplane of modern type for an expenditure of 25 h.p., but there is no reserve and the pilot could not climb or cope with down currents. His speed would be about 55 m.p.h. The necessary horse-power for the same load could be reduced by providing bigger wings and flying slower, and it has been pointed out by various writers that the most economical design aerodynamically requires speeds of flight below those of commercial utility.

Using the curves of fig. 63, it can be seen that the aerodynamic quality of the aeroplanes at the beginning of the war was not appreciably less than those of the present day, for all give performances indicated by the curve. Progress has followed the development of the aero-motor which now permits the use of one horse-power for each 8 lbs. of gross weight, whereas in 1914 the same power was yoked to a load of nearly 25 lbs. The most recent of our large aeroplanes carries nearly 20 lbs. per horse-power, and its performance on speed and ceiling is not greatly different from that of the 'Avro' or B.E.2C. It is now accepted as a fundamental truth that the weight-carrying aeroplane cannot be the fast aeroplane, and the rate at which the horse-power curve is rising shows that the conditions become progressively worse. It needs little imagination to see that increase of top speed beyond present limits will not easily be attained, and that no great increase such as that during the war period is within the limits of reasonable expectation. The table given below is instructive in the economics of aeroplane carriage.

Speed of flight, m.p.h.	Gross weight, lbs. per h.p.	Percentage of gross weight available for passengers and merchandise.
60	38	45
70	35	44
80	28	41
90	21	38
100	17	33
110	13	27
120	10	20
130	8	10

It will be seen that the choice lies between a time of six hours and a useful load of 40 per cent. of the total and a time of four hours and 20 per cent. of load useful. Only the particular need of the moment can determine a final choice. (*Leonard Bairstow, F.R.S.*)

* Extract from the Wilbur-Wright Lecture 1919, 'Progress in Aviation in the War Period,' delivered before the Royal Aeronautical Society by Leonard Bairstow, F.R.S., O.B.E.

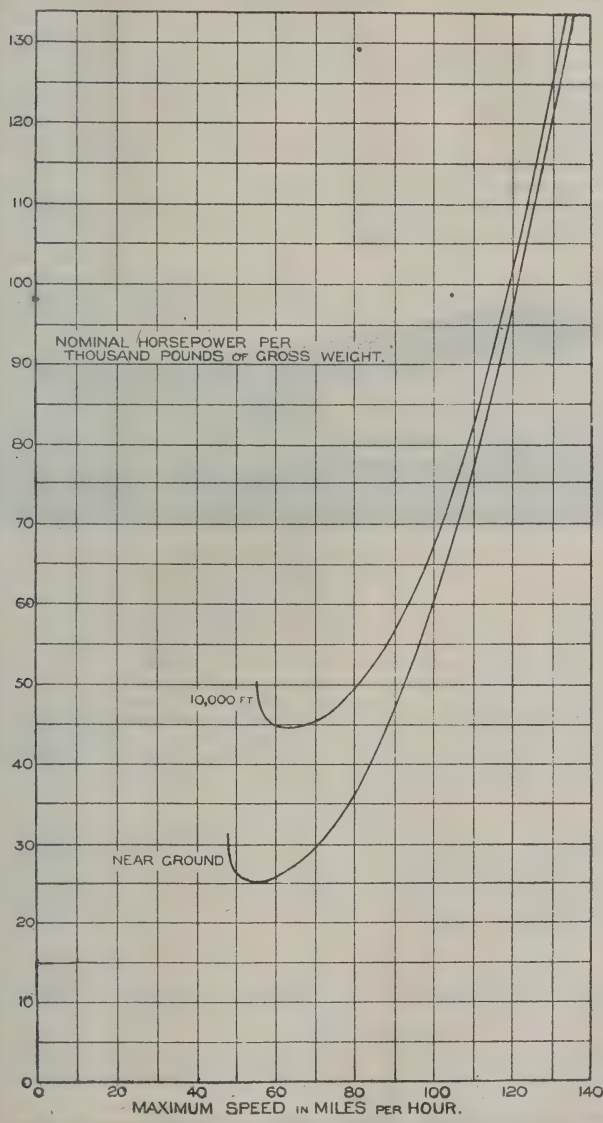

FIG. 63.—Curves showing how speed varies with ratio of H.P. to gross weight.

Notable Flights.

Atlantic Flights.

The first crossing was made by the seaplane N.C.4, piloted by Commander Read, which accomplished the journey from Newfoundland to Plymouth in three stages, as follows :—

Newfoundland to Azores	1,381 miles	15 hours	19 mins.
Azores to Lisbon	1,034 ,,	9 ,,	42 ,,
Lisbon to Plymouth	895 ,,	5 ,,	1 ,,

The gallant attempt made on May 18, 1919, by Mr. H. G. Hawker and Lieut. Commander Grieve in a single-engine Sopwith machine failed, the aviators being picked up 1,000 miles from land by the small ship *Mary*.

Three weeks later the direct crossing was successfully accomplished from St. John's to Galway Bay, Ireland, by a Vickers-Vimy double-engined (Rolls-Royce) aeroplane (fig. 64), piloted by Captain John Alcock, D.F.C., and navigated by Lieut. Arthur Whitten Brown. The 1900 nautical miles was compassed in 15 hours 57 minutes.

FIG. 64.—Atlantic Flight: Vickers-Vimy Rolls-Royce Aeroplane.
(Now in Victoria and Albert Museum.)

Length 47 ft.	Carried 867 galls. of petrol.
Span 70 ft.	(Used two-thirds of this.)
H.P. 700 (2 Eagle Rolls-Royce of 350 h.p.)	Cruising speed 80 m.p.h.
Total weight 16,000 lbs.	Maximum speed 105 m.p.h.
Time crossing Atlantic 15 hrs. 57 mins.	Climbs to 25,000 ft.

For this fine performance, the airmen were knighted by His Majesty the King.

In the following month, a British airship, R34, starting on July 2, 1919, from England, crossed the Atlantic to Newfoundland, and went on to New York, whence it returned direct to its starting point, arriving on July 13. This flight was remarkable for the fact that the airship was, during the whole of its six-thousand-mile trip, in wireless communication with the Air Ministry in London. Moreover, it was furnished with continuous information as to weather conditions ahead of it, and was able to modify its route in order to avoid storm-swept areas.

Anglo-Australian Flight.

The Australian Government prize of 10,000*l.* for a flight from England to Australia, in a heavier-than-air machine of British construction, was also won by a Vickers-Vimy aeroplane, piloted by Captain Ross Smith, accompanied by his brother, Lieut. K. M. Smith, and two sergeant mechanics. This wonderful journey, commenced on November 12, 1919, was completed in twenty-eight days, the total flying time being only 124 hours. This makes it evident that by organising relays of machines it would be possible to provide a mail service to Australia with a transit time of less than one week.

First Flight across Asia.

Lieuts. Ferrarin and Masiero started from Rome on February 14, 1920, and flew across Asia to Japan, arriving at Tokyo on May 31. Intermediate stops were made at the under-mentioned cities: Adalia, Bagdad, Bunder Abbas, Delhi, Calcutta, Rangoon, Bangkok, Canton, Tsingtao, Peking, Seoul, and Osaka.

London to Turin, Direct Flight.

On May 31, 1920, Mr. Bert Hinkler, an Australian pilot, left Croydon at 4.50 A.M., flying a Baby Avro with a 35 h.p. Green engine—which engine had been built in 1910.

Passing over Dover, Paris, Lyons, and clearing the Alps, he arrived, without an intermediate stop, at Turin at 2.20 P.M. on the same day.

Six hundred and fifty miles in 9½ hours on twenty gallons of petrol.

For fuel economy this flight brings the aeroplane into competition with the motor-car.

Aerial Derby.

The 1921 Aerial Derby was won by Mr. J. H. James on a Bamel aeroplane built by The Gloucester Aircraft Company with a 450 h.p. Napier 'Lion' engine. The speed of the winner for the two-circuit 200 miles route worked out at 163·34 m.p.h.

Mr. James also won the Handicap Race, being the last competitor to start and the first to finish.

British Speed Records.

At Martlesham Heath, July 17, 1920, Mr. R. L. Tait Cox in a Nieuport Goshawk (300 h.p. A.B.C. Dragonfly engine) attained a speed of 167·5 m.p.h.

In December 1921, at Martlesham Heath, Mr. J. H. James achieved a maximum speed of 212 m.p.h. over the measured kilometre, and averaged in four trials 196 m.p.h. This was accomplished on the same Bamel machine, with Napier 'Lion' engine, which had won the Aerial Derby, and when passed by the authorities, will constitute a world speed record.

Civil Aviation.

Half-yearly reports on the progress of civil aviation are issued by the Air Ministry in March and September.

The reports for 1921 deal with improvements and developments in ground organisation and night-flying arrangements, particularly on the Continental route.

The safety of the machines and passengers is being carefully safeguarded.

All British machines operating on cross-Channel routes are now fitted with wireless apparatus, and this will be made compulsory for all machines capable of carrying ten or more passengers.

Both Croydon and Pulham air stations have now been provided with wireless direction-finding stations which, working in conjunction, enable an aircraft to 'fix' its exact position by means of the junction of the bearings obtained simultaneously by the two stations.

In addition, experiments are being carried out with satisfactory results into the possibilities of using radio-telephony as a means of directing an aircraft into an aerodrome when it is invisible to the pilot owing to fog or mist.

Some success has also been obtained in using pyrotechnic signals for this purpose, and a system for colouring the beam of a high-power searchlight is being investigated.

Arrangements are now being completed by which the Croydon-Lympne air route could be opened at short notice for night flying; these include the provision of an automatic apparatus placed mid-way, to indicate by a system of coloured lights the strength and direction of the wind prevailing at any given moment.

It has been decided that, while a monopoly is undesirable, unrestricted competition would tend to prevent the development of air routes on a commercial basis.

Three companies, Handley Page Transport, Limited, Instone Air Line, Limited, and Daimler Hire, Limited, have been chosen to operate the London-Paris routes, with extensions, if desired, to Manchester and Basle or Zurich.

One company only, which the Aerial Route Syndicate, Limited, proposes to establish, has been selected to operate the London-Brussels route, on which considerably less air traffic is at present anticipated.

The Air Council reserves the right to approve at a later date other firms for the Paris-Brussels routes. The London-Amsterdam route, the prospects of which appear less promising, is, for the present, in abeyance.

During the six months ending September 30, 1921, the number of departures and arrivals of British aircraft to and from the Continent amounted to 671, and the passengers carried in British machines on the cross-Channel routes to 4,006.

The total machine mileage for British civil aviation was 321,500 miles, the number of passengers carried 31,853, and the weight of goods 9 tons. Imports by air amounted to £206,357 and exports to £110,400.

Notes on Airships for Commercial Purposes.

(Published by the Air Ministry.)

(*Abstract.*)

The airship is essentially a long-distance weight-carrying craft as compared with the short-distance high-speed aeroplane. An airship with a speed of 77·6 m.p.h. can be considered slow only relatively to the aeroplane, being fast in comparison with land and sea methods of transport.

An airship is not liable to forced descent in case of engine failure, as is the aeroplane. Quite large repairs to engines, such as the changing of a cylinder, are possible in an airship.

The airship can be used over land of a wooden or broken nature, such as to be unsuitable for the landing of aeroplanes, and on journeys involving non-stop flights of 1,000 miles and upwards. It can be used in flying at night or in fog or clouds, and the great lift permits of much more comfortable accommodation being provided than is possible in an aeroplane. In the case of a rigid airship, for example, a walk of 400 or 500 ft. may be taken along the keel.

Official statistics show that only one airship has been lost in this country owing to catching fire in the air, although 83,360 hours have been flown and over 2½ million miles covered during the war. In the case referred to the flight was an experimental one with a new type of ship, and the cause has since been ascertained and eliminated.

For commercial purposes large rigid airship stations should be established at distances of 2,000–3,000 miles apart, mainly for trans-oceanic traffic, while the aeroplane would be used for bringing passengers and merchandise to these from the neighbouring countries.

Although airships are generally considered to be fair-weather craft, up to the end of November there were only nine days in 1918 when no airship flight took place in the British Isles—which are notorious for possessing almost the worst weather conditions of any country in the world.

The latest German rigid airship has a disposable lift available for crew, fuel, merchandise, etc., of over 38 tons, which gives her a theoretical endurance (if all the available lift be employed in carrying petrol) of 177·5 hours (7 days) at a cruising speed of 45 m.p.h.—the maximum speed being 77·6 m.p.h.—during which 8,000 miles would be covered.

An airship has been successfully moored out for six weeks in a perfectly open expanse to a specially designed mast. Only two or three men are required to look after the ship, and winds of up to 52 m.p.h. have been ridden out without any damage resulting.

A system of recovering water-ballast during flight would obviate waste of hydrogen by preventing the ship becoming 'light,' owing to the consumption of fuel during a long voyage.

Increase in size of aeroplanes brings many difficulties in its train with no compensating improvement in efficiency, but increase in size of airships results in a reduction of the difficulties experienced at present, and gives improved efficiency.

Progress in Heavier-than-Air (H/A) and Lighter-than-Air (L/A) Machines: 1914–1918.

In 1914, the average endurance of a German rigid at cruising speed was under one day, and the maximum full speed about 50 m.h.p. In 1918 (German L.70 class, 2,195,000 cub. ft. capacity), the endurance at 45 m.p.h. has risen to 177·5 hours (7·4 days) and the maximum full speed to 77 m.p.h. The ceiling has correspondingly increased from 6,000 ft. to 23,000 ft. The British R.38 class (2,720,000 cub. ft. capacity) has an estimated cruising endurance at 45 m.p.h. of 211 hours (8·8 days), 54 hours greater than the German L.70 class.

The D.H.10A has been taken as the best all-round machine in August, 1918. Although the two-engined Handley-Page and Caproni have greater endurance and weight-carrying capacity, their all-round efficiency appears inferior to the D.H.10A. The Handley-Page V. gives promise of having a slightly better performance than the D.H.10A, but this machine is still in the experimental stage and reliable performance figures are not available.

Tables 1 and 2 give the progress in L/A and H/A since 1914. Table 3 shows the difference in performance between corresponding L/A and H/A craft of 1918.

Table 1. L/A.

—	August, 1914. Average figure for German Naval Zepp.	August, 1918. German L.70.	Progress.
Maximum speed at 10,000 ft.	50 m.p.h.	77·6 m.p.h.	55%
Endurance at 45 m.p.h.	20 hours	177·5 hours (7·4 days)	787·5%
Total lift.	30 tons	66·64 tons	122%
Disposable lift	8·5 tons	38·84 tons	357%
Efficiency ratio	27·3%	58·3%	113·5%
Static ceiling	6,000 ft.	21,000 ft.	250%
Indicated H.P.	800	2,100	162·5%

TABLE 2. H/A.

—	August, 1914. Avro.	August, 1918. D.H.10A.	Progress.
Speed at 10,000 ft.	70 m.p.h.	125 m.p.h.	78·3%
Endurance	4 hours	10 hours	150%
Total weight loaded	·737 tons	4·02 tons	445%
Useful load	·268 tons	1·45 tons	445%
Efficiency ratio	36·3%	36·1%	0·55% (Decrease)
Ceiling	14,000 ft.	22,500 ft.	35·7%
Indicated H.P.	80	810	913%

	August, 1914. Avro.	August, 1918. Handley-Page.	Progress.
Speed at 10,000 ft.	70 m.p.h.	85 m.p.h.	21·4%
Endurance	4 hours	12·5 hours	212·5%
Total weight loaded	·737 tons	5·97 tons	524%
Useful load	·268 tons	2·17 tons	709%
Efficiency ratio	36·3%	36·4%	0·28%
Ceiling	14,000 ft.	15,000 ft.	7·1%
Indicated H.P.	80	720	800%

TABLE 3. COMPARISON OF EXISTING H/A & L/A MACHINES.

August, 1918.	H/A. D.H.10A.	L/A. German L.70.	Percentage Superiority.
Speed at 10,000 ft.	125 m.p.h.	77·6 m.p.h.	H/A. 61·1%
Cruising endurance	14 hours	177·5 hours	L/A. 1,167%
Total lift (=weight loaded)	4·02 tons	66·64 tons	L/A. 1,557%
Disposable lift (=useful load)	1·45 tons	33·84 tons	L/A. 2,580%
Efficiency ratio	36·1%	58·3%	L/A. 61·5%
Ceiling	22,500 ft.	21,000 ft.	H/A. 7·1%
Indicated H.P.	810	2,100	L/A. 159%

It will be seen that at the present time the largest rigids in commission have over 10 times the total lift of the corresponding H/A, and that the disposable lift is about 25 times greater.

The proportion of useful lift compared to gross lift is much higher in airships than in aeroplanes. An approximate figure for an aeroplane of average engine power is $\frac{1}{3}$, while in a rigid the useful lift available for fuel, crew, passengers, freight, etc., is well over $\frac{1}{2}$. In the case of L. 70 the figure is 58·3 per cent., although this ship is the most heavily engined and fastest airship yet built.

It cannot be too strongly emphasised that many of the advantages apparently possessed by H/A at the present time result from their relatively small lift. Thus, an aeroplane of 60 tons total lift, if found to be possible at all, would certainly be very much less convenient to land and handle on the ground than aeroplanes of existing sizes, and would require overall dimensions about twice those of the largest existing machines.

It is important to note that in H/A there is no automatic improvement in efficiency resulting from greater dimensions. In L/A, on the other hand, such an automatic improvement takes place to a very marked degree. The reason for this difference is as follows:—In similar H/A machines of different dimensions, the total lift, air resistance, and b.h.p.—other things being equal—all very nearly as the plane areas, i.e. as the square of the linear dimensions.

It follows that the ratio $\frac{\text{weight of machinery}}{\text{total lift}}$ does not vary much with size of machine. The ratio $\frac{\text{weight of structure}}{\text{total lift}}$ tends to increase with size of machine. Unit area of wing surface can only exert a definite lifting effect, and as the machine increases in size it is necessary to increase proportionally the weight of each preceding unit area of wing surface to make the machine proportionally strong. A point is finally reached where every additional unit of wing surface results in as much increased weight as its lifting effect, so that any further increase in size will involve a definite falling off in the total lifting capacity of the machine. A further small increase in size can be effected by increasing the number of planes; but, owing to the inefficiency of middle plane surfaces, due to the blanketing effect of the top and bottom planes, the resulting gain in endurance will not be large, and it will only be effected at the price of a loss in efficiency.

A 10,000,000 cub. ft. capacity rigid has five times the lift of the present 2,000,000 cub. ft. capacity rigid, but the length of the former is only 1·7 times greater, and therefore the weight of the structure only five times greater $(1{\cdot}7)^3$.—i.e. the weight of the structure is directly proportional to the total lift.

This theoretical property of structure may, to a certain extent, be modified by the material used. Thus, for ships of 2,000,000 to 4,000,000 cub. ft. capacity duralumin is the most suitable material for the hull structure, while for ships of 8,000,000 to 10,000,000 cub. ft. capacity a saving in weight can be effected by the use of steel.

In H/A machines, therefore, all-round efficiency, as measured by the ratio of $\frac{\text{disposable lift}}{\text{total lift}}$ tends to decrease with greater dimensions. Greater efficiency will, therefore, not result from increase in size, but, on the contrary, great increase in size will not be attainable until greater efficiency has been first obtained by progress in design and materials.

In L/A, the total lift varies as the cube of the linear dimensions, while the air resistance and b.h.p.—other things being equal—vary as the square of the linear dimensions. Hence the ratio $\frac{\text{weight of machinery}}{\text{total lift}}$ decreases automatically. Values for this 'coefficient of tractive resistance' for airships are given in Table 4.

TABLE 4.

Gross Lift of Rigid.	Coefficient of Tractive Resistance at		
	45 m.p.h.	60 m.p.h.	80 m.p.h.
	Per cent.	Per cent.	Per cent.
60 tons	1·9	3·8	7·7
80 „	1·7	3·4	6·7
100 „	1·5	3·0	6·0
150 „	1·3	2·5	5·0
200 „	1·1	2·2	4·4
250 „	1·0	2·0	4·0
300 „	0·9	1·8	3·6

It will be seen that they vary from ·9 per cent. for a large rigid at 45 m.p.h. to 7·7 per cent. for a small rigid at 80 m.p.h., compared with 15 per cent., which may be taken as an average figure for H/A craft.

It will further be seen that as the size of the rigid increases, the coefficient of tractive resistance decreases to a marked extent. With a proportionate increase in h.p., it is easier and proportionately more economical for a 10,000,000 cub. ft. capacity rigid to fly at 80 m.p.h. than for a 2,000,000 cub. ft. capacity rigid to fly at 60 m.p.h. In the case of H/A craft, however, increase in size effects no decrease in the coefficient of tractive resistance.

The figures for tractive resistance are based on the German L.33 streamline form, and from the experimental results already obtained by the National Physical Laboratory it is reasonably certain that a more efficient streamline form can be obtained which will appreciably reduce these figures.

As the ratio $\frac{\text{weight of structure}}{\text{total lift}}$ is, in airships, fairly constant, it follows that the ratio $\frac{\text{disposable lift}}{\text{total lift}}$ increases with dimensions. The natural tendency will, therefore, be towards larger airships, in order to secure the benefit of the resulting gain in efficiency.

A further point of great importance emerges from the above. As the total lift varies as $(\text{dimensions})^3$ in H/A, and as $(\text{dimensions})^3$ in L/A, increase in total lift is secured in the latter with less increase in dimensions than in the former. Thus, to secure five times the total lift we must increase the dimensions 124 per cent. in H/A and only 70 per cent. in L/A.

If total lift is increased indefinitely in both types, the dimensions of the H/A will, therefore, ultimately pass those of L/A, when almost the last remaining advantage of the former over the latter will disappear.

The proportion of useful lift compared to gross lift is much higher in airships than in aeroplanes. An approximate figure for an aeroplane of average engine power is 33 per cent., while in a rigid the useful lift available for fuel, crew, passengers, freight, etc. is well over 50 per cent. In the case of the German L.70 the figure is 58·3 per cent., as has already been mentioned.

It is concluded that the outstanding characteristics of H/A will remain as at present: high speed, handiness, moderate lift, independence of all weather conditions except the worst.

As regards L/A, the functions now performed by the smaller airships will be usurped more and more by H/A. Airships may be expected to develop in the direction of increased size to a limit

which is not yet in view. The outstanding characteristics of L/A will be reasonably high speed very long endurance, great weight-carrying capacity for freight, stores, passengers, etc.

The line of policy to be adopted is to develop the aeroplane for transport over distances under say, 500–800 miles, and the rigid airship for trans-oceanic and possibly trans-continental flight of over this length.

Table 5 shows the approximate dimensions of a series of airships similar in form to R.33.

TABLE 5.

Capacity in cubic ft.	Gross lift in tons.	Length.	Diameter.
2,000,000	60·7	643′	79′
3,000,000	91·1	736′	90·4′
4,000,000	121·4	810	99·5′
5,000,000	151·8	872′	107·2′
6,000,000	182·2	927′	113·9′
7,000,000	212·5	976′	119·9′
8,000,000	242·8	1021′	125·4′
9,000,000	273·3	1061′	130·4′
10,000,000	303·6	1100′	135·1′

It will be seen that although a 10,000,000 cub. ft. capacity rigid has five times the gross lift and over five times the disposable lift of the present 2,000,000 cub. ft. capacity rigid, the dimensions of the large ship are only 1·7 times greater, and it could be docked in a shed of no more than one-third larger dimensions than those at Killeagh, i.e. 1,150′ long × 160′ high × 180′ wide. compared with 850′ long × 130′ high × 150′ wide, for Killeagh.

As regards constructional sheds, the most economical method of accommodating such large airships would perhaps be to lengthen existing constructiona sheds, which are sufficiently wide, to at least 1,150 ft. long (present length 700 ft.), and lower the floors as necessary to secure the required height. A somewhat similar course could probably be taken with existing housing sheds.

If the endurance of a rigid is increased to a sufficient extent, it will be possible to carry out flights with a regularity comparable to that maintained by surface craft. The range is almost unlimited, and the weight-carrying capacity large. A 10,000,000 cub. ft. capacity rigid will have a disposable lift of over 200 tons, which is available for petrol, ballast, crew, passengers, and freight.

There is no other type of vessel which is so efficient.

With a rigid of about 10,000,000 cub. ft. capacity, and endurance of approximately three weeks at 40 to 45 m.p.h., with a maximum speed of 70 to 80 m.p.h., a ceiling of some 30,000 ft. can be obtained, and a maximum range of over 20,000 miles.

Standard Data for Airship Calculations.

(1) *Lift of Hydrogen* to be taken as 68 lbs. per 1,000 cu. ft. of gas space at sea level.
The variation of lift with height to be taken as proportional to the density of the 'Standard Atmosphere.'

(2) *The Volume of Gas* assumed in lift calculations to be as follows:—

For rigids, the total volume of the gasbags when filled with a slight pressure not exceeding 5 mm. at the bottom.

For non-rigids, designed volume of the envelope with ballonets empty, plus an allowance of 5 per cent. for stretch.

(3) *Gross Lift*, at sea level, is defined as the volume, determined as in para. (2), multiplied by the lift per unit volume, as given in para (1).

(4) *Standard Flying Height* to be taken as 2,000 ft. above sea level in the case of rigid airships, and 1,000 ft. above sea level in the case of non-rigid airships.

Values of atmospheric density, pressure, and temperature at sea level and standard flying height are :—

	Density. Lbs. per cu. ft.	Relative Density. Per cent.	Temperature. ° C. Abs.	Pressure. Mb.	Pressure. Lbs. per sq. in.
Sea level	·0782	100·0	282·0	1,014·0	14·70
1,000 ft. above sea level .	·0757	96·8	281·0	978·0	14·18
2,000 ft. above sea level .	·0733	93·8	279·7	943·4	13·68

(5) *Fixed Weights* are defined as all constant and non-consumable weights which an airship would carry under all conditions of service, including :—

Structure.
Fabric.
Cars.
Machinery—including liquids in the system and radiators (not petrol or oil in service tanks or float tanks, or water in radiator headers intended as a reserve supply).
Gun mountings (ex guns and ammunition.)
Wireless telegraphy equipment.
Approved navigating equipment (including instruments).
Approved allowance of handling and mooring ropes, etc.
Internal gassing hose.
All fixed tanks.
All pipe systems.
All electrical systems.

In the case of commercial ships, all passenger cars and car fittings should be taken as fixed weights.

(6) *Disposable Weights* are defined as all weights other than fixed weights, and therefore include :—

Crew and effects.
Food and fresh water.
All water ballast.
All fuel and oil.
All reserve water for radiators.
All slip containers.
All bedding.
Parachutes.
Life-saving jackets.
Oxygen apparatus.
Spares and tools.
Water ballast bags and all other approved gear and equipment not included in the fixed weights.
Passengers, merchandise, guns, ammunition, and bombs.

(7) *Dischargeable Weights* are defined as :—

All fuel and oil except reserve as defined in para. (9).
All ballast except emergency as defined in para. (9).
All slip containers (except such as may be necessary to contain reserve fuel, oil, and ballast).
Bedding.
All other loads which may have been raised by the ' Useful Lift ' (see para. (9)).

(8) *Maximum Static Height or ' Static Ceiling '* to be calculated on the following assumptions :—

(*a*) The ship to be lightened by removal of all dischargeable weights (para. 7), and no others.
(*b*) All other disposable weights to be carried in accordance with approved complement and equipment (see para. (9)).
(*c*) The variation of lift with height to be taken in accordance with the standard atmosphere, as in para (1).

(9) *Useful Lift* is defined as the lift available for :—

Fuel and oil,
Passengers and merchandise.
Food and drinking water,
Guns, ammunition, and bombs,

and to be determined by deducting from the gross lift at sea level the following :—

All fixed weights.
Ballast necessary to reach the standard flying height, amounting to :—
For non-rigids . . . 3·2 per cent. of gross lift, (at 68 lbs. per 1,000 cu. ft.).
For rigids . . . 6·2 " " " "
(See para. 4.)
Emergency water ballast, amounting to 3 per cent. of the gross lift at sea level.
Reserve fuel and oil for two hours' flight at normal full speed at standard flying height.
All tanks and containers not already included in the fixed weights.
Approved reserve of water for radiators.
Crew : Approved complement, the weight of each member being taken as 180 lbs., including clothing and personal kit.

All approved spares and tools.

Approved equipment:

Bedding.	Oxygen apparatus.
Parachutes.	Fire extinguishers.
Life-saving appliances.	Emergency ration (iron ration).

All other approved disposable equipment, e.g. First Aid equipment, which would be taken on board at commencement of flight under all conditions of service.

(10) *Speed* to be stated in knots, i.e. nautical miles (6,080 ft.) per hour, for all classes.

Speeds in all cases to be calculated under the standard atmospheric conditions corresponding to standard flying height, as laid down in para. 4.
Maximum speed.
Normal full speed, to be defined as 90 per cent. max. speed.
Cruising speed, to be defined as 80 per cent. max. speed.
Comparison speed. 40 knots.

(11) *Endurance* to be calculated on the following assumptions :—

The whole of the useful lift (para. 9) to be employed for fuel, oil, food, and drinking water.
Rate of fuel and oil consumption to be the approved figure for the ship at the speed in question and at the standard flying height (para. 4), with corresponding atmospheric conditions.
Rate of consumption of food and fresh water to be taken as 10 lbs. per day for each member of the approved complement of crew ; that is $a_s \frac{\text{complement} \times 10 \text{ lbs.}}{24}$ per hour.

Thus if ' A ' be the total fuel and oil consumption in lbs. per hour at a given speed, and if ' B ' be the consumption of food and fresh water in lbs. per hour. The endurance in hours at that speed $= \frac{\text{Useful Lift.}}{A + B}$

High-flying Oxygen Breathing Apparatus.

High-pressure Apparatus

In this apparatus the oxygen in gaseous form is stored in a specially constructed seamless cold-drawn steel tube charged to a pressure of 2,250 lbs. per sq. in. (150 atmospheres).

The tubes were produced during the war in two sizes, one capable of holding 500 litres at the above-mentioned pressure and the other 300 litres. They are extremely light, weighing 4 lbs. and 6¾ lbs. respectively for the smaller and larger sizes.

The tubes before being passed by the Aeronautical Inspection Department are subjected to an internal pressure test of 3,750 lbs. per sq. in., being inserted in suitable water-jackets for measuring any increase in volume. The cylinders are rejected if the permanent increase of volume (after the hydraulic pressure is removed) exceeds the increase of volume under pressure by 20 per cent. Two per cent. of each batch of tubes after manufacture are also subjected to a proof pressure test to destruction, and if the bursting pressure is less than 4,250 lbs. per sq. in. further samples are selected and treated in like manner, and if these fail under destruction test the whole batch is rejected. They may, however, be heat-treated again.

The final test (flattening test) is carried out on the uninjured portion of those selected from batches in previous destruction test, and the cylinders are flattened until the inner surfaces are 1 in. apart. If cracking results from this treatment, as before, the rest of the batch are scrapped, although they may be re-heat treated.

In the necks of the cylinders are sweated valves with forged bronze bodies and parallel-threaded shanks, with screwed inlet and outlet connections, each valve weighing approximately 9 ozs. All valves are tested hydraulically to 2,250 lbs. per sq. in. The cylinders when valved are subjected to a final compressed air test at about 1,000 lbs. and immersed in water to ensure a perfect joint between cylinder and valve.

The cylinders are fixed in the machines in convenient positions by means of specially constructed spring clips, and from the cylinders the gas is led through fine copper tubing some 10 ft. in length to the oxygen regulator, which performs the double function of reducing the gas from high to low breathing pressure and at the same time regulating the flow to the airmen.

The regulator consists in the main of a pressure gauge for indicating the pressure of gas as received from the cylinders already described; a reducing valve for reducing the pressure of gas from the pressure in the cylinder to a normal breathing pressure of between 1 to 2 atmospheres absolute; a control valve for regulating the delivery according to the height of the aeroplane and a flow indicator to indicate that gas is flowing.

An improved indicator has a graduated tube introduced which has the additional function of recording the exact rate of flow of gas.

There are two distinct types of control valve, an automatic control by means of a diaphragm valve in one model and a hand-controlled valve in the other model. In aerial combat the hand-controlled instrument was preferred, whereas on long-distance flights the automatic valve was favoured. In the former case the airmen were able to inhale any quantity and cut off at leisure if otherwise engaged, and in the latter case, where long duration was necessary, the oxygen was consumed economically.

The low-pressure gas after leaving the regulator passes along a flexible tube to the breathing mask, which in the latest type is embodied in the pilot's headgear, being readily detachable by means of a separate strap on the main portion of the helmet. The pilot inhales the oxygen by means of a pipe-mouthpiece which is swivelled and can be easily discarded.

The 300-litre cylinder at altitudes between 10,000 ft. and 15,000 ft. is capable of supplying oxygen at an average rate of flow of 1·35 litre per minute continuously for approximately 3½ hours, but between altitudes of 15,000 ft. and 20,000 ft., where an increased rate of flow is necessary, owing to decrease in atmospheric pressure, the same quantity of gas at an average rate of flow of 2·55 litres per minute would only be available for approximately two hours.

Liquid Oxygen Breathing Apparatus.

In this type of apparatus the liquid oxygen is first placed in a vaporiser, which has an inner spherical chamber varying in sizes to accommodate from 1 to 5 litres, according to the length of flight and altitude.

The vaporiser embodies the ordinary vacuum flask principle where an inner and outer vessel are constructed and the space between the two rarefied down to about 1/1000 mm. vacuum.

A small quantity of specially selected charcoal is placed in a tube in the inner vessel to absorb any moisture. The ends of the tube which terminate in the vacuum space are covered with gauze. The vaporisers vary in weight, the largest, of 5 litres capacity, weighing approximately 12 lbs. when empty and capable of holding 12 lbs. of liquid oxygen when charged.

The vaporiser thus consists of nner and outer vessels, neck, and charcoal receptacle, and in the neck is a syphon tube which passes into the body of the vessel. The oxygen in liquid form passes up this tube into the heating and evaporation coils, which are bent round the neck in the form of solid drawn copper tubes. The oxygen after leaving these tubes passes into a flash boiler which, not being evacuated, is at a much higher temperature than the liquid oxygen, and in consequence the latter is converted into the gaseous state.

To cause additional radiating surface a number of blind tubes are added underneath the flash boiler.

The oxygen then passes along to the pressure gauge which indicates the pressure of the oxygen from the vaporiser, and is graduated to accommodate pressures from 0 to 25 lbs. per sq. in.

From experiments it has been ascertained that the best results are obtained when the oxygen passes from the vaporiser at a pressure of about 5 lbs. per sq. in.

The oxygen from the vaporiser passes by means of a rubber connection to the control fitting, the function of which is to control the supply of oxygen to the airmen. The fitting consists simply of control valve and pressure release valve, which is used to indicate the quantity of oxygen passing to the airmen's breathing masks. The flow of oxygen is indicated by the impact of a jet of gas upon a pivoted vane provided with a pointer moving over a dial. The calibration of the flowmeter is from 0 to 6 litres per minute and the quantities of oxygen required for airmen at varying altitudes are as given in the description of the high-pressure breathing apparatus.

Liquid oxygen storage vessels known as containers, and capable of holding approximately 27 litres of the liquid are also specially constructed on the vacuum principle and used for charging the vaporisers. The container forms a convenient means of storing the liquid, and owing to the very high vacuum which is created between the inner and outer vessels the loss of liquid oxygen due to evaporation is brought to an absolute minimum.

The liquid oxygen apparatus has one great advantage over the high-pressure type in that there is no danger in connection with the use thereof in serial warfare, owing to high-pressure gas being non-existent. In the case of the gaseous oxygen apparatus, the very high pressure to which the steel tubes are charged creates a source of danger which frequently results in damage to pilot and machine when the tubes are struck by enemy bullets.

Liquid Oxygen Plant.

The plant as manufactured by Messrs. Société L'Air Liquide, Boulogne-sur-Seine, Paris, was designed for the purpose of mounting on a railway truck and capable of delivering at least 15 litres of liquid oxygen per hour with 96 per cent. purity. The plant, fig. 65, works on the well-known Claude principle and is made up of the following components :—

1. Petrol engine to supply motive power (the particular engine used was the 100 h.p. Ricardo engine as supplied by the Mechanical Warfare Department).

2. Air compressor.

3. Water separator.

4. Purifier and drier to decarbonise the air.

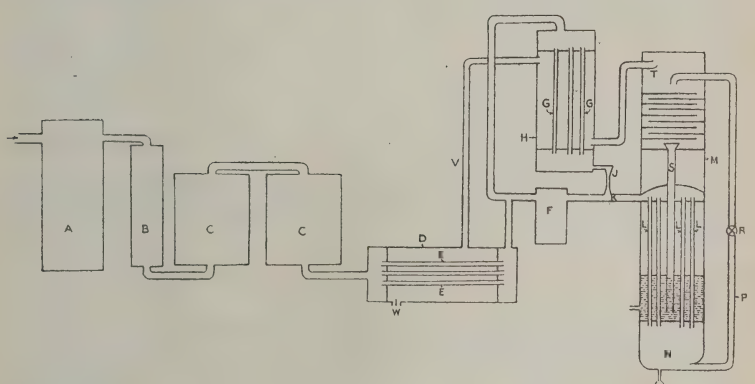

FIG. 65.—Diagram illustrating Liquid Oxygen Plant.

5. Liquefaction and rectification column, each in itself comprises :—(a) A temperature exchanger to cool the compressed air. (b) An expansion engine which is responsible for rapid drop in temperature. (c) Brake dynamo and rheostat to absorb the power given out by the expansion engine which would be otherwise wasted. (d) Liquefying column embodying rectifier.

The air is first drawn into the two-stage compressor (A), fig. 65, from the atmosphere, and passed at a high pressure of about 45 atmospheres to the separator (B) where moisture absorbed from the injection water in the cylinders of the compressor is removed. The air then passes successively through the purifying chambers (C, C), filled with caustic soda or caustic potash, rom whence it emerges perfectly dry and free from CO_2.

The dried and purified air passes into the temperature exchanger (D) and traverses the nest of small tubes (E) therein, which are cooled by expanded and cold gas flowing in the opposite direction. The air, considerably cooled, leaves the temperature exchanger, part entering the expansion engine (F) and the other part a nest of tubes (G) in the liquefier (H). The air entering the expansion engine does external work on the piston and is expanded and thus cooled.

The air in the nest of tubes (G) in the liquefier is cooled by expanded and cold gas flowing in the opposite direction, and, under the continued action of cooling and pressure, liquefies, and, passing through the needle valve (J), mixes in the pipe (K) with the cold and expanded air issuing from the expansion engine. The cold air and the liquid air enter the top of another nest of tubes (L) called the vaporiser, which is contained in the rectification column (M). On leaving these tubes the mixture of gas and liquid enters a sump (N) at the bottom of the column, and from thence rises through the pipe (P) and regulating valve (R) to the top of the column. The top portion of the rectifying column contains a series of staggered and perforated trays. The liquid in the mixture descends through the trays and enters the vaporiser by means of the pipe (S). The gas in the mixture, which contains a large quantity of nitrogen, since nitrogen has a lower boiling point than oxygen, leaves the top of the column by the pipe (T), entering the

liquefier in the space surrounding the nest of tubes (G), thus cooling the compressed air in the tubes, and from thence enters the temperature exchanger (D) by the pipe (V) in the space surrounding the nest of tubes (E). Thus it fulfils the same function of cooling the compressed air flowing in the opposite direction; it ultimately leaves by the pipe (W) warmed, but still at some degrees below the temperature of the incoming air.

When the liquid air supply is sufficiently large for liquid oxygen to be formed, the valve (R) is slowly closed down, but not completely shut. The exhaust pressure in the expansion engine then rises to the same as that of the liquid air in the nest of tubes (L) in the vaporiser, and causes the surrounding liquid to boil. The gas thus formed, and consisting mainly of nitrogen, rises through the plates, while all the liquid formed rises through the valve (R) and flows into the top of the column; the liquid thus descends through the trays, while the gas ascends and eventually finds its way into the atmosphere through pipe (W). Thus it will be seen that the continued action of progressive refrigeration gradually purifies the liquid in the column (M) and which approaches pure liquid oxygen. In the same manner the gas, passing through pipe (T) and eventually through pipe (W), gradually becomes richer in nitrogen and with greater cooling effect on the oncoming compressed air in the temperature exchanger.

At a test, the first signs of liquid were not observed until two hours after the starting of the plant. It was not possible to analyse the purities of the liquid oxygen directly, although the purity of the evaporated gas was taken. The relative density of the liquid oxygen was found to be approximately 1·11, and the flow of liquid per hour was never less than 17·2 litres.

The original specification called for 18 to 22 litres. At a second test, the liquid was produced one and a half hours after the plant was re-started, and a further two hours realised the total of 43·6 litres, giving an increased average per hour of 21·8 litres.

The compressor was running at an average speed of 245 r.p.m., and in two stages compressed the gas to a maximum of 45 atmospheres.

The expansion engine was running at about 160 r.p.m. and the dynamo for absorbing the waste energy from the expansion engine was able to give an average output of 35 amps. at average pressure of 70 volts. The average purity of the oxygen gas was 92 per cent. and the average purity of oxygen liquid 97 per cent.

Parachutes.

In the early days of the war the use of man-carrying parachutes was confined entirely to kite balloons and proved of very great service in life saving. It is estimated that at least six hundred of our balloon observers effected their escape by this means.

At this very early period on the Western front the parachute then in use was of Spencer manufacture, known as the 'conical' type, afterwards superseded by another Spencer type, known as the 'flat-case' type.

The conical type of parachute consists of a silk body having a flattened hemispherical form with 48 cords attached to its periphery at equal distances and terminating in a single rope. In the centre of the body there is a hole 9 ins. in diameter through which the current of air escapes as the parachute descends. This gives stability to the parachute, which would otherwise swing violently, although the swinging to a certain extent cannot be prevented in any parachute. The parachute and cordage are packed into a conical canvas case which is hung mouth downwards from the basket of the kite balloon.

The flat case type of parachute is another method of packing and consists of a flat case fastened to the side of the basket and into which the parachute is packed.

It was towards the end of the war before parachutes were seriously considered by the Air Ministry for use with aeroplanes. The urgency for aeroplane man-dropping parachutes was so apparent that a special parachute department of the Air Ministry was created. When this section was formed there were in existence several types of parachutes, of which perhaps three stood out prominently from the rest as being very suitably adapted for aeroplanes.

The effect of additional weight and bulk occasioned by the parachute case was found to reduce the speed of the machine by three miles an hour and the climb by 50 feet per minute.

When an aeroplane is under control and flying on a level keel, exit by parachute is comparatively safe provided always that ordinary precautions are taken, but with a machine on fire or completely out of control escape is always problematical and dangerous. The parachute does, however, provide the airman with a chance of saving his life, whereas without this chance he would otherwise go to almost certain death.

The 'Guardian Angel' type of parachute differs from other types in that it has the advantage of a 'positive opening,' which means that the parachute on delivery always leaves its case with its mouth open. This is effected in the A1 type by the following means:—The silk body is pleated until it forms a tube and is then folded down upon a disc of duralumin some 24 inches

in diameter, another similar disc being placed above it. The two discs are separated by a duralumin distance tube of about five inches diameter. The rigging lines (in the form of stout tapes) are folded in fillets below the discs and fastened by boxwood toggles to the periphery of the parachute and the whole is covered and kept weathertight by a waterproof cover. The parachute when folded resembles in outline an ordinary plum cake with a handle on the top, the lower extremities of the tapes, twelve in number, being fastened to a central bolt of duralumin, which is ultimately attached to the harness of the aviator. When the aviator leaves the aeroplane and his weight comes upon the centre bolt the lower portion of the cover comes away, the tapes are pulled out to their full extent, and the parachute body is pulled out over the lower disc in the form of a pleated silken tube 2 ft. in diameter and 14 ft. long filled with air. The parachute, continuing to descend in this condition, cannot fail to expand to its full extent, and this fact gives great confidence to the user. This parachute when packed weighs 30 lbs. and measures 24 ins. in diameter and about 12 ins. through and its cost is considerable, being in the neighbourhood of 100*l*. The rate of descent averages 15 ft. a second for a 12-stone man, a perfectly safe rate of speed. From 80 to 90 yards of silk are required for the manufacture of this parachute. In its latest form the parachute is packed upon a bent wood ring, the duralumin discs done away with, and other modifications made, so that the 'Guardian Angel' D4 type with Taylor-shaped body now weighs 18 lbs., measures 20 ft. across, and is compressible into about 5 ins. in depth. The cost is also proportionately reduced.

Drops from an aeroplane going at 130 miles per hour have been made.

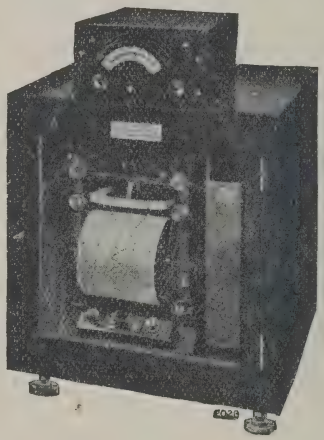
The 'Guardian Angel' parachute invariably opens in the first 100 ft. of falling.

The 'Mears Knapsack' type is a Spencer parachute pleated and folded in such a way as to make its opening a practical certainty.

It has never been known to fail to open, but has no mechanical means of extending its mouth upon delivery. After longitudinal pleating of the body a strip of canvas ending in a length of webbing is placed upon it and is rolled up with the silk in much the form of a snail. The parachute with rigging is then placed in a weather-proof knapsack with the webbing protruding, which is attached to the aeroplane. The knapsack is worn by the aviator either on his back or attached to his harness in front. When the aviator jumps, the reaction between his falling weight and the moving plane causes the webbing to pull the parachute out of the knapsack, and the parachute then unfolds and expands, leaving the strip of canvas and the webbing still attached to the machine. This parachute has many good qualities in that the aviator is well clear of the moving plane before the parachute unfurls and is, therefore, more or less free from the danger of fouling. It is also cheap and easy to pack and comparatively light in weight.

The 'Smiths Salvus' parachute also possesses the good quality of the positive opening like the D4 and also is better adapted for the forward positions in large machines such as Handley-Page or Vickers-Vimy, as the distance of fall before the body inflates can be regulated according to the type of machine it is to be used for. In this parachute the periphery of the body is held to a wooden ring, making it a positive opening type until a certain distance from the machine has been covered, when the periphery is released automatically and the body expanded to its full extent.

The weight of this parachute is about 19 to 20 lbs., the diameter packed, 21 ins., and the depth about 8 to 10 ins. It is a very good and reliable appliance.



SECTION XXXI

FUELS: SOLID, LIQUID, AND GASEOUS.

(Contributed by Harold Moore, M.Sc.(Tech.), A.I.C., F.C.S., Consulting Chemist.)

Fuels may be most conveniently classified according to their physical state, as 'solid,' 'liquid,' and 'gaseous.' Another division may also be made into fuels for external combustion (e.g., for boiler firing, for furnaces, etc.), and fuels for internal combustion, that is to say, fuels which are consumed in internal combustion engines.

COMBUSTION.

The heat yielded by burning any fuel is produced by the combination of the carbon, hydrogen, and sulphur present in it with the oxygen of the atmosphere. A little heat may be either liberated or absorbed by the decomposition of the compounds present in the fuel into their elements. When a fuel is burned in a furnace, or in an internal combustion engine, under correct conditions, the carbon burns to form carbon dioxide (CO_2), the hydrogen to form water (H_2O), and the sulphur, which is not usually present in large quantities, to form sulphur dioxide (SO_2). If insufficient air be present the carbon is incompletely burned, and forms to some extent, carbon monoxide (CO), a considerable amount of heat being lost by this reaction taking place. The weight of air theoretically required for complete combustion, may be ascertained by the formula:

$$\text{Air required in lbs.} = 0{\cdot}116\ [C + 3\ (H - \tfrac{1}{8}\ O)]$$

where C, H, and O are the percentages of carbon, hydrogen, and oxygen respectively present in the fuel.

Both the theoretical quantity of air required, and the percentage of carbon dioxide theoretically correct in the flue gas, are dependent upon the ultimate composition of the fuel.

COMPOSITION OF FLUE GASES.

With an average steam coal the theoretical quantity of air for combustion would yield a flue gas containing some 18·5 per cent of carbon dioxide, but if only the calculated quantity of air be admitted to the furnace there is danger of loss of heat by the formation of some carbon monoxide, and if the supply of air be any less than the calculated quantity, a very serious loss is certain to take place for this reason. On the other hand, a slight excess of air over the calculated amount does not result in great loss of heat. It is therefore desirable to allow a slight excess of air. The best working is obtained by endeavouring to maintain a proportion of about 14 per cent. of carbon dioxide in the flue gas.

The thermal value of all combustible mixtures containing only the quantity of air required for the complete combustion of the fuel is, for all practical purposes, a constant, the value of which is 120 British thermal units per cub. foot of air used. Or, conversely, the number of cubic feet of air required for the complete combustion of any fuel equals the calorific value in British thermal units divided by 120. This applies to either gaseous, liquid, or solid fuels, and may be used where the calorific value is given by volume or by weight indifferently.

(*Jas. Dunlop.*)

The majority of methods for the estimation of carbon dioxide are based on the absorption of this gas by potassium hydrate (caustic potash) solution, the process consisting in measuring a volume of flue gas at a definite temperature, and then absorbing the CO_2 by means of a 33 per cent. solution of caustic potash, after which the volume of gas is again measured, the reduction in volume indicating the volume of CO_2 originally present. Many simple forms of chemical apparatus are available for this purpose.

It is frequently desirable in gas analysis to estimate carbon monoxide and oxygen as well as carbon dioxide. Similar apparatus with other absorbent solutions for the respective gases may be used. In the common form of Orsat apparatus, pipettes containing absorption solutions

of caustic potash (for CO_2), acid cuprous chloride (for carbon monoxide), and alkaline pyrogallol (for oxygen) are used. The apparatus also contains a measuring burette and levelling bottle, and is generally built up in a wooden case to make the complete set easily portable.

In some cases it is necessary to estimate methane or other hydrocarbons in gas, in which case means are provided for exploding the gas with oxygen, after which the newly-formed CO_2 may be estimated, and the content of hydrocarbon gases calculated therefrom. Special forms of apparatus, made solely for the object of estimating methane and carbon monoxide, are available.

For the control of combustion, beyond occasional tests of carbon monoxide, the only product which requires frequent estimation is carbon dioxide, and in view of the importance of knowing the carbon dioxide content of flue gases, several forms of continuous recording instruments have been marketed for measuring this gas.

CO_2 Recorders.

The majority of CO_2 recorders depend upon the absorption of CO_2 by caustic potash solution, a definite quantity of flue gas being intermittently measured out, and then the CO_2 absorbed and a record made of the diminution of volume, the chart being adjusted to read in volume-percentages of CO_2 present in the flue gas.

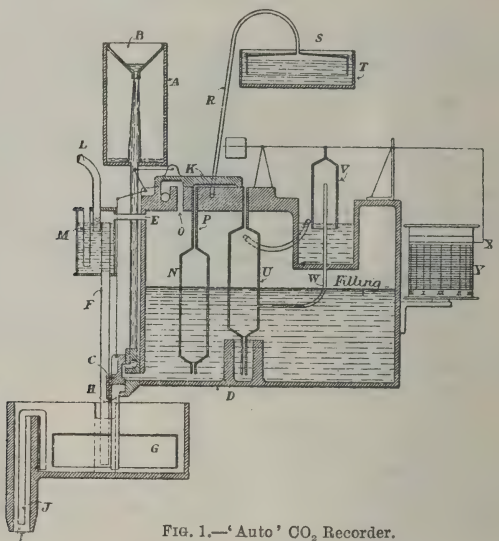

FIG. 1.—'Auto' CO_2 Recorder.

The method employed in the 'W.R.' Patent CO_2 Recorder depends on the difference of pressure generated on the two sides of a porous pot, one side of which is exposed to flue gas whilst the other contains caustic potash, which absorbs the incoming CO_2.

The Cambridge Scientific Instrument Company have recently marketed a recorder the action of which depends upon the greater heat conductivity of gas containing CO_2. In this instrument electrical resistance coils are exposed to air and flue gas, the extra heat conductivity of the flue gas being denoted by the lower resistance of the coil.

In fig. 1 is shown, in diagrammatic form, the construction of the instrument known as the 'Auto' CO_2 Recorder, which has been designed and constructed by the *Auto Recorder Company*, and is now in successful operation in connection with a large number of boiler installations in this country and on the Continent. The action of the apparatus is as follows:

A small stream of water is allowed to run into the tank A through the small funnel B, which only allows sufficient water to pass to work the instrument at a suitable speed. The water runs from the tank A through the valve C into the chamber D. When the chamber D is filled up to the pipe E, the water overflows down the pipe F and under the float G, which it raises, thereby moving the valve C upwards and shutting off the water supply from the tank A into the chamber D. This motion of the valve C opens a communication from the chamber D through the pipe H, the water rising over the float G until it flows down the pipe I, and the chamber D is empty; the

pipe J then acts as a syphon and drains the water from under the float G, which is then allowed to fall again, and the chamber D to be once more filled. By this means the chamber D is alternately filled and emptied, and, as the float is connected by a system of levers to the distributing slide valve K, the water flowing through is the prime mover of the instrument.

The operation of gas analysis is very simple. The pipe L is connected to the supply of gas to be analysed and, as the end of the pipe dips slightly into the water seal in M, no gas can be drawn back. When the water in the chamber D is running out, there is a slight vacuum in this chamber which draws the gas through the pipes L and E, and, as the first measuring vessel N is in communication with the chamber D through the passages O and P and the slide valve K (this valve having moved over to the right by the rising of the float G), it is entirely filled with flue gas. Much more gas is drawn in than is analysed, in order that the sample may be as fresh as possible. When the water reverses and begins again to run into D (the valve K having moved over to the *left*, by the sinking of the float G), the gas enclosed in the vessel N is sent through the pipes P and R, and under the dome S, which stands immersed in a solution of caustic potash contained in the vessel T. This dome is of large area, and the gas is in a thin layer between the wet dome and the top of the solution, so that the absorption of the CO_2 is rapid. After the water has risen and expelled all the gas from the vessel N into the absorber, and has again begun to run out, the valve K having moved over to the *right*, the water, as it descends in the second measuring vessel U, draws in from the absorber S the gas which has not been absorbed. As the measurer U is of the same capacity as the measurer N, it follows that, if there is not sufficient gas received from the absorber S to fill it, it will, after emptying the absorber, draw the remainder from under the bell V through the pipe W, and cause the bell to descend; the greater the amount of CO_2 absorbed, the lower the bell V will be pulled down. As the bell is suspended from a balanced lever, which has a pen X attached to it, the pen marks the chart Y, which is placed round a clockwork drum, the lines made by the pen being of varying lengths, according to the amount of CO_2 which was in the quantity of gas in the first measurer N.

It has been found that one of the greatest troubles with recorders of this kind is to keep the pipes from the flue to the instrument clean; in the 'Auto' Recorder this is effected by a special filter.

The 'W.R.' Patent CO_2 Indicator.

(W.R. Patents, Ltd., London and Leeds.)

The present-day high cost of coal renders the use of a CO_2 indicator highly necessary. Fig. 2 shows a new type recently introduced and placed on the market, which can be used in

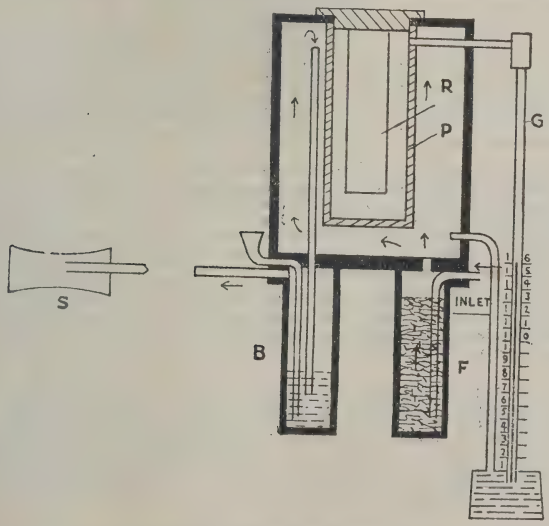

FIG. 2. (Small Indicator.)

all cases of combustion where any class of fuel is used, and where CO_2 is a product of this combustion. The arrangement adopted, differs materially from other CO_2 indicators.

An aspirator, S, fig. 2, worked by the natural draught which it increases, is fixed at a point as near the chimney base as possible, and continually aspirates gases from the flue it is desired to keep under observation. The path of gases is shown by the arrows. They are first drawn through a filter F, and pass from thence into a chamber containing a porous pot, inside which is a dry reagent, R. The flow of gas is shown by continuous bubbling through water in vessel B. A pipe connects the chamber with a vessel containing water into which dips one end of another pipe, G, the other end of which is taken into the inside of the porous pot. Some of the gases penetrate into the interior of this pot, and are absorbed by the reagent, with the result that a partial vacuum is formed, and the water is forced up the pipe G. The latter is provided with a scale so graduated that the percentage of CO_2 in the flue gases can be read.

CO_2 or Carbon Dioxide.

The process of distillation which goes on in a boiler furnace, resulting in the separation of the gases and fixed constituents in the fuel, requires widely different and constantly varying conditions in the matter of air supply for the attainment of perfect combustion. Efficient combustion (i.e. economical combustion) is secured by burning the correct proportion of fuel and air under the varying conditions of coal and atmosphere. The point, therefore, to aim at is to generate the required steam by burning as much air as possible and as little fuel as necessary. The burnt air given off passes up the flue in the form of carbon dioxide (CO_2), therefore the object to achieve is to secure as large an amount of CO_2 (say from 10 per cent. to 14 per cent.) as is possible. The relation of coal consumption to CO_2 in the flue gases has been worked out, and the result is given in standard treatises on fuel. These results are as follows:

Temp. of Exit Gases.		Percentage of CO_2 in Exit Gases.											
		4%	5%	6%	7%	8%	9%	10%	11%	12%	13%	14%	15%
F.°	C.°	Total Percentage of Fuel wasted.											
400	204	32·4	26·2	21·8	18·9	16·4	14·9	13·4	12·3	11·4	10·6	9·8	9·2
500	260	40·5	32·7	27·3	23·6	20·8	18·6	16·8	15·4	14·2	13·2	12·3	11·6
600	316	48·6	39·3	32·8	28·3	24·9	22·3	20·2	18·5	17·1	15·9	14·8	13·9
700	371	56·7	45·8	38·2	33·1	29·1	26·0	23·5	21·6	19·9	18·5	17·2	16·2
800	427	64·8	52·4	43·7	37·8	33·2	29·7	26·9	24·7	22·8	21·2	19·7	18·5

The above figures necessarily include the unavoidable loss present in every boiler plant, and the performance of any plant must be judged by comparing the total losses given in the respective columns. The figures in the columns below the 'Percentage of CO_2 in Exit Gases,' represent the wastage of coal with that percentage of CO_2. For example, take the third column and the second line. Temperature of Exit Gases °F. 500—percentage of CO_2, 6 per cent. The wastage of coal is 27·3 per cent. Following the line on to the tenth olumn, it is shown that with 13 per cent. of CO_2 the coal wastage is 13·2 per cent. Thus by increasing the CO_2 from 6 per cent. to 12 per cent. a saving of 14·1 per cent. of coal is effected. The W.R. CO_2 or Combustion Indicator is an apparatus which continually, automatically, and accurately, indicates the percentage of CO_2 which is passing throrgh the flues at any hour of the day and night. With this Indicator installed on the boiler plant the percentage of CO_2 obtained can be seen at once, and the necessary steps taken to increase this amount and thus save fuel.

The Indicator is prompt in its action, having a lag of three minutes only. Its deviation from absolute accuracy has been found to be only 0·1 per cent. It is well constructed; has no mechanically moving parts; is fireproof and foolproof, and can be worked by any boy of average intelligence. With each Indicator the manufacturers furnish a blue print showing the method of fitting to each particular boiler, also special detailed instructions for installing the apparatus, which operation can be completed in from four to six hours by any works' engineer or fitter. In cases where a recording graph is desired, one of a specially approved form can be supplied by W.R. Patents, Ltd.

All recording graphs are necessarily somewhat complicated, and are apt to get out of order through dirt, etc., but even if the instrument should go out of order when fitted to the Indicator, the Indicator itself will still continue to work. The cartridges last 24 hours of continuous working.

The exhaust gases from internal combustion engines are subject to the same considerations as flue gases. They, however, cannot be regulated so as to produce a definite CO_2 percentage, as to obtain this result it would be necessary to throttle down the incoming air, thus loading the engine by increasing the difference in pressure between exhaust and inlet, in which case a loss of efficiency would occur. The graphs in fig. 3 show the composition of the exhaust gases

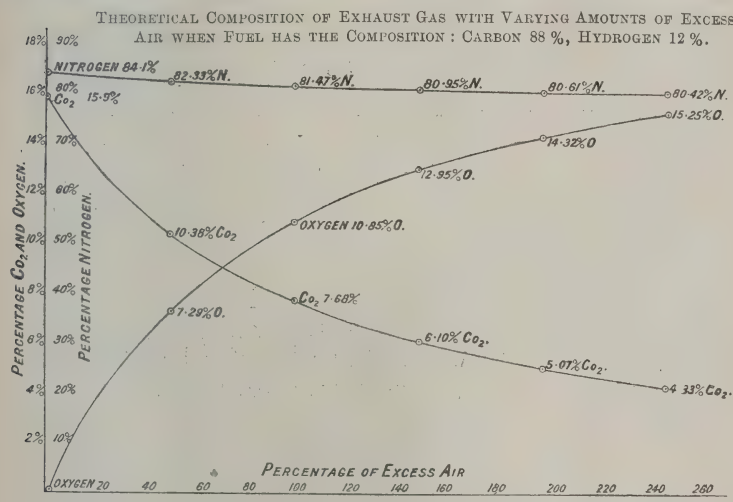

FIG. 3.

of an engine burning heavy petroleum (about 88 per cent. C and 12 per cent. H) with various quantities of excess air. Diesel oil engines running at full load generally take about 100 per cent. excess air : semi-Diesel engines a somewhat greater percentage excess air.

Thermal Efficiency.

The following table gives the thermal efficiency obtainable when converting the heat of fuels into work by various types of engines :—

Type of Engine.	Thermal Efficiency.
	Per cent.
Reciprocating steam engine and boiler	12
Steam turbine and boiler	18
Petrol engine	22
Gas engine with producer	24
Gas engine with suction producer	26
Petrol engine (aircraft)	27
Semi-Diesel oil engine	34
Alcohol engine	36
Diesel oil engine	36

THERMAL EFFICIENCY CURVE.

Curve A (fig. 4) represents the best thermal efficiency that can be expected from gas-engine plants ; B, a moderate efficiency from the same plant ; C, a poor efficiency from gas plant, but

probably the very best that can be expected from a large gas-fired turbo-generator plant; D may be considered a good thermal efficiency for the latter.

These efficiencies can only be expected in power plants working at a high load factor

(*A. Hugh Seabrook.*)

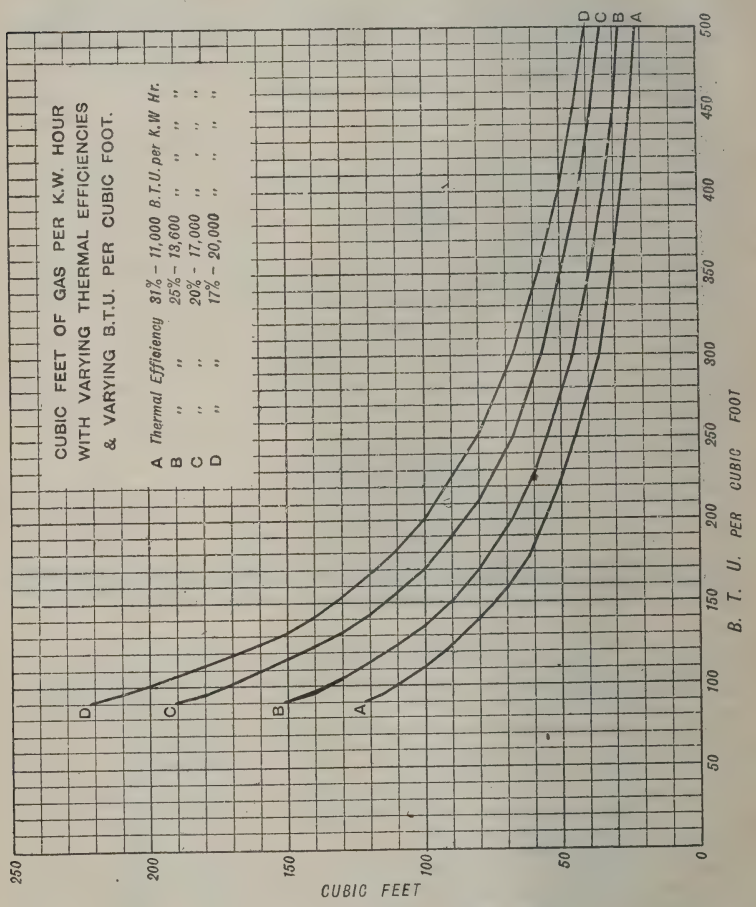

FIG. 4.—Thermal Efficiency Curve.

TEMPERATURES OF SPONTANEOUS IGNITION.

The thermal efficiency of internal-combustion engines is dependent upon the compression pressure employed in the engines. The compression pressure permissible in engines is dependent upon the temperature of spontaneous ignition of the fuel employed.

The following are recent figures for the spontaneous ignition temperatures of fuels:—

SPONTANEOUS IGNITION TEMPERATURES (IN OXYGEN).

Liquids.	Sp. Gr.	S.I.T.	
Pratt's perfection spirit No. I.	0·710	272 C.°	522 F.°
" " No. II.	0·724	270	518
Paraffin oil	0·782	253	487
Gas oil (petroleum)	—	254	489
Various crude petroleums and residua	—	254 to 275	489 to 527
Shale oil	—	253	487
Commercial 100 per cent. benzol	0·875	566	1,051
Creosote oil	1·010	415	779
Coke-oven tar oil	1·046	478	892

(*Moore*, '*J.S.C.I.*', Feb. 15, 1917.)

Gaseous Fuels (in Air).

Hydrogen	758 C.°	1,396 F.°
Carbon monoxide	910	1,670
Ethylene	895 to 905	1,643 to 1,661
Coal gas	850	1,562
Petrol gas	900	1,652
Methane (No ignition below 1,000)	1,000	1,832

(*McDavid*, '*J.C.S.*,' *Nov.* 1917, p. 1003.)

To determine whether a coal is likely to ignite spontaneously, take a convenient quantity of the coal and weigh it pretty accurately. Heat the sample to 250° F., hold it at that temperature for three hours, and then weigh it. If the weight has gone up 2 per cent. or more, the coal is a dangerous one from the point of view of spontaneous combustion. The sample must be dry coal, the drying being done at about 100° F. (*J. F. Springer in* '*Power.*')

SOLID FUELS.

The most important naturally occurring solid fuels are:—

Coal; Lignite; Peat; Wood

These may be burned in the raw state, or may be subjected to destructive distillation. In the latter case solid, liquid and gaseous products are evolved. The more important solid fuels which may be prepared by this treatment are coke (of two kinds, metallurgical and gas-works coke), lignite coke (of little value), peat charcoal, and wood charcoal.

Powdered coal is sometimes made into briquettes by the addition of a small percentage of coal-tar pitch or other binding material, and pressing in moulds.

Coal.

The composition of coal from various fields varies considerably according to the conditions to which the coal has been subjected during its formation. Its variation in composition can be seen from the following table of coal analyses:—

ULTIMATE COMPOSITION OF COAL (*Brame*).*

Type of Coal.	Carbon.	Hydrogen.	Oxygen and Nitrogen.	Fixed Carbon.	Volatile Matter.
Lignites and brown coals	69·5	5 5	25·0	52·0	48·0
Splint coal (Fife)	82·0	5·0	12·8	61·0	39·0
Gas coal (Durham)	85·0	5·5	8·2	66·0	34·0
Coking coal	87·3	5·05	6·9	73·5	26·5
Smokeless steam (Welsh)	91·3	4·05	3·9	85·5	14·5
Anthracite (Scotch)	91·1	3·5	4·65	88 5	11·5
Anthracite (Welsh)	91·0	3·9	4·28	93·0	7·0

* '*Fuels: Solid, Liquid and Gaseous*,' p. 32.

Coal possesses a sp. gr. of from 1·2 to 1·5 (water = 1) mainly depending on its composition. It also varies considerably in hardness and texture. The combustible portion of coal usually consists of from 73 to 93 per cent. carbon, 3 to 6 per cent. hydrogen, 2 to 20 per cent. oxygen, 1 to 2·5 per cent. nitrogen, and 0·5 to 5 per cent. sulphur. When completely burned coals yield from 1 to 15 per cent. ash. The moisture content varies within very wide limits. The heat value of coal is generally from 14,000 to 16,000 B.Th.U. gross. A comparison of the properties of coal with those of other solid fuels may be seen in the following table :—

CALORIFIC PROPERTIES OF VARIOUS FUELS.

Substance.	Calorific Power.		Observed by
	Calories.	B.Th.U.	
Scotch peat briquettes (16 per cent. H_2O)	4,754	8,558	F. Mollwo Perkin.
Coke from Scotch peat	7,600	13,680	,,
Oak (containing 13·3 per cent. H_2O)	3,990	7,182	Gottlieb.

Asphaltum (extracted from petroleum).	9,550	17,190	,,

ANALYSIS OF COAL.

The chemical tests usually made upon coal are to ascertain the calorific value, coke value, ash content, moisture content, and ultimate composition. The volatile matter per cent. is obtained by deducting the coke value plus ash content of any coal from 100. The 'fixed carbon' is obtained by deducting the ash content from the coke value.

Of these only the first four are necessary for ordinary fuel purposes, and they are known as proximate analysis. The analysis for ultimate composition is expensive, difficult to make, and not essential. The determination of the calorific power is indispensable (unless actual evaporation tests are made on a boiler, in which case it is useful for comparison). When comparing two fuels, the value of the fuel of higher calorific power is generally greater than might be calculated by considering the value to be proportional to the calorific value. It is, however, advisable to note the number of B.Th.U. per penny when buying coal.

CALORIFIC VALUE OF COAL.

If it is impossible to determine the calorific values of coal in a calorimeter it can be roughly estimated from the ultimate composition by the formula :—

Net calorific value = 8,137 C + 29,100 (H − $\frac{1}{8}$O) + 2,500 S − 600 H_2O, where C, H and O are the percentages of carbon, hydrogen and oxygen respectively present, and H_2O the percentage of hygroscopic water present.

When the ultimate analysis is not known and it is desired to obtain a rough estimate of the calorific power from the proximate analysis, this can be obtained by the formula :

$$\text{Calorific value} = 1{\cdot}8(82C + aV)\ \text{B.Th.U}$$

in which C = per cent. fixed carbon, V = per cent. volatile matter, and a is a constant computed from the following: $a_1 = 100V/(C + V)$.

a_1	5	10	15	20	25	30	35	38	40
a	145	130	117	109	103	98	94	85	80

The question of ash content is a serious one, as its removal from boilers involves labour and expense. The clinker to be removed from a steam plant is greater in quantity than the weight of ash content obtained by calculation from the results obtained in the laboratory.

High moisture content not only shows that water is being bought for coal. It must be remembered that this moisture has to be driven off in the form of steam, and in this way takes up heat from the combustion zone, and is liable to cause smoking.

ECONOMIC EFFECTS OF IMPURITIES IN COAL.

Each per cent. of sulphur reduces the boiler capacity by about 1·5 per cent. In experiments made in America with a chain grate stoker, using Illinois coal mixed with various percentages of ash, the efficiency dropped gradually as the ash increased up to 35 per cent., after which the efficiency dropped to zero rapidly with a fuel containing 40 per cent. of ash.

LOSS OF THERMAL VALUE OF COAL BY STORAGE.

An average of 741 tests, in America, of a particular coal showed, after three years in the open air, a reduction of from 35 to 28·3 per cent. of volatile combustible matter, indicating a thermal value loss of 20 per cent.

Coal in storage should be inspected regularly. If the temperature reaches 150° F. the pile should be carefully watched, and if the temperature rises to 175° or 180° F. the coal should be removed as promptly as possible. The coal should be thoroughly cooled before being replaced in storage.

UTILISATION OF ANTHRACITE WASTES.

A series of tests made in America, consisting of 30, 50, and 70 per cent. run-of-mine coking coal mixed with anthracite culm, showed that the pulverised bituminous coal alone produced better results, except the mixture of 30 per cent. culm with 70 per cent. bituminous, which was equal to that of the bituminous coal alone.

STOWAGE SPACE OF COAL.

The stowage space occupied by coal is 40 to 42 cubic feet for one ton of Welsh steam coal 45 cubic feet for one ton of North country coal, and 45 to 50 cubic feet per ton of Scotch coal.

EVAPORATIVE POWER.

The heat required to evaporate one pound of water at boiling point is 967 B.Th.U.

To raise water from 100° F. to boiling point and evaporate into steam at 212° F., 1,078 B.Th.U. per pound of water are required.

By dividing the calorific power (in B.Th.U.) of a fuel by 1,078 we obtain the *theoretical* quantity of water which it will raise from a feed-water temperature of 100° F. and evaporate at 212° F.

In practice a good boiler develops a thermal efficiency of about 70 per cent., and the actual evaporation obtained is therefore about 70 per cent. of the theoretical figure.

EVAPORATIVE POWER OF COAL.

F. 1777

Coke.

Coke is produced by the destructive distillation of bituminous coal either in coke ovens or in gasworks.

High-temperature Distillation of Coal.

Coke-oven coke is produced by slowly heating the coal to a high temperature, about 1,000° C., by which means a hard product, almost entirely free from volatile matter, is obtained. This coke is employed in blast-furnaces, and commands a slightly higher price than the product of the gasworks. It possesses a calorific power slightly lower than that of pure carbon (14,540 B.Th.U.).

The process employed in coke ovens, namely, the gradual heating of the coal to a very high temperature, results in the production of a very hard, unfriable coke, which will withstand the high crushing stresses necessary for metallurgical operations, especially blast-furnace work. It contains all the ash, and nearly half the sulphur, present in the original coal.

Gasworks coke is a product from the horizontal, inclined, or vertical retorts used in the manufacture of coal gas. In all such plants the heat is applied more rapidly than in coke ovens, and the resulting coke is softer and more friable than coke-oven coke. The process is, of course, primarily designed to give a high yield of gas, and the coke is a by-product.

Gas coke of average quality has a calorific power of about 12,500 B.Th.U. per lb., as sold, including moisture. Coke breeze, or coke dust, is about 10,000 B.Th.U. per lb.

Experiments made with quite dry coke and a sample artificially watered up to 16 per cent. of its weight show that a given quantity in a given time furnished 228 B.Th.U. wet and 365 B.Th.U. dry, approximately 39 per cent. advantage in favour of dry coke. The proportion of moisture in coke may vary from 2 per cent. to 20 per cent., and in the condition indicated in the experiment the heat in the grate or boiler was partly used to dry out the water, which escaped as moisture into the flues, carrying heat with it and thereby reducing efficiency.

Low-temperature Distillation of Coal.

This consists in the gradual heating of bituminous coal to a comparatively low maximum temperature (500 to 600° C.). The retorting vessels employed are designed in such a way as to ensure the rapid removal of the volatile products. By such a process a low yield of very rich gas is obtained, and a high yield of thin tar. The tar is richer in low boiling-point fractions than the tars produced by the gasworks or coke-oven plants. The residual coke contains approximately 10 per cent. of volatile matter, and may be marketed for use in domestic fires, for which purpose it is claimed to be easily ignitable, and at the same time to give off the major portion of its heat as radiant heat, and to burn without generating smoke. Until recently the process has not met with success, largely on account of mechanical difficulties in the operation of the retorts; these difficulties, however, appear to be now overcome by 'Low-temperature Carbonisation, Ltd.,' in their production of 'Coalite.'

Coalite.

The following are results obtained in the manufacture of Coalite :—

Coalite and tar obtained from 1 ton of coal	Coal used	70 % Claycross 30 % Thorncliff
	Coalite, 72 %	1,612·8 lbs.
	Tar	17 gallons

Heat Balance Sheet

Raw Materials	B.Th.U.'s	Products in B.Th.U.'s		B.Th.U.'s
Coal	30,000,000	Coalite 72%	1,612·8 lbs. =	22,000,000
		Tar	17 gallons =	3,000,000
		Loss		5,000,030
	30,000,000			30,000,000

The foregoing, which shows a heat balance in B.Th.U.'s, does not include the surplus gas, since it is not certain what amount will remain over after heating the retorts. Also, the B.Th.U.'s value of the benzol to be recovered from the gas is not included. This latter is omitted, because the quantity is not definitely known. Without these, the balance is good and efficiency high. A good gas works' practice will give 22,000,000 B.Th.U.'s, or 73 per cent. efficiency, against the 25,000,000 (coalite and tar) B.Th.U.'s, or 82 per cent. efficiency.

(T. M. Davidson and R. H. S. Abbott.)

YIELD FROM ONE TON OF AVERAGE COAL (say 25-30 per cent. volatile matter).

	Low-temperature Carbonisation.	High-temperature Carbonisation.	
		Gasworks.	Coke Ovens.
Temperature of carbonisation	1,000° F.	About 1,800° F.	About 1,800° F.
Gas	6,000-6,500 cubic feet of rich gas, 700–750 B.Th.U. per cubic foot.	12,000 cubic feet of medium quality (town's) gas, 550 B.Th.U. per cubic foot.	11,500 cubic feet of poor quality coke-oven gas, 450 B.Th.U. per cubic foot.
Liquid	20 gallons coalite oil (fractionated to, say, 3 galls. motor spirit, 8-9 galls. Diesel or fuel oil, and 8-9 galls. lubricating oil).	10 gallons coal tar. (Fractionated to about half-gallon motor spirit, carbolic acid, a large amount of naphthalene, fuel oil, &c.)	8 gallons coal tar.
Sulphate of ammonia (from the ammonia)	15 lbs.	25 lbs.	28 lbs.
Residue in retort	14 cwt. of smokeless fuel coalite containing about 9-10 per cent. volatile matter.	13½ cwt. of soft coke, containing about 1 per cent. volatile matter.	14-14½ cwt. of hard coke, containing less than ½ per cent. volatile matter.

(*David Brownlie, A.I.Mech.E.*).

COKE AS A BOILER FUEL

(Contributed by E. W. L. Nicol, M.I.Mar.E., A.I.E.E.)

With a view to cheapening the cost of steam raising by improving steam-boiler efficiency, and to eliminate the emission of visible smoke, gas coke is now largely used as fuel in lieu of crude

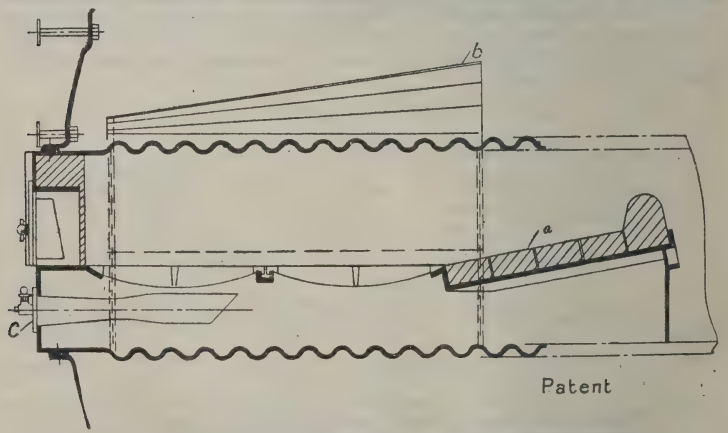

FIG. 5.—*a*, Gallagher Crompton baffle bridge; *b*, Ross Schofield circulator.

coal. In hand-fired boilers, coke exclusively is used under ordinary natural draught conditions. With a draught of 0·25 in. W.G. over the fire, the average rate of combustion is 12 lbs. to 14 lbs.

of suitably graded coke per sq. ft. of grate area per hour. Some form of impelled draught is necessary if this rate is insufficient. The forced draught apparatus usually employed is some form of steam-jet blower applied to the enclosed ashpit of the boiler, and used to maintain a 'balanced' draught over the fire (fig. 5). The steam consumption of the jets should not exceed 3 per cent. of the total steam generated when burning graded coke at a rate of 20 lbs. per grate-foot-hour. For hand-fired boilers the minimum allowance of grate area should be 1 sq. ft. per 22 to 25 lbs. of coke consumed per hour. In practice it is found that this rate can be exceeded only at the expense of efficiency.

Unlike coal, the combustion of coke is practically completed on the grate, a supply of secondary air over the fire being unnecessary. This tends to localise the heating effect to the boiler furnace area. The introduction of a circulator, *b*, tends to neutralise this effect and set up active circulation of the water in the boiler. The operation of cleaning fires, and the losses incidental thereto, due to inrush of cold air and consequent loss of steam pressure, are minimised by the use of the Gallagher Crompton baffle bridge *a*, also shown in the figure. During the cleaning operation the live fuel is heaped up on the baffle bridge.

In mechanically-stoked boilers fitted with both forced and induced draught, average rates of combustion exceeding 40 lbs. of graded coke per grate-foot-hour are maintained. Types of mechanical stokers specially adapted for use with coke or coke breeze include the 'Underfeed travelling grate' and the 'Babcock balanced draught chain grate.' Existing chain grate

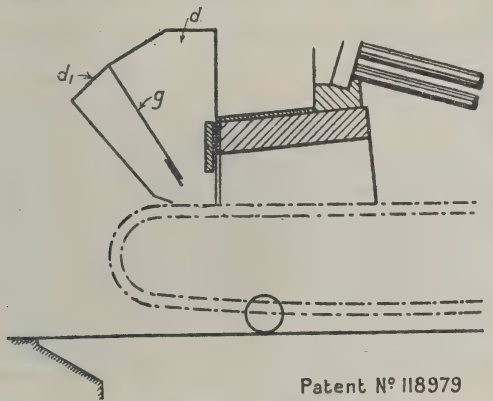

FIG. 6.—Sandwich System as applied to Chain-grate Stoker. d_1, coal hopper; d, coke hopper; g, separating diaphragm.

mechanical stokers have largely been adapted to use admixtures of coke or breeze up to 75 per cent. at full normal rates under ordinary natural draught conditions, by means of the patent 'Sandwich' system (fig. 6), which is designed to feed, from a double hopper, well-defined layers of coal slack and suitably graded coke of any desired thickness, the coal being uppermost. Using this system at the L.C.C. Greenwich Power Station, the General Manager gives the following data relating to the year 1919–1920 :—

Tons of fuel burnt	. 176,400	Average percentage of ash	10·0
Average price for coal	. 41*s.* 11·3*d.*	calorific value of breeze	9,000 B.Th.U.
,, calorific value	. 10,780 B.Th.U.	,, percentage of ash	18 to 20
,, percentage of ash	. 14·59	Coke and breeze consumed	25,000 tons
,, calorific value of coke	11,500 B.Th.U.		

With coal at 42*s.* per ton, and coke breeze at 22*s.* 6*d.* per ton, the fuel cost per 1,000 gallons evaporated was 19*s.* 6*d.* with equal quantities of each fuel, as against 23*s.* 2*d.* with Scotch nuts alone, a saving of about 16 per cent. The official report says. 'Apart from the saving in money, low grade classes of fuel can be dealt with on the Sandwich system at a much higher efficiency than would be the case if burnt separately. The results have been extremely satisfactory and a saving of about £8,000 a year can be effected.' Average evaporation obtained with 50 per cent. mixture of coal and breeze, 7·25 lbs.; with coal and coke 9 lbs. from and at 212° Fahr. Gas coke is also used extensively as fuel for road transport vehicles of both the under-type ('Sentinel,' 'Leyland,' and 'Atkinson') and the over-type wagon ('Foden' and 'Garrett,' etc.). The following table shows the fuel cost of evaporation from and at 212° Fahr. with common solid fuels at varying prices :—

APPROXIMATE FUEL COST OF EVAPORATION FROM AND AT 212° FAHR.

Lignite.

The composition of lignite, and its properties, lie between those of wood and coal.

Lignite occurs in most European countries and is abundantly found in the Colonies, but does not occur in quantities in the British Isles. Lignites vary widely in composition, but generally between the following limits : carbon 55 to 80 per cent., hydrogen 5 to 7 per cent., oxygen 10 to 35 per cent (in the dry state). The calorific value is from 9,000 to 14,000 B.Th.U. on dry sample. The high ash and water contents of lignite frequently make it unsuitable for direct combustion, but good grades may be used for steam raising. Lignite is frequently subjected to destructive distillation, whereby valuable liquid products are obtained. It may also be used for the manufacture of fuel briquettes, or be utilised in gas producers.

Peat.

Large deposits of peat occur within the British Isles, but little use has been made of them hitherto, the high water content (80 to 96 per cent. when in bog, and 30 to 60 per cent. after air drying) being a great drawback to their utilisation. Peat is suitable for use in gas producers, and is sometimes carbonised, when peat charcoal is the main fuel product.

Anderson and Dillner (*Jour. Soc. Chem. Ind.*, 1902, 459) give the following calorific powers for peat (in the dry state) :—

Average from bog	8,100 to 11,000 B.Th.U.
Reed grass peat	7,450 to 9,820 „
Mud peat	7,825 to 8,200 „

Wood.

When freshly cut, wood contains up to 50 per cent. of water, but this can be reduced to about 20 per cent. by air drying. The composition of dry wood is about 49·5 per cent. carbon, 6 per cent. hydrogen, 44 per cent. oxygen, and ·5 per cent. ash, and the heat value is generally a little

below 9,000 B.Th.U. It only finds use in countries where large forests exist and where coal is not readily obtainable.

Wood Charcoal.

Wood charcoal consists mainly of carbon and possesses a calorific value of 11,000 to 13,500 B.Th.U. (Brame). Its use as a fuel is very limited.

Briquette Fuel.

Small coal cannot be burnt so economically in the furnaces of boilers in its original state as when in the form of briquettes. Briquettes made exclusively with anthracite coal burn too slowly, and it is advisable to mix a certain proportion of bituminous coal to overcome this objection. Up to the present, no kind of agglomerating material other than pitch or resin, or a mixture of these, has given satisfactory results. Briquettes made with resin alone become soft and lose their shape in the fire; those having a mixture of 4 per cent. of pitch and 1½ per cent. of resin give better results.

Briquette fuel is compounded from small coal which is mixed with cementing material and pressed into blocks or cakes. Highly bituminous coal may be formed into briquettes by heating considerably and pressing while hot. Certain lignites may be similarly agglomerated. Less bituminous coal requires about five to eight per cent. of pitch. The pitch is ground fine and mixed with the small coal, and the mass is heated until the pitch softens sufficiently to enable hard compact briquettes to be pressed. The rectangular block occupies least space, but it requires to be stacked by hand and broken for burning. The best form of briquette otherwise is the soap cake variety sufficiently flat not to roll. These can be moved in mass, lifted by a grab, and easily shovelled. They are not too mobile and do not flow out of a bunker door with the freedom of spherical briquettes. Clay, mucilage, Irish moss, lime, solidified petroleum, and many other starchy or sticky substances have been and are used in the cementing material of briquettes. Nothing is better than pitch; it must be of such quality as not to soften in the hottest climate to which the briquettes may be exposed; softer pitch will serve for home use. Pitch may be tempered with tar, and the following qualities are secured, according to mixture :—

	Dry Pitch.		Pitch and 9 per cent. Tar.		Pitch and 17 per cent. Tar.		Pitch and 25 per cent. Tar.	
	F.	C.	F.	C.	F.	C.	F.	C.
Ductile at . .	167°	75°	158°	70°	122°	50°	104°	40°
Pasty at . .	203°	95°	194°	90°	140°	60°	131°	55°
Liquid at . .	230°	110°	212°	100°	176°	80°	140°	60°

Briquettes are tested for toughness by tumbling, and noting the proportion wasted.

When made of pulverised coal of good quality the calorific power of briquettes is fully equal to that of round coal of the same variety. A pressure of 1,200 kilos per square centimetre will agglomerate a bituminous lignite alone. Ordinary briquettes are made with a pressure of 100 to 140 kilograms per square centimetre, or say 1,500 to 2,200 lbs. per square inch. Mr. Middleton recommends a pressure of as much as double these figures.

Preparation of Fuel Briquettes.*

Medium hard coals are best adapted to the production of fuel briquettes. Material suitable for briquetting should all pass through a ½-in. sieve; that is, it should consist of a mixture of grains of all sizes from ½ in. downwards. The presence of a certain amount of dust is required, in order to fill up the spaces between the coarser grains so as to produce a dense and strong briquette. If the dust employed, however, be in excess, the use of an increased amount of binding material is necessary. The average ash content of the coal should not exceed 12 per cent. if pitch is to be used as a binding material. In other cases it must be less than this amount, so that the ash content of the finished briquette shall not be above 10 per cent. There is no difficulty, however, in reducing the ash content of even the finest coal to 12 per cent. in the modern washing plant.

For successful briquetting it is essential to use a pitch that softens between 40° and 70° C., and yields a hard sintered residue on coking. About 70 per cent. of this residue should be extracted by the use of carbon disulphide; its hydrogen content should not exceed 5 per cent., and its calorific value should not be less than 8,500 calories. Blast furnace pitch is not suitable as a binding material, as this material always gives a puffed residue on coking. The amount of pitch necessary to effect a proper adhesion of the particles of coal in the finished briquette varies between 7 and 10 per cent. of the mixture. Generally speaking, the amount to be added increases with the hardness of the coal, with the increasing proportion of dust, with the increasing moisture content, and with a decrease in the pressure used in moulding the briquette.

* Abstract of paper read by F. C. A. Lantsberry and J. Drummond Paton, before the Manchester Geological and Mining Society, December 19, 1916.

Firebars.

The following proportions are for the usual cast-iron bars :—

5 0	5 1/4	2 1/4	2 1/2	1 1/2	1 1/8	7/16	5/8

Firebars require to be suited to the fuel. Clean riddled coal-nuts or cobbles may be burned on a $\frac{1}{4}$-in. bar with $\frac{1}{4}$ in. to $\frac{1}{2}$ in. spaces, but slack coal requires wider bars and narrow spaces. Bars are often made with projecting fingers or corrugations in plan, thus increasing the length of air space considerably, though reducing it in respect of the increased width of the bar body. Such bars are made to rock for the purpose of shaking the ashes out of the fire and of breaking up clinker. Air, to supply a secondary demand behind the bridge for the combustion of the gases, is often admitted through hollow bars which heat the air and keep themselves cooler thereby, and under suitable conditions good results may be obtained.

Some firegrates are built up of short bars or links pinned together to form a side travelling band or chain ; such grates are self-cleaning and are much used in mechanical stokers, and are good, if provided with suitable air control damper plates below. Other firegrates have a somewhat steeply inclined surface, and may be built up either of longitudinal bars or of transverse bars, in which latter case they form the so-called ' step ' grate. Such grates may have a creeping or a shaking movement of the bars in order to assist gravity to lower the burning fuel down hill to make up at the foot of the slope the vacant space left as the fuel burns away. The fuel is mechanically fed in, above, or at the head of the sloping grate surface, and gradually descends under the combined influence of gravity and the moving bars. A dumping device is often added at the foot of the slope, by means of which the ash and refuse may be cleared from the furnace by movement of a lever.

Grates for anthracite coal, which develops an intense heat in the fire—not sending off much gas by the heat-absorbing process of distillation—are often made in the form of flat plates with a number of perforated nipples or little mounds raised half an inch above the general surface. The space between the air mounds fills level with dust and preserves the iron surface from heat and checks the adherence of clinker.

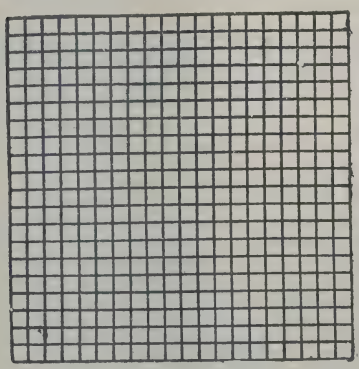
Firegrate bearers must never be rested upon the actual plates of furnace tubes of internally fired boilers, but must rest on angle bracket pieces riveted to the plates by not less than two rivets each. For convenience in handling it is usual to employ two or three bars in the length of a 6-ft. grate.

Hollow bars are necessarily (or more conveniently) made in one length ; this, however, makes them cumbersome, and is one cause of their being sometimes unpopular, for they are heavy to remove and replace when cleaning ; but where conditions are favourable, hollow bars with outlets to the surface and a steam-impelled supply of air through the bars will beget economy, by enabling a cheaper grade of fuel to be employed.

Coal Combustion and Smoke.

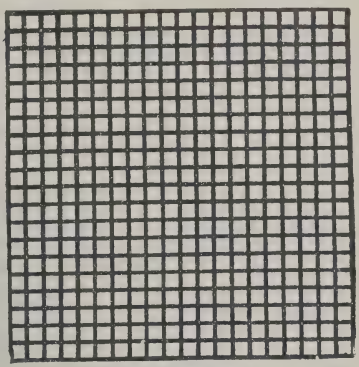
Bituminous coal cannot be burned smokelessly except under certain proper conditions. These are that the whole of the products of combustion must be allowed to travel over the full length of the fire towards the bridge ; that additional air must be admitted in fine streams above the fire after each fresh charge of fuel. The fresh air thus admitted mingles with the gases from the fuel, and the mixture must be hot enough to burn at the bridge, beyond which point there must be a clear space in which combustion may complete itself. The combustion chamber may with advantage be wholly or partially brick-lined. The draught necessary should be not less than 30 ft. per sec. To compel air to enter over the fire, dampers are sometimes fitted to the ash pits.

The most satisfactory results in coal combustion are obtained with the thickest possible fires, but the thickness of a fire depends on the draught and on the size of the fuel. The largest fuel will bear the thickest fire and the strongest draught. The three factors are interdependent.



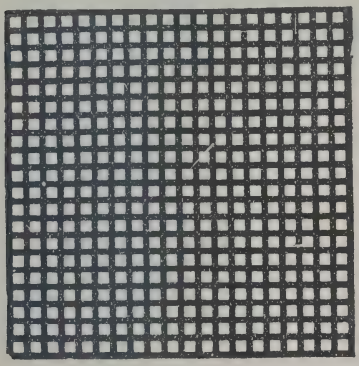
Where gases rise directly upwards from a grate amongst water tubes without the admixture by travel pointed out above, smoke is inevitable.

Fine dust fuel can now be burned at the rate of 40 lbs. per sq. ft. of furnace area per hour. Given furnace room, the cheapest fuel is usually the most economical. In practice the best

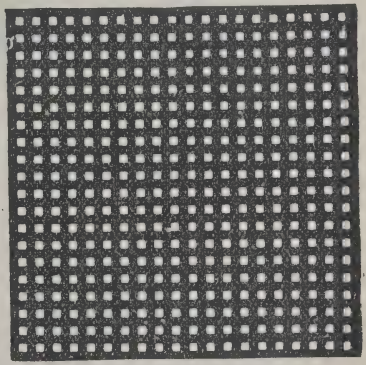


economy is that due to the use of the cheapest fuel which can be employed to raise the steam necessary.

The foregoing, of course, is qualified by the amount of ash in the coal where the extreme of removal is great.



With externally fired boilers which permit of a liberal design of furnace with suitably disposed firebrick, smoke can readily be prevented. It is less easy to secure perfect combustion with internally fired boilers, because of the difficulty of applying durable firebrick linings. But the question of smoke prevention is wholly one of air mixture and temperature. The burning gases must not too soon be brought into contact with cold plates or tubes.



2. Light grey smoke.

3. Darker grey smoke.

4. Very dark grey smoke.

5. Black smoke.

FIG. 8.

In burning bituminous coal only a part of the total heat is generated at the grate. Part of the heat of the fuel is absorbed in driving off the volatile parts of the coal in gaseous form. This heat becomes latent and very materially reduces the furnace temperature. The gases pass off, containing a third of the total heat capacity of the coal, as well as the heat of gasification. Unless mixed with air and burned later, these gases may be totally lost. To burn bituminous coal not only demands thorough air mixture, but also a sufficient temperature, and the heat of the burning gases must not be abstracted by too early bringing them into contact with the cool surfaces of the boiler. Sufficient length and clear space must be afforded for combustion to complete itself, or black smoke will be formed. The furnace arrangements of the Lancashire boiler are correct in

form, but the water-cooled plates are a hindrance to certain combustion in the case of hand-firing: when high temperature mechanical-stoker conditions are obtained, however, it is much easier to prevent smoke with bituminous coal in a Lancashire boiler than it is in a water-tube boiler.

Water-tube boilers require a special setting to enable them to burn coal smokelessly. No furnace can be smokeless where the gases from the fire rise vertically and pass amongst cold-water tubes. Bituminous fuel can rarely be burned satisfactorily unless there is some extent of firebrick lining to protect the gases from too early chilling. Cross water-pipes in the inner flues of the Lancashire or Cornish boiler are bad, and will seriously hinder perfect combustion and produce black smoke.

Colour of Smoke.

The colour of smoke is best indicated by Ringelmann's smoke charts, which are numbered from No. 1, all white, to No. 6, all black. In fig. 8 intermediate sizes 2, 3, 4, 5, are shown, the ratio of line to space breadth being respectively, 10 : 90; 23 : 77; 37 : 63; and 55 : 45. Large charts drawn to these proportions and hung about 50 feet from the observer where the chimney top can be seen simultaneously, if possible, are very great aids in correctly estimating the relative blackness of smoke.

The four scales of the figure are called light grey, darker grey, very dark grey, and black, the extreme all white or all black being respectively no smoke or dense black.

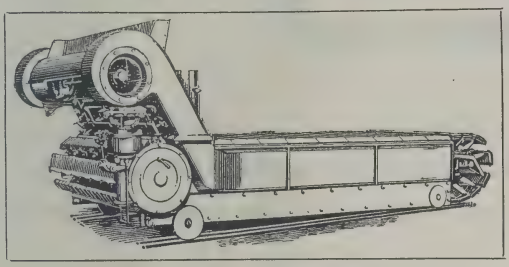
MECHANICAL STOKERS.

Mechanical stokers are of two types, coking, and sprinkling. In coking stokers the combustion of the volatile hydrocarbons contained in the fuel is effected at a different portion of the grate surface from the combustion of the fixed carbon or coke. Sometimes an independent air supply is provided for the combustion of each portion of the fuel. In coking stokers the fuel is usually fed on to the front of a moving grate, the volatile portion being expelled and burnt near the front, while the fixed portion is burnt whilst being conveyed towards the back of the fire by the movement of the grate surface. The incombustible portion of the fuel (ash) is dropped into a chamber behind the grate. The movement of the grate surface may be reciprocating, or it may be a continuous movement backwards. The 'Underfeed' class of grate also belongs to the coking type. In this class the fuel is forced onwards and upwards in a central trough by a helix conveyor or ram; it rises along the whole length of the trough, to the apex of the grate surface which is like a flattened $\wedge$ in cross-section; the hydrocarbons are expelled and burnt near the apex, and the coke is supposed to be burnt whilst it is conveyed (often by a rocking movement of the overlapping grate-bars) to the sides of the furnace. In sprinkling stokers the fuel is thrown on to the grate surface by means of a throwing shovel or equivalent device, and almost the whole of the grate surface is utilised for the combustion of both volatile and fixed portions of the fuel. The furnace bars of this type of stoker are usually given a reciprocating movement in order to provide for the continuous and automatic removal of clinker.

The relative advantages of the two types of machine stokers depend largely on the class of fuel to be burnt; but, in general, it may be said that, if properly worked, the sprinkling type will usually generate more steam from a given boiler, and with at least equal efficiency. On the other hand, with coals containing a high percentage of volatile matter, machines of the coking type can be worked smokelessly with less skill on the fireman's part than is needed by sprinkling machines.

The Babcock and Wilcox Patent Improved Mechanical Chain Grate Stoker.

The grate of this stoker (*Babcock & Wilcox, Ltd.*), as illustrated on page 1493, consists of an endless chain of short interlocking cast-iron grate bars, linked together, running on angle irons and rollers, and driven by a revolving shaft and sprocket wheels at the front end of the stoker. The necessary power to drive the revolving drum is transmitted through a link chain and sprocket wheels from a shaft arranged either overhead or underground. The starting or stopping of the stoker, or the variation of speed, is effected through the Babcock and Wilcox patent gear box, which can be driven at varying speeds. This box forms an oil bath in which the gear runs, and also contains an efficient clutch for putting the driving gear out of action should any unusual strain arise from an obstruction on the grate. Any small repair, such as replacing a link, can be carried out with the stoker in place under the boiler; but in case of need the whole stoker can be brought out clear of the boiler, the frames being provided with wheels running on rails placed at the sides of the ashpit. The slack of the chain can be taken up from the front end of the stoker, thus avoiding the necessity for obtaining access to the back end for tightening the grate. The grate bars or links are of a special interlocking pattern, which allow the smallest coals to be used, and, while providing for an ample supply of air for the combustion of the fuel, prevent the influx of cold air at the back of the grate. The coal is fed over the whole width of the grate, and the depth of the fire is regulated by the adjustment of the vertically lifting fire-door.



The feed of the coal is slow, and the gas evolved from the fresh fuel as it drops on to the grate readily perfects its combustion by passing over the incandescent fuel further on. The depth of the fire being regulated by a vertically lifting fire-door, the stoker can be adjusted in

a moment to suit the class of fuel to be consumed and varying demands for steam, both by the depth of the fire and the speed of the grate. Where the special requirements of the work make it desirable, the stoker can be fitted with an arrangement of vanes for cutting off the air supply to a portion of the grate during periods of light load, thus enabling the general efficiency to be kept up under all conditions of work.

Babcock & Wilcox also manufacture forced draught boxed-in chain grate stokers for efficiently burning low-grade and other difficult fuels. When average quality coal is used forced draught is not necessary, and by simply opening the two front ashpit doors—an operation occupying only a few minutes—the stoker can be used as an ordinary natural draught plant.

The Bennis Sprinkler Stoker.

This apparatus, fig. 9 (*Ed. Bennis & Co. Ltd., Little Hulton, Bolton*), affords a perfectly regular output of steam under the most trying conditions; its flexibility permits a rapid response to urgent demands for increased steam. Minimum labour costs, low fuel bills, and smokelessness are a few of the leading advantages that accrue where the sprinkler stoker is in

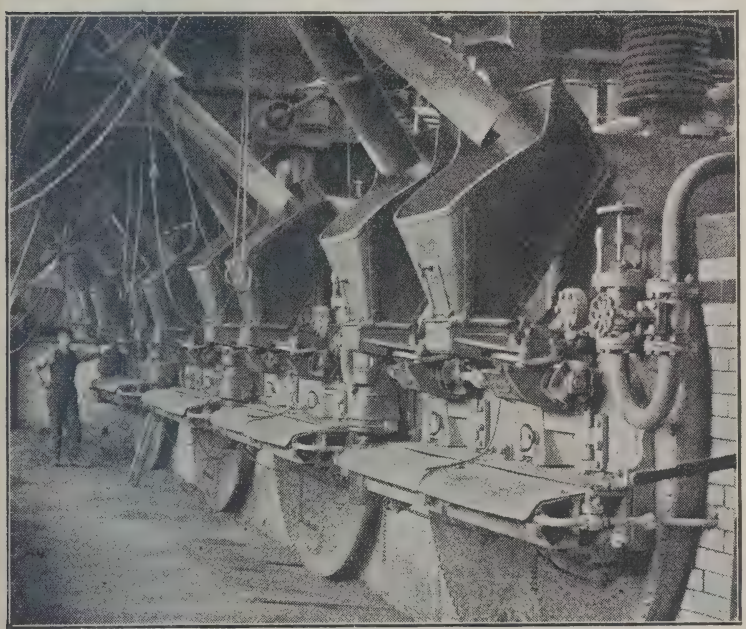

Fig. 9.

operation. The fuel fed into the hopper of the stoker—preferably mechanically fed—is led to the front of the pusher plate where it is evenly pushed over a ledge formed by the base of the feeding-box. The weight of fuel pushed is regulated, the fuel being deposited on to a flat plate called the shovel box, and then projected into the fire at intervals by an angular shovel actuated by patent pneumatic gear and effectually scattered over different portions of the grate where and as the fire requires it.

The pneumatic gear actuating the shovel, which includes an air cushion to obviate the possibility of shock or jar on the boiler front, is noiseless in operation.

An integral portion of the sprinkler stoker is the self-cleaning compressed air furnace, which prevents clinkering, and ensures perfectly clean fire-bars.

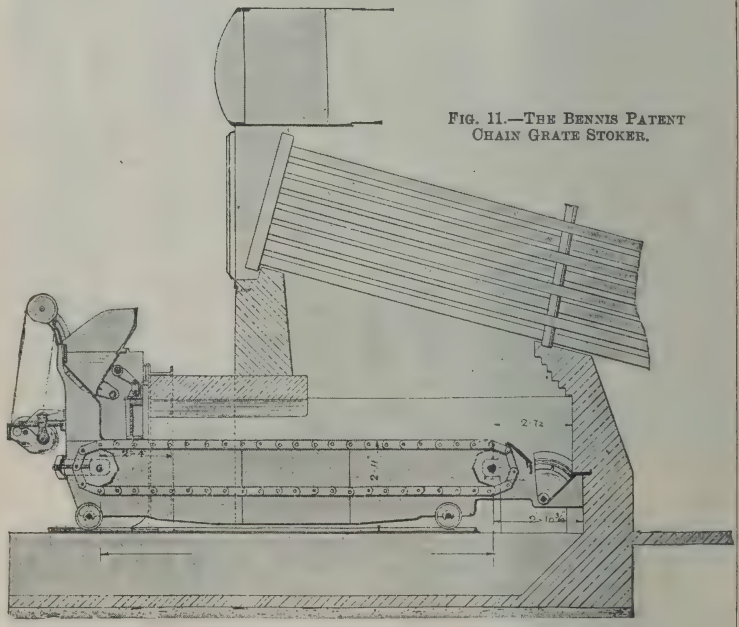

FIG. 11.—THE BENNIS PATENT CHAIN GRATE STOKER.

THE BENNIS HIGH TEMPERATURE SMOKELESS AND GRITLESS COKING STOKER.

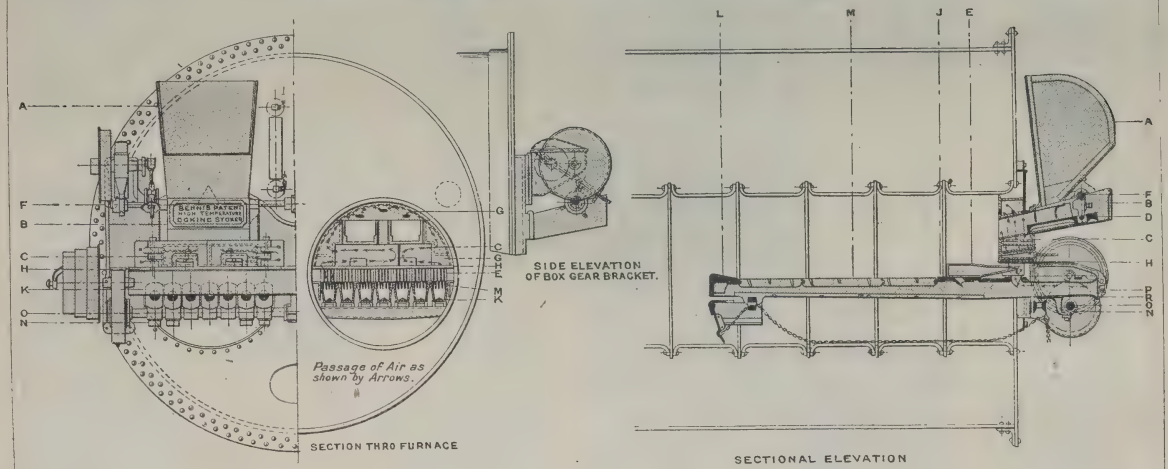

FIG. 12.

The Bennis Self-Cleaning Compressed Air Furnace Arranged for Hand-Firing in Collieries.

This furnace, fig. 10 (*Ed. Bennis & Co. Ltd., Little Hulton, Bolton*), thus arranged burns any class of fuel, large or small, and burns with special advantage poor quality and refuse fuels, pond settlings, coal pickings, large lumps or small, coke dust, shale, or material which contains a large percentage of ash or clinker. With such refuse it is stated to be able to generate steam as quickly as furnaces fitted with stationary bars burning a higher grade coal. The furnace consists of a strong cast-iron front lined with fire-brick, and fitted with a door of ample size for hand-firing.

The Bennis Patent Chain Grate Stoker.

This arrangement, fig. 11 (*Ed. Bennis & Co. Ltd., Little Hulton, Bolton*), is applicable to any water-tube boiler or to return-tube boilers—where the fire is under the boiler shell and the flame returns through the tubes—to brewers' coppers and similar furnaces. One of the principal advantages claimed for this particular chain grate is that a larger grate area can be obtained under the boiler than with those of other makes. The Bennis chain grate with the patent halved link was the first chain grate capable of satisfactorily burning fine slack coals. There are many improvements connected with this grate, in addition to the central improvement which gives to the grate its distinction.

The chain grate stokers at Neasden, London, N.W., the power station of the Metropolitan Railway, have all been fitted with the Bennis improved link, in the place of that of another make, with the result that considerable economies have been effected by using cheaper coal.

The Bennis Coking Stoker.

This stoker, fig. 12 (*Ed. Bennis & Co. Ltd., Little Hulton, Bolton*), is an improvement on the ordinary type of coker, as it ignites the fuel and cokes it at a more rapid rate than is possible with other types. It is claimed that the immediate result is a higher evaporative boiler duty and greater economical efficiency. It consists of a machine supplied with hoppers into which the fuel is fed. Beneath the hoppers are duplicate feed-boxes with reciprocating feeder rams which feed the coal into the furnace intermittently. A sight hole situated between the feed-boxes makes it easily possible to ascertain the state of the fire at any moment. The feeder rams are worked by means of levers. The rate of the coal feed is easily adjustable. Large air-cooled fire doors are provided beneath the feeder-boxes, their object being to pass cool air into the protection plates fitted immediately round the stoker front on the fireside, thereby preventing damage to the stoker front and also to the boiler.

The Underfeed Stoker.

In this stoker (*The Underfeed Stoker Co. Ltd.*) the fresh fuel for the maintenance of the combustion is continuously supplied from *below* the level of the fire and gradually advanced upward to the zone of combustion by the mechanism shown by fig. 13.

A is a retort or fuel magazine, in the lower or circular part of which revolves a taper-feeding worm which conveys the coal; B, terraced grates; C, windbox; and D, green coal; the latter being gradually pushed up to the burning point, commences to ignite at the point E, where it

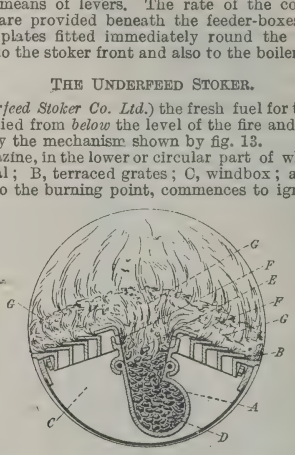

Fig. 13.—Cross-Section of Underfeed Stoker in the Flue of a Lancashire Boiler.

meets the incoming air from the tuyeres F and F'. Here the coal is coked, i.e. deprived of its volatile hydrocarbon gases. This being mixed with air introduced at this point through the air inlets of the fuel magazine, and escape being possible only by rising through the glowing coke above, the gases are heated to such a high temperature that they are completely consumed without smoke, while the combustion of the fixed carbon of the coal is completed by the air introduced through the apertures in the sides of the terraced grates B.

The effect of this method of underfeeding is to keep a continually clear, bright surface of incandescent fuel, combustion with even highly bituminous coals being complete.

The Underfeed Stoker Co.'s Class 'A' Stoker.

In this stoker, the unit idea of construction adopted combines the impelled draught fans and driving mechanism with the grate itself, with many resulting advantages. It will be seen from fig. 14 that the fans are mounted one on each side of the fuel hopper, with short, easy connecting air ducts leading to the air chambers of the grates. The driving motor, bolted to a base plate which forms the front side of the hopper, has its armature shaft extended at each end to carry the fan wheels. This shaft runs at from 850–1,090 r.p.m., and by means of a chain of the 'silent' type in conjunction with a worm and wheel, both encased in a common chamber, the speed is reduced to 9–10 r.p.m. From this mechanism a direct connection is made to the grate

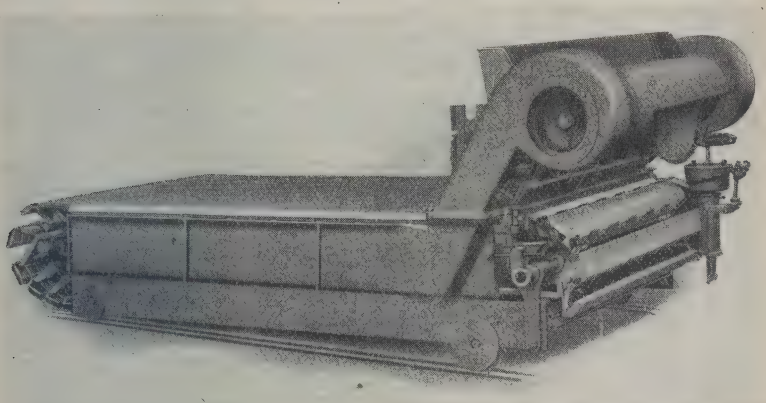

Fig. 14.

change-speed gear. This gear has eight different adjustments for speed, varying the travel of the grate from a combustion of fuel for 8 lbs. per sq. ft. to 60 lbs. per sq. ft. of grate area.

The whole of the driving mechanism, whether high speed or low speed, runs in dust-tight oil bath chambers, and the oiling arrangements are reduced to the greatest simplicity. Some of the advantages claimed are :—The reduction of the power required to drive the complete machine, comprising fans and grate, to one-third of one per cent. of the steam generated by the boiler ; the removal of the dust and dirt of the boiler room at the point where it is created, thus keeping a clean, well-ventilated room ; the avoidance of large air-carrying ducts, and what was formerly the necessity of breaking joints with duct at such times as it was necessary to remove the stoker from the furnace.

The air pressures employed in the air chamber of the stoker vary from $\frac{1}{4}$ in. to $\frac{7}{8}$ in., depending upon the nature of the fuel. The higher pressure is employed in such fuels as coke breeze, which is very fine in texture and lies very closely upon the grate.

The Underfeed Stoker Co.'s Class 'E' Stoker.

In this stoker, figs. 15 and 16 (*The Underfeed Stoker Co. Ltd.*), the fuel is deposited by coal-conveying machinery or hand labour, in a large hopper, and conveyed under the fire by means of a reciprocating sliding bottom which runs the full length of the trough. As the coal rises from the trough it is distributed to the sides of the furnace by means of moving bars.

The coking and burning coal is constantly carried, by the action of the moving bars, to the dumping trays along each side wall, where the resulting clinker and ash are deposited. These dumping trays are operated by levers on the outside of the furnace, enabling the ash and clinker to be automatically discharged.

The sliding bottom is actuated by a steam motor shown in fig. 15 at C, the number of strokes of which may be varied from one in three minutes to fifteen in one minute, each stroke carrying into the furnace about 6 lbs. of coal.

The movement of the piston of cylinder C is transmitted directly through the piston rod to the crosshead D, which is bolted to the sliding bottom E. This sliding bottom extends the full length of the retort. The block B has the same movement as D and E ; thus the coal is fed by

THE GALLAGHER-CROMPTON
BAFFLE BRIDGE
for Boiler Furnaces.

(Patent.)

The above diagram shows the utility of the Baffle Bridge when 'cleaning out.' The live fuel, being banked up on the Bridge, prevents the inrush of cold air during the operation, thus obviating the cooling down of the flues, preventing loss of steam pressure, saving fuel, and enabling the fireman to remove the clinker more effectively and quickly, without withdrawing an undue amount of combustible matter along with it, while a much larger body of live fuel remains to restart the fires. The Baffle Bridge is suitable for all classes of coal and coke and can readily be adapted to all types of boiler furnaces with stationary grates, whether of the forced, induced, or natural chimney draught type.

block B from the bottom of hopper A on to the sliding bottom E, which not only carries it to the back end of the furnace, but forces it to rise the full length of the trough. As the coal rises in the trough, or coking retort, it is flooded on to the bars F. These bars are alternately moving and fixed. The moving bars work transversely to the retort. The extent of the movement is from ½ in. to 1 in., depending upon the size of the furnace and other conditions. On the bottom of each moving bar are cast two lugs which engage with the bulb of the longitudinal rocking bars H, shown in fig. 11. These rocking bars in turn receive their movement through the agency of two spirals and nuts, which mechanism is entirely outside the furnace. The nuts are bolted to the crosshead D and therefore reciprocate with the bottom E. The reciprocation of the nuts causes the spiral to rock to and fro.

The movement of the grates, in addition to carrying the burning fuel to the sides of the furnace, also conveys the clinker down and deposits it on dump plates K, which are fastened to hinge-bar L This hinge-bar is actuated by a lever, conveniently placed outside the furnace, to dump the accumulation of ash and clinker into the ash-pit.

One of the important features of this stoker is the distribution of the air, which enters the stoker through the aperture N, controlled by the wind gate O. This wind gate is adjusted by the crank P. The air, upon entering the wind box Q, passes upward along each side of the trough, or retort, and is discharged, partly through the holes R, into the retort. The remaining air passes through the bars F, which are made hollow. These bars have no openings in their top surfaces, and no air can find its way into the fire above until it has passed through the aperture S at the bottom end of the bar, from which aperture it is discharged into the enclosed air chambers T. From here the air rises and passes through the small spaces between the bars into the coked fuel. The action of the air in passing through the bars keeps them cool, thus greatly prolonging their life. The heat taken off the bars in this way raises the temperature of the air in the air chambers T to from 350° F. to 400° F. The pressure of air in the chamber T varies from zero to ⅜ of an inch of water.

As the casing forming the air chambers T is sealed from the main ash-pit of the furnace there is no escape of air into the furnace when the dump plates K are dropped.

MECHANICAL DRAUGHT.

Various mechanical methods have been introduced for increasing the draught for boilers; this may be accomplished by an exhausting fan drawing the products of combustion through the flues, or by blowing air into a closed stokehold or an enclosed ashpit, and forcing the air through the fire with the necessary pressure, which varies according to rate of combustion desired. There is also a combination of these mechanical means, termed 'balanced draught,' in which air is forced under pressure into the ashpit by one fan and the gases are drawn off by an exhausting fan so arranged that there is neither pressure nor vacuum above the fire. Another method is the 'ejector draught' system in which the flue gases are drawn up the chimney by a high speed jet of air.

The advantage of mechanical draught produced by a fan is that the first cost is less than half that of a chimney: also the draught is independent of atmospheric conditions, can be varied instantaneously to suit the demand for steam, permits of economisers, and allows the reduction of the temperature of the waste gases to be carried to the lowest practicable point. It increases the capacity of the boiler, and permits of a more perfect combustion with less excess of air. It allows the use of lower grade and less expensive fuel, and so produces steam more cheaply.

Any desired rate of combustion from the normal of 20 lbs., to 30 or 40 lbs. of coal per square foot of grate area, may be maintained with a mechanical draught plant. The air volume required depends upon the style of boiler, condition of boiler setting, skilful stoking, the kind of coal used, and other factors; in round numbers 250 to 300 cub. ft. of air will be required per lb. of coal; these figures represent about 12 per cent. and 10 per cent. CO_2 respectively.

To drive a fan requires about ½ to 1 per cent. of the total power generated. The full benefits of mechanical draught are only obtained where means are employed to utilise to the fullest extent the heat of the flue gases (by means of superheaters or economisers) before the latter are discharged into the chimney. The cost of installing a fan and engine is very much less than the cost of a chimney, so that mechanical draught is economical in first cost.

Fan draught enables a heated air supply to be employed, and it is said that by heating the air supply to 180° the fire temperature will be raised an additional 360°, owing to better combustion, etc.

The Musgrave System.

(Musgrave & Co. Ltd., Belfast.)

To obtain flexibility and perfect control in a mechanical draft installation, an independent fan drive by steam engine or electric motor is preferable to a drive from a line shaft by means of belt or rope. The speed of the engine or motor can be immediately adjusted to suit the varying draft requirements, and in suitable cases an entirely automatic control can be utilised.

To obtain maximum economy the design of the fan must be correctly proportioned to the

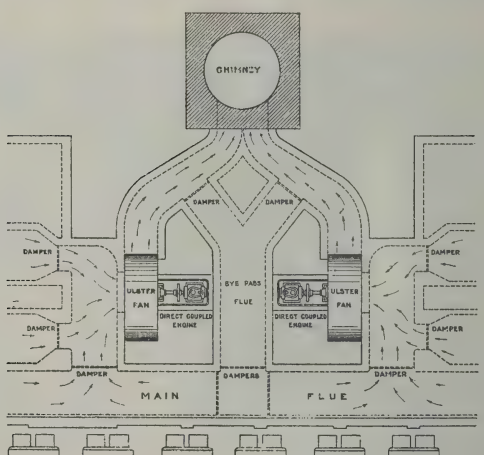

Fig. 17.

required duty, so that the air supply necessary for efficient combustion may be obtained with the minimum expenditure of power under all conditions. All flues should be as short and direct as possible, avoiding all unnecessary bends, changes of section and obstructive dampers.

Reliability is assured by the provision of ample bearing surface on engine and fan bearings, liberal design throughout, an efficient water cooling system to the fan bearings in the case of induced draft work, and fans of sound scientific and mechanical design.

Fig. 17 shows a well-designed arrangement of two engine-driven induced draft fans working in conjunction with a large battery of Lancashire boilers. The plant is compact and accessible, and the passage of the gases from the boilers to the stack direct and unobstructed.

The Sturtevant Systems.

Figs. 18 to 19 show the various systems installed by the *Sturtevant Engineering Co. Ltd., London*, which are in use in power stations, workshops, factories, warships, passenger and freight steamers, etc.

Induced Draught (fig. 18). This is the most commonly adopted system, as it is generally applicable to an existing boiler installation, and is economical in operation. The products of

combustion are drawn through the flues, economisers, etc., by an exhaust fan, and discharged to an existing stack or to a short length of steel chimney built just high enough to carry the gases above surrounding buildings. The fan is fitted with water-cooled bearings.

Forced Draught (fig. 19) is advantageous for burning small or low grade fuel. The fan blows air under pressure into the closed ashpit, and the gases are discharged either to existing stack or short steel chimney. For ship use the closed stokehold method is generally used.

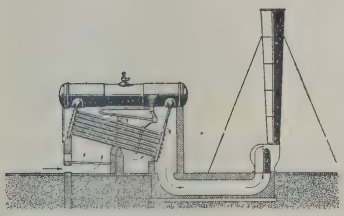

FIG. 18.

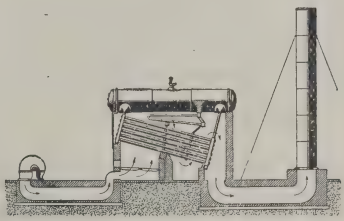

FIG. 19.

Balanced Draught (fig. 20) is a combination of induced and forced draught. Air is forced under pressure into the closed ashpit by one fan, and the gases are drawn off by an exhausting fan so arranged that there is neither pressure nor vacuum above the fire. This is only used in special cases, owing to the cost being much higher than either fig. 18 or fig. 19.

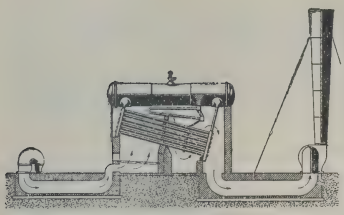

FIG. 20.

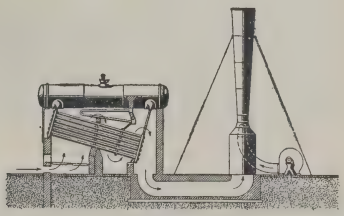

FIG. 21.

Indirect Induced Draught with Ejector (fig. 21). The combustion gases are drawn up a chimney of special design by the effect of a high speed jet of air, which if desired can be mixed with a portion of hot gases. This system is of special value in cases where the flue gases are corrosive or excessively hot, as they need not pass through the fan. This plant requires very careful designing, otherwise the efficiency is very low indeed.

THE HOWDEN FORCED DRAUGHT SYSTEM.

The principles on which this system of forced draught (*James Howden & Co. Ltd., Glasgow*) is based are (1) the supplying under pressure of hot air for combustion in quantities suited to the quality of coal used; and (2) the utilisation of the heat in the waste gases for the purpose of raising the temperature of the air for combustion.

Briefly stated, the following are the principal advantages of this method of combustion :—

(1) Great increase in the steaming power of the boilers. (At least 30 per cent. and probably much more over best natural draught conditions. Probably as much as 50 per cent. could be obtained if necessary, though quite such a high rate is not recommended for regular working.)

(2) Unequalled economy in fuel. (At least 10 per cent. and frequently 15 per cent. per lb. of water evaporated over the best natural draught conditions and probably much more.)

(3) Reduced size and weight of boilers for a given power, giving correspondingly additional space available for other purposes.

(4) Complete control of combustion and steam supply under all conditions of the atmosphere. (With this system of draught the volume and pressure of the air for combustion is entirely controlled by the fan and the manipulation of the air valves in the furnace fronts.)

(5) Capability of burning all classes of steam coal. Low grade fuel can always be burned satisfactorily where this system of forced draught is applied. Under natural draught conditions this is often difficult and sometimes impossible owing to the inability of supplying the greater volume of air always required where the greater quantity of inferior fuel is used. For the reasons stated in (4) this difficulty is surmounted, the additional quantity and pressure of air necessary being easily obtained by running the fan a little faster.

(6) Preservation of the boilers on account of the more uniform temperature maintained in the furnaces. Boilers fitted with the Howden system of draught are less liable to the leakage and trouble generally present under natural draught conditions; the reasons being that no cold air ever enters the furnace during the period of working, and much greater uniformity of temperature is maintained than under natural draught conditions. Sudden alternations from heat to cold, and the consequent contraction and expansion, have an injurious effect on the internal parts of steam boilers, and such sudden fluctuations in temperature are prevented by the use of this system. When the furnace doors are opened the air pressure in the ashpit immediately ceases, and only the hot air from the upper air supply valve passes into the furnace, first in a direction vertically downwards, thereby forming a hot screen over the furnace mouth and preventing access of cold air. Such conditions when firing or cleaning fires are also conducive to economy. The benefit of the system regarding fluctuations of furnace temperature is most marked and appreciated when it is compared with the working conditions of the closed stokehold system. In the latter a considerable air-pressure is generally used, so that the fluctuation in temperature of furnace is both rapid and violent and puts a severe strain on the boiler structure. This is quite obviated in the Howden system.

(7) Reduction of smoke.

(8) No high chimney required. For land installations a small iron funnel, sufficient to carry off the waste gases clear of the surrounding buildings, is ample for the purpose.

(9) Coolness in boiler-room and ease of working. With this system the air casing, reservoirs, and furnace fronts on the boiler end effectually prevent radiation into the stokehold, which is thereby kept quite cool, making the work easier than with the closed stokehold system, which is very trying for the firemen.

(10) Great reserve power available in case of emergency.

The general arrangement of the Howden system consists of a fan (driven by a steam engine, electric motor, or belt), which supplies the air for combustion, discharging it through a conduit into the air-heating chambers. In these air-heating chambers the air circulates round a series of tubes. The waste gases, after leaving the boiler, and before entering the uptake, pass upward through these tubes in the air-heating chambers, or in the Lancashire type of boiler horizontally through tubes in air heaters in the side flues, thus giving up part of their heat to the air, which then passes along passages into air-tight reservoirs or chambers surrounding the furnace fronts. From these chambers the air is passed through furnace fronts by valves into the ashpits, and over the fires through air distributing boxes in proportions exactly suited to the kind of fuel used and the rate of combustion required, thus ensuring a very perfect combustion of fuel.

In the furnace fronts the ashpit air valves are operated by one handle, and a safety locking device is also fitted, which prevents the furnace door from being opened until the ashpit air valves are closed. In marine type boilers, retarders are also fitted (one in each boiler tube).

Silley patent smokebox door fastenings form an important adjunct to the forced draught apparatus. These fastenings ensure a thoroughly air-tight smokebox and entirely obviate the trouble usually experienced with buckling, etc., in doors secured by other methods.

At the present time there are about 6,600 installations of the Howden system fitted, and the number is rapidly increasing every year. The aggregate i.h.p. of these is over 24,000,000. They comprise steamers for almost all the principal steamship companies of the world, and a considerable number of installations on land boilers. Many warships, and the principal fast Channel steamers, are also fitted with the system.

PULVERISED COAL.

(Contributed by L. C. Harvey, London.)

General.

Coal in pulverised form was first successfully applied to cement burning kilns. This method of heating cement kilns has now become universal practice, the steady long flame with its resulting continuous and unvarying heat development inside the rotary kilns being ideal for this work. Moreover, the ash which has always been a source of trouble in other applications does not apply in this industry, where ash forms a useful addition to the ultimate product.

For cement burning the coal is reduced to a fineness of about 80 per cent. through a 100-mesh screen (10,000 holes to the square inch). This is now considered to be a coarse degree of fineness.

For metallurgical work coal is reduced to 85 per cent. through a 200-mesh screen (40,000 holes to the square inch). This fine degree of coal-dust, coupled with a low pressure on the air supply, thereby decreasing the velocity of the gases passing through the furnace or boiler, has resulted in the removal of the former troubles due to the formation of ash slag in chequer-work, on metal to be heated, or on boiler tubes.

Mill House Plant.

Fig. 22 shows an outline arrangement of a typical coal pulverising plant.

The coal delivered by rail wagon is crushed to ¾-in. cube and passed up the No. 1 elevator to the crushed coal storage bin.

From this bin the crushed coal is fed by gravity into the rotary drier, wherein the moisture content of the coal is reduced to 1 per cent.

From the drier the coal passes up No. 2 elevator to the dried coal bin, passing over a magnetic separator pulley in order to remove iron bodies from the coal, and is fed by gravity into the pulveriser.

The latter may be a mill of the 'air separator' or 'screen separator' type.

Screen separator mills, such as the 'Fuller,' made by the Fuller Lehigh Company, have been universally used in the cement industry for pulverising the coal and for grinding the cement clinker. In this type of mill the fine particles of coal are thrown tangentially through the mill screen; the fine product is then raised by means of No. 3 elevator to the powdered coal bin, or it is delivered direct into the screw conveyor or into a Fuller-Kinyon pump, for transport to the bins at the furnaces.

In the air-separator type of mill the fine coal-dust is exhausted through a fan and deposited by means of the upward air current into the cyclone collector, whence it is delivered into the powdered coal storage bin, or direct on to the screw conveyor in the manner shown in the figure.

A great number of the American companies supplying special powdered coal apparatus, or systems, use the screen separator 'Fuller' mill, but certain firms prefer the air-separator type, such as the 'Raymond' or special 'Fuller' mill, whilst the Bonnot Company, which controls the Holbeck patents, supplies the 'Bonnot' type of air-separator mill.

'Griffin' roller mills are also in use in a few instances for pulverising coal.

The air-separator mill combination requires considerably more power, but tends towards a cleaner mill house than the screen separator outfit.

Coal Driers.

These are fitted with furnaces, either hand fired, stoker fired, or arranged for burning powdered coal. The hot gases from the furnace should not pass through the drier in direct contact with the coal until these gases have been considerably cooled off. Some of the driers are fitted up so that the hot gases do not pass over the coal before they have travelled the full length of the drier through a central tube, when they are diverted into the outer portion of the drier and pass back to the furnace end in direct contact with the coal.

The average coal consumption in the drier is about 20 to 30 lbs. of coal per ton for a reduction of 10 per cent. in the moisture content. When coal is very wet it then becomes necessary to pass the coal twice through the drier. The final temperature of the coal leaving the drier should not be above 250° F.

Transportation of Pulverised Coal.

The original method of transporting coal-dust was by means of weathertight screw conveyors, and this method, Fig. 22, p. 1796, is very extensively used at the present time.

The Quigley Furnace Specialities Co. have recently introduced an excellent system of transporting the coal-dust from 'blowing tanks' situate at the mill house. The coal-dust is forced from these tanks by means of compressed air applied to the top of the coal, and the coal is forced through 3-in. or 4-in. pipes to the bins at the furnaces.

Semi-automatic solenoid controlled switch valves are placed at the branches from the main supply pipe. This method of transportation is very compact, convenient, and successful in use.

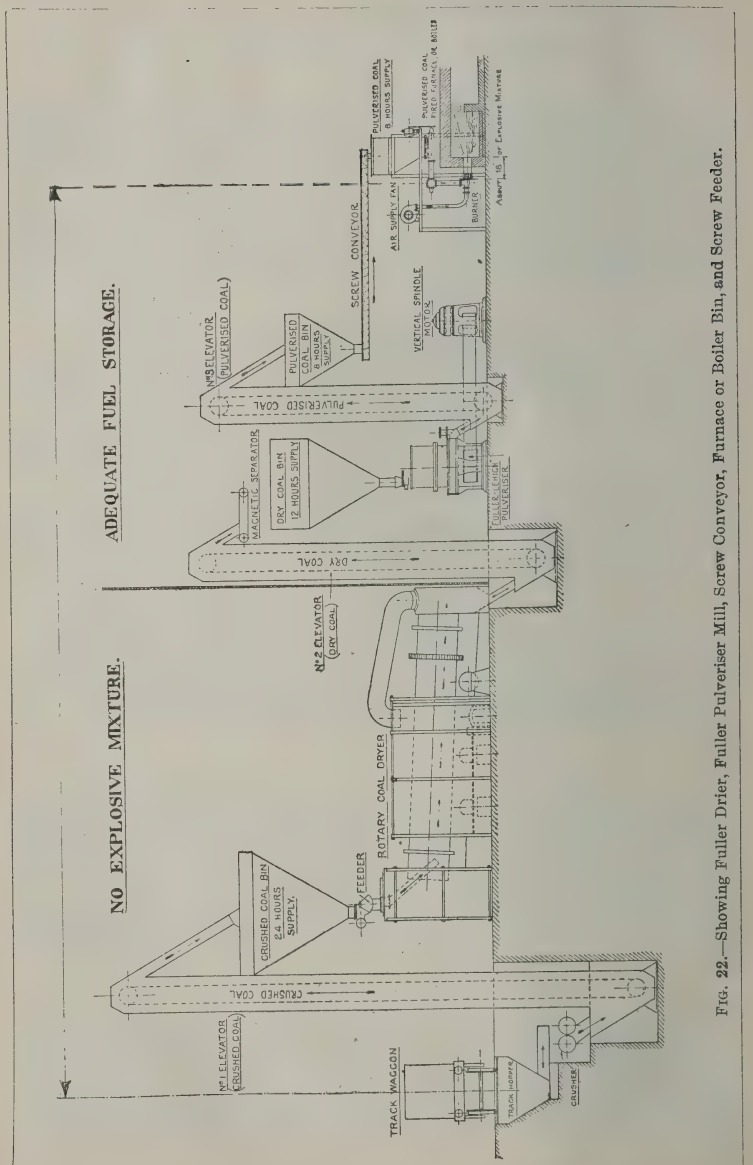

FIG. 22.—Showing Fuller Drier, Fuller Pulveriser Mill, Screw Conveyor, Furnace or Boiler Bin, and Screw Feeder.

THE FULLER-KINYON PULVERISED COAL PUMPING SYSTEM.

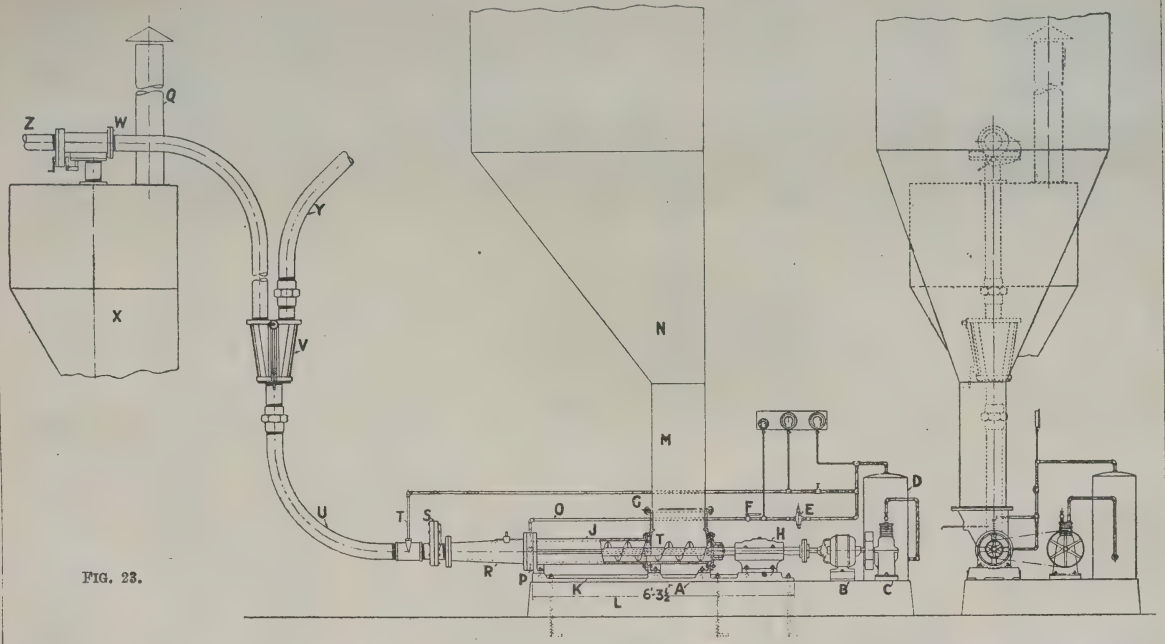

FIG. 23.

A, Fuller-Kinyon 6" Pulverised Material Pump. B, Electric Motor. C, Air Compressor. D, Air Receiver. E, Pressure Reducing Valve.

S, Single Diverting Valve. T, Conduit Clearing Air Line. U, Convertor Conduit. V, Distributing Valve. W, Double Diverting Valve.
X, Receiving Bin. Y, Branch Conveyor. Z, Continuation of Conveyor.

In another system, the 'air-transmission system,' the coal-dust is mixed at the mill house with approximately 50 per cent. of the air required for combustion. The mixture is forced through the supply pipes at a velocity of about a mile a minute, and ordinary branch pipes are taken to the furnaces. No furnace bins are therefore needed with this system. Care must be exercised in arranging this system to suit existing conditions, so that danger of accidental explosion taking place in conveyor mains may be realised and necessary precautions taken.

The Fuller-Kinyon system of pumping powdered coal through supply pipes has now been developed by the Fuller Engineering Company, whereby a small quantity of air delivered by a pressure blower is pumped into the powdered coal to prevent 'packing,' so that the fuel can be transported long distances with a minimum of power. Ordinary pipes are used which can be laid underground or placed overhead in the same way as for water pipes. (See Fig. 23.)

Feeders.

Whenever coal-dust is supplied to furnace bins, feeders fitted with screws or worms must be employed to introduce the dust into the air-blast as it enters the furnace.

The screw or worm of the feeder is usually operated by means of a variable speed motor, but the Quigley Company now supply feeders with adjustable jaws to govern the supply of dust, and in this way constant-speed motors can be used.

In the Holbeck air-transmission system no feeders at all are required.

Burners.

A coal-dust burner is usually of very simple construction. It merely consists of an air-carrying supply pipe into which the coal-dust is fed by the screw feeder.

Some special burners have been devised whereby a premixing of coal-dust and air is effected before the final stream of air for combustion is introduced.

Power of Motors.

Mill House Plant (for 40 tons per 10 hours).

Preliminary crusher (not required with slack coal)	15 to 20 h.p.
Nos. 1, 2, and 3 elevators	5 h.p. each.
Drier	10 to 15 h.p.
Pulveriser mill, screen separation	60 „ 75 h.p.
„ „ air „	80 „ 100 h.p.

(Mill capacity, 4 to 5 tons per hour.)

Fuel Transportation (say 5 tons per hour, 300 ft. and 40 ft. lift).

*By screw conveyor	15 h.p. (motor).
†By air pressure	75 „ (compressor).
*By air mixture	60 „ (fan mixer).
*By screw pump	20 „ (screw pump and compressor)

* Continuous operation. † Intermittent operation.

Coal-dust Feeders.

Constant or variable speed motors . . . . . 1 to 3 h.p.

(½ h.p. motors are sometimes used, but are generally unsuitable under mill conditions.)

Air Fans.

No accurate figure can be given for the power required for air fans, as this will depend upon the size of burner used. The total quantity of air per pound of coal allowed is usually 180 cub. ft., 120 cub. ft. being supplied at a pressure of 3 or 4 ozs. per square inch; the remainder is induced at the burner

Progress in America.

The amount of pulverised coal used in the U.S.A. up to 1912, chiefly in the cement industry, was approximately six million tons per annum. Since this date in the copper, steel, and iron industries for locomotives and boiler work, and including the cement industry, the annual usage of coal in powdered form has been increased to some 18 million tons. Pulverised coal firing has been adopted for use at a 200,000 kw. super-power station.

Self-contained Pulveriser Units.

The figures given in the table on page 1803 represent the capital outlay required for complete mill-house plants of various capacities. The initial cost of same, with transportation system, furnace bins, motors feeders, etc., necessitates an expenditure which, in many cases, will or can only be contemplated when actual results have proved that the collective advantages and economies thereby introduced render such an investment wholly attractive.

For smaller fuel requirements and for testing pulverised-coal firing upon individual boilers or furnaces, a self-contained pulveriser unit should be installed. The 'Aero,' 'Raymond,' or 'Stroud' machines are of this type, but built upon entirely novel principles is the 'Atritor' unit, which embodies the use of eddy currents of air within the grinding zone for the dual purpose of rapid agitation and deflocculation of coal particles and the exposure of maximum surface for driving off moisture. In this unit, therefore, is combined for the first time the operation of drying and pulverising.

Coal containing comparatively high percentages of moisture—20 per cent. or so—can be fed into the 'Atritor' pulveriser, and through the medium of hot air, up to 500° C., the resultant fuel powder will be practically bone dry. Coal containing 5 per cent. to 10 per cent. of moisture can be dried and pulverised with air at atmospheric temperature, the resultant degree of fineness depending upon the humidity in the atmosphere at the time of grinding.

By the installation of self-contained units the value of pulverised-coal firing for any specific purpose can be ascertained, so that the question of capital outlay upon a complete mill-house plant and attendant equipment can be based upon the results ascertained in this manner.

Pulverised Coal for Locomotives.

The advantages for pulverised coal, lignite, etc., as a locomotive fuel are—
30 to 40 per cent. fuel economy as against hand-firing, running mileage and cylinder power of engines increased, cost of firing tools and repairs to fire grating eliminated, no cinders or sparks from the smoke stack, reduction of fire-box strains, firing conditions with pulverised-coal firing analogous to oil-firing with similar fuel-bunkering facilities. Any local fuel within reason can be used.

The following fuels have been and can be used:

Pennsylvania anthracite culm	0·5 – 8·3	72·09	12·22	12,000
" bituminous	0·5 –33·0	57·50	9·0	13,750

A. Range of moisture. C Volatile matter.
B. Ash. D. Calorific value. B.T.U. per lb. (dry).

On the Lehigh Valley Railway a locomotive has been run on a mixture of 55 per cent. raw anthracite silt and 45 per cent. bituminous coal. Full steam pressure is maintained easily at all times, and the anthracite silt contains 38·42 per cent. of ash, and has a B.T.U. value of 9,675, while the soft coal which is mixed with this has an ash content of 11·6 per cent. and a B.T.U. value of 12,650. Analyses of these coals are as follows:—

Anthracite Silt.	Per Cent.	Soft Coal.	Per Cent.
Moisture	2·26	Moisture	1·90
Volatile	10·39	Volatile	36·59
F.C.	49·30	F.C.	49·89
Ash	38·42	Ash	11·60

Some approximate savings in fuel consumptions that have been realised in practice are as follows :—

Boilers—80 per cent. efficiency, and savings of 15 to 50 per cent. over hand firing.

Open-Hearth Steel Furnaces—a saving of 300 lbs. per short ton of steel as against producer gas for small plants.

Puddling Furnaces—a saving of 1,500 lbs. per short ton of iron over hand firing, and from 300 to 500 lbs. over mechanical stokers.

Reheating Furnaces—20 to 40 per cent. saving over hand firing.

Heavy Forge Furnaces—25 per cent. saving over hand firing.

Light Forge Furnaces—20 to 40 per cent. saving over hand firing.

Annealing Furnaces—30 per cent. saving over hand firing.

Tinning and Galvanising—20 to 30 per cent. saving over hand firing.

Sheet and Pair Furnaces—30 to 40 per cent. saving over hand firing.

Copper Smelting Furnaces—40 per cent. saving over hand firing.

Locomotives—30 to 50 per cent. saving over hand firing.

The output from many of these furnaces has been greatly increased by reason of coal-dust firing, what are known as 'stickers' in the tin-plate trade having been reduced 60 per cent., whilst the quantity of tin and zinc used has been reduced considerably owing, in a great measure, to the improved surface of the metal, and also to the more even heating of the kettles.

Reduced oxidisation of steel and iron heated in powdered coal-fired furnaces and increased life of annealing boxes have accounted for an annual saving of many thousand pounds in some works.

In a properly designed plant, and with due attention to ordinary common-sense regulations there is *no fear of explosion* from the coal-dust, and, as has been already stated, the old troubles with the ash slag have been overcome.

There are certainly many instances where the use of fuels in powdered form would show a handsome return for capital invested, and the following table will enable an estimate to be made as to economy that can be expected.

APPROXIMATE COST OF COMPLETE MILL HOUSE, PLANTS AND OPERATION EXPENSES.

(Average 1920 Figures.)

Daily Output in Tons.	Labour, Cost per Ton.	Power, Cost per Ton.	Drier Fuel, Cost per Ton. 2 per cent. of coal dried.	Repairs, Cost per Ton.	Without Stand-by Plant.				With Stand-by Plant.

Cost of plant exclusive of foundations and erection.

Table of costs is based on the following assumptions :—

Labour at £4 per man per 44-hour week.

Power at $1\frac{1}{2}d.$ per kilowatt hour and an average allowance of 20 kw. hours per ton of coal pulverised and delivered to the exit of mill house, including power for all operations. Driers to be fired with pulverised coal, which is taken as 40*s.* per ton at the drier burners; an average allowance of 2 per cent. of the coal dried is made for drier fuel, assuming the moisture content of coal to be reduced from 15 per cent. to 1 per cent.

Yearly output is based on 300 working days.

REFUSE DESTRUCTORS.

Calorific Value of Refuse.

The calorific value of refuse is about $\frac{1}{5}$ to $\frac{1}{4}$ that of an equal weight of good dry coal.

Average composition and calorific value of London ashbin refuse, containing the average percentage of water :—

Component parts of Refuse.	Amount in 100 lbs. of Refuse.	Calorific Value.
	Lbs.	B.Th.U.
Coal	·35	3,260
Coke	·15	1,200
Bones and offal	·37	1,970
Breeze and cinder	25·55	102,000
Rags	·40	1,330
Paper, straw, fibrous material, and vegetable refuse	13·15	33,100
Ash	47·00	Nil
Dust and dirt	9·75	,,
Bottles	·48	,,
Metals, including tins	·68	,,
Crockery	1·72	,,
Glass	·37	,,
	99·97	142,860

The above is the average of 1,000 cart-loads.

About 60 per cent. of the refuse is combustible.

The character of the refuse varies a great deal. In factory districts the percentage of unburnt cinder is high, whereas in residential districts with gardens it is much lower.

When it is considered that ordinary green garden refuse when piled in a heap over a nucleus of fire will consume itself, it is obvious that refuse containing cinders will contain enough heat, if properly applied, for its perfect destruction. It is essential that combustion should take place in brick cells, and that no heat should be abstracted until combustion is complete, after which the gases may be used for steam raising. If 40 per cent. only of the refuse is combustible, its calorific value per pound will be about 5,800 B.Th.U. if it were dry. Taking it only as 1,500, this is more than would raise the temperature of the whole gaseous and solid matter to a red heat. If half the weight were water, this would absorb about 600 B.Th.U. to evaporate and about 300 to become red hot, or 900 in all. The remainder of 600 B.Th.U. would raise the gases and solids to nearly 5,000° F. Thus destruction may be perfect with only the equivalent of one-tenth its weight of dry carbon. Inodorous combustion demands high temperature, and hence must occur in brick cells, with suitable movement of the fuel, so that the gases and steam cannot escape until fully incandescent.

Extract from Official Test of 'Heenan' Refuse Destructor at Pontypridd.

U.D.C. Electricity Generating Station, Treforest.

Date of test	February 10, 1910.
Plant tested	One unit (3 cells of 25 sq. ft.) 75 sq. ft. grate area, B. & W. Water Tube Boiler of 2,010 heating surface, Green's Economiser of 96 tubes, 4 ins. in diameter.
Duration of test, 10 A.M. to 6 P.M.	8 hours.
Weight of refuse burnt	18 tons, 1 cwt. 1 qr. = 40,460 lbs.
Rate of burning per hour	$\frac{18{\cdot}0625}{8}$ = 2·257 tons per hour.
Equivalent evaporation from and at 212° F. of destructor plant without economiser	3·223 lbs.
Mean temperature in combustion chamber over 8 hours.	2,437° F. (1335° C.)
Average percentage of carbon dioxide in products of combustion under boiler	14·65 per cent.
The station is working non-condensing, the consumption basis being 40 lbs. of steam. Estimated per kilowatt, the units generated on test (an equivalent of 151 units per ton of refuse)	2,724 B.Th.Us.
The actual was 104 B.Th.Us. The total, 1,905 B.Th.Us.	

Feb. 11, 1910. (*Signed*) J. E. Teasdel.

* This does not take into account steam wasted in blowing off.

Total works costs reduced from 1·10 to ·82 per unit—1,500*l.* per annum on 100,000 units per month (four weeks).

Value of coal 13·5 shillings per ton (2,240 lbs.).

Note, in the preceding tables, that from September 1908 to the end of January 1909 the destructor had not been installed. In the corresponding months of 1909 and 1910 note the large reduction in the coal consumed, notwithstanding the increased current consumption.

At Rotterdam Messrs. *Heenan & Froude, Ltd.*, have installed a large combined destructor and generating station. The refuse collected daily suffices to drive a 1,250 kw. generator and supplies current for operating the whole of the cars of the city. This is one of the largest and best equipped stations in the world, having a destroying capacity of about 500 tons per day of 24 hours, although, at the present time, only something approximating one-half of this is available.

The following tables give particulars of the evaporation and the electrical output, as well as the refuse burnt on representative weeks during the months of September and October 1912. It will be noted that the quantity of refuse collected and delivered at the Destructor Depot is an increasing one, and it will further be noted that the calorific value of the refuse during the winter months rises appreciably.

THE 'HORSFALL' DESTRUCTOR.

(The New Destructor Company, Ltd., Pershore.)

In the 'Horsfall' automatic tub-feed destructor the refuse arrives at the destructor in carts, being tipped through a shoot into storage tubs placed conveniently in a pit. Each tub will accommodate one cart or van load of refuse; when charged, the tub is lifted by an overhead travelling crane and deposited on the upper storage platform, level with charging door on top of furnaces. At regular intervals a cell is charged, a full tub being lifted by the crane and placed on a cradle on the top of the cell. The weight of the tub causes this cradle to descend, and by a simple system of levers a large charging door is lifted from its water-sealed seat and travels away, permitting the lower edge of the cradle to descend over the mouth of the charge hole. The crane continues to lower, and the bottom of the storage tub thereupon opens and the whole load of refuse falls directly into the furnace and spreads itself over the grate.

Immediately the refuse is discharged the crane lifts the empty tub, and by means of counterbalance weights the cradle ascends, bringing back automatically the large charging door which drops into its water seal, and the operation of charging is over, the time taken to deposit 20 to 30 cwts. of refuse into the furnace occupying about thirty seconds, and this is done entirely by one man who controls the crane.

In this tub-fed system no inclined road is necessary, the refuse is kept out of sight, and there is no hand shovelling required.

Good examples of this type of destructor may be seen in operation at Greenock, Leeds, Liverpool (Mersey Dock and Harbour Board), Poplar, and Zurich (Switzerland).

Several large 'Horsfall' destructor plants are at work in the tropics, the most recent installation being at Colombo, Ceylon, where about 60 tons of tropical refuse is dealt with per day, in addition to carcases of bulls, and other offal.

The 'Sterling' type of destructor is also manufactured by the firm, and successful plants on this system are in operation at Abertillery, Bath, Blantyre, Farnborough, Larkhall, Luton, Napier (N.Z.), New Stevenston, Manly (N.S.W.), Pembroke (Dublin), Sutton Coldfield, Sydney (N.S.W.), and Yeovil.

A special feature of the 'Sterling' destructor is the patent cast-iron surround to the grate, which is designed for durability, and is recommended where refuse of high calorific value is to be dealt with, such as is found in colliery districts.

Upwards of 150 destructor installations on the 'Horsfall' system have been erected in the United Kingdom and abroad, varying in capacity from 10 tons to 360 tons of refuse per day; also a large number of smaller plants have been installed in connection with hospitals, sanatoria, and factories.

The 'Horsfall' self-contained single unit destructor was adopted by the British and Allied Governments for use in military camps and hospitals during the recent war.

For dealing with small quantities of refuse in hospitals, factories, and small communities, the single unit self-contained destructors have proved highly successful, and have been very widely adopted.

The 'Horsfall' and 'Stirling' system of refuse disposal includes front-fed, back-fed, and top-fed furnaces, and many plants of all these types are still in work after twenty years' continuous service.

INFLUENCE OF INTRODUCTION OF DESTRUCTOR ON FUEL AND TOTAL WORKING COSTS OF ELECTRICITY WORKS.

NOTE.—The figures in black type indicate the year in which the Destructor's influence commenced to be felt.

The above figures are taken from the *Electrical Times*, and the fuel costs would include such payments as have been made by the Electricity Department to the Cleansing Department for steam supplied by the latter, and therefore the difference shows the saving made by the Electricity Department irrespective of the saving made by the Cleansing Department due to payments received from the Electricity Department, as referred to above.

LIQUID FUELS.

Whereas solid fuels are solely used for external combustion it is possible to employ almost all liquid fuels for either external or internal combustion. On comparing the most important liquid fuel petroleum with the most important solid fuel, coal, many remarkable advantages of the former over the latter are found to exist. The heat value of petroleum is some 50 per cent. greater than that of average coal, the stowage space being slightly less. Liquid fuels are more convenient to store (places inaccessible to coal may be employed) and are more easily transported than solid fuels. Liquid fuel is almost entirely free from ash. When used for internal combustion the thermal efficiency of liquid fuels is double that of the solid fuels used for power production. Certain liquid fuels can be employed in high speed engines, whereby a higher power per unit weight of engine is obtainable than by any other type of prime mover.

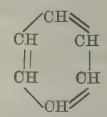
The most important liquid fuels are petroleum, shale oils, coal tars and their products, and lignite tars and products.

Petroleum.

Petroleum occurs in the earth, and is generally found in strata of conglomerate or of oil sands. It is generally accompanied by gaseous and also by solid hydrocarbons. The crude oil is usually brown or black, and the products of different fields vary greatly both in physical and chemical properties.

Petroleum consists almost entirely of carbon and hydrogen. These are present in the form of compounds known as hydrocarbons. Hydrocarbons may be divided into three main groups, known as aliphatic, aromatic and hydroaromatic hydrocarbons. These groups may be subdivided into numerous series, the members of which possess certain definite relationships between the number of carbon and hydrogen atoms present in the molecules. The physical properties of the members of these series generally progress by fairly regular steps. The carbon atoms in the aliphatic hydrocarbons are connected together in the form of chains, and the more important series of this type of hydrocarbons are :—

Paraffin Series.
General formula—C_nH_{2n+2}



Methane	CH_4
Ethane	C_2H_6
Propane	C_3H_8
Butane	C_4H_{10}
Pentane	C_5H_{12}

Olefine Series.
General formula—C_nH_{2n}

Ethylene	C_2H_4
Propylene	C_3H_6
Butylene	C_4H_8
Pentylene	C_5H_{10}

The carbon atoms of the aromatic compounds are connected together in the form of rings, a typical compound being :—

Benzene, formula C_6H_6 . . . .

The hydroaromatic compounds also contain carbon rings, but are richer in hydrogen than the aromatic hydrocarbons. A typical hydroaromatic compound is hexamethylene, C_6H_{12}.

Petroleum oils contain members of all these series, but the proportion varies according to the locality from which the oil has been obtained. Pennsylvanian oils consist mainly of aliphatic hydrocarbons, Russian oil mainly of hydroaromatic compounds. The products of the destructive distillation of coal consist mainly of aromatic compounds. Crude petroleum from Mexico and South America generally contains quantities of a viscous sulphur-containing body known as asphaltum, which has great influence on their properties as fuels. Little petroleum is consumed in the crude state, it being usual to separate it into fractions boiling over various ranges by means of repeated distillations. Many petroleum fractions are also treated with sulphuric acid and with caustic soda in order to remove certain undesirable constituents.

The principal fuels obtained from petroleum are :—

Benzine	boiling from 70°–150° C., 158°–302° F.	Specific gravity	·700–·760
Kerosene, illuminating, or paraffin oil	boiling from 150°–300° C., 302°–572° F.	„ „	about ·800
Gas oils, solar oils, etc. .	boiling from 250° C., 482° F. upwards.	„ „	„ ·850
Petroleum residuum, 'fuel oil,' boiling point varies greatly		„ „	·880–·950

The world's production of petroleum in 1918 was in round figures 67 million metric tons, and the U.S. production was about 46 million tons, or over two-thirds of the total.

The import of motor spirit or petrol into the U.K. in 1919 was 200 million gallons.

Benzine.

Benzine is the petroleum fraction from which motor spirits are prepared. Motor spirits are generally called petrol in this country. Petrol contains about 14 per cent. hydrogen and 86 per cent. carbon. Heavy fuel oils contain about 12 per cent. hydrogen and 88 per cent. carbon.

Kerosene.

Illuminating oil or kerosene, generally known in this country as 'Paraffin Oil,' possesses a specific gravity in the neighbourhood of ·800. It is slightly lower in calorific value than petrol, but on account of its higher specific gravity it yields more heat per unit volume of fuel. The ultimate composition of kerosene is approximately carbon 87 per cent. and hydrogen 13 per cent. Apart from illuminating purposes, kerosene finds frequent use as a fuel for vaporising engines. A large number of heavy distillates of petroleum are prepared for various technical purposes. Of these gas oil is probably the most important. Gas oil is prepared with a view to its use in the preparation of carburetted water gas or oil gas, and is also used as fuel for semi-Diesel and Diesel engines. It is a brown clear liquid of specific gravity about ·850, and has a net calorific value of about 18,000 B.Th.U. The distillates, whether prepared from asphaltic or non-asphaltic petroleum oils, are generally very similar in quality, though the proportion of each distillate yielded by the different crude oils may vary considerably. The residuum which is run off the still at the end of distillation, and is frequently marketed as 'fuel oils,' varies very greatly in properties according to the nature of the crude oil from which it originates. The non-asphaltic petroleum residuum which is sold as fuel oil is generally dark brown or black, almost opaque, quite mobile, and has a specific gravity of ·870 to ·920. It is largely used as a fuel for semi-Diesel and Diesel engines, also for boiler firing in the Navy. The residua prepared from asphaltic oils are usually black opaque liquids possessing high viscosities and specific gravities from ·920 to ·980, the viscosities and specific gravities being dependent on the asphaltum content.

Examples of analyses of the more important petroleum fuel products are given in the table on page 1814.

Shale Oil.

Shale exists in many parts of the British Empire, the shale oil industry being most fully developed in Scotland. The shale is mined in a similar manner to coal, and is then subjected to destructive distillation, the principal products of value being ammonia and crude shale oil. The crude oil is subjected to distillation, whereby a series of products similar to the petroleum distillates is obtained. The shale oils are richer in unsaturated bodies than petroleum. In fuel properties they very closely resemble the petroleum products.

Petrol.

Petrol, known in France as 'Essence' and in America as 'Gasoline,' is a mixture of liquid hydrocarbons principally composed of the chemical 'paraffins,' Hexane C_6H_{14}, Heptane C_7H_{16}, Octane C_8H_{18}, and Nonane C_9H_{20}: these have boiling points 155°F., 208° F., 248° F., and 302° F. respectively. It is obtained by distillation from crude petroleum and, as now used, varies in sp. gr. at 60° F. from about 0·70 to 0·76, the average being about 0·725. The consumption in Great Britain rose from about nineteen million gallons in 1905 to upwards of two hundred million gallons in 1919. Petrol, being a mixture of hydrocarbons, has no fixed boiling point, and its density increases during evaporation; it was largely from this cause that surface carburettors proved unsatisfactory, selective evaporation occurring and a heavy non-volatile residuum being finally left; with the jet-carburettors now almost universally employed no selective action is possible.

As petrol is very expansible, tanks and closed vessels should never be quite filled with the liquid, so as to avoid risk of rupture following a rise in temperature. Coefficient of expansion, 0·0004 per ° F. (0·000224 per ° C.).

The composition of commercial petrol averages about 85¼ per cent. carbon and 14¾ per cent. hydrogen, and the net calorific value per lb. varies but little from 18,600 B.Th.U.

Heavy petrol gives quite satisfactory results with modern carburettors; motor omnibuses employ ·760 spirit very largely on account of its lower cost.

Petrol vapour is, roughly, 3½ times as heavy as air; hence at atmospheric pressure and 60° F. 1 lb. of petrol vapour occupies about 4 cub. ft.; in the liquid form its volume is about 38⅝ cub. ins.; hence, converted into vapour it increases its volume by 180 times. For complete conversion into CO_2 and H_2O 1 lb. of petrol requires about 3·45 lbs. of oxygen, corresponding to 15 lbs. of air; the exhaust consists, by weight, of 3·13 lbs. CO_2; 1·32 lb. H_2O (vapour); and 11·55 lbs. nitrogen. Total, from 1 lb. of petrol = 16 lbs. of exhaust. Exhaust composition is always, however, reckoned by volume, and, moreover, the water vapour is condensed to (practically) zero volume and accordingly does not directly appear. Hence, when combustion is just perfect, the exhaust should consist, by *volume*, of 14·6 per cent. CO_2 and 85·4 per cent. of nitrogen. If there be insufficient air to complete combustion, the exhaust contains, in addition to CO_2 and water vapour, CO, CH_4, and H; these being combustible gases, some of the heat of combustion is in such cases carried away in the exhaust and wasted. If α denote the volume percentage of CO in the exhaust, and β be the per cent. of CO_2, then the fraction of the total heat of the fuel wasted in the exhaust is:—

$$\text{Proportion of heat wasted in exhaust} = \frac{0{\cdot}7}{1{\cdot}12 + \frac{\beta}{\alpha}} \qquad (\textit{Burls.})$$

On the other hand, if the air supply exceed about 15 lbs. per lb. of petrol, there is an air excess and no CO appears in the exhaust; instead one gets free oxygen. The practical range is from about 11 air to 1 petrol, to 17 air to 1 petrol; recently the Royal Automobile Club has adopted as the standard for carburettors such a mixture as would give an exhaust containing about 1 per cent. of free oxygen; this prevents the presence of CO, and gives nearly the highest thermal efficiency and also nearly the maximum power. Maximum thermal efficiency usually occurs with a somewhat greater excess of air, and maximum power with a slight defect of air, due in this latter case to the higher mean pressure obtained by reason of the considerable expansion in the products of combustion with 'rich' mixtures. One lb. of petrol, occupying 4 cub. ft., requires for its complete combustion roundly 15 lbs. of air occupying 196 cub. ft. at 60° F.; the 16 lbs. of mixture thus occupies a volume of 200 cub. ft. at 60° F., and contains 2 per cent. by volume of petrol vapour.

Taking 0·7 pint of 0·72 sp. gr. petrol, i.e. 0·63 lb. per b.h.p. hour as an average good performance for well-designed engines, we see that for a 15 to 1 air-petrol ratio this corresponds therefore to $\frac{200 \times {\cdot}63}{60} = 2{\cdot}1$ cub. ft. of mixture per b.h.p. min.—a useful figure in design.

COMPARISON OF PROPERTIES OF FUELS FOR PETROL ENGINES.

Description.	Sp. Gr. at 20° C.	Gross Cal. Value.	Retort Test.	Sulphur.	Sulphuric Acid Colouration Test.

The specific gravities and distilling temperatures of petrols are liable to be varied from time to time as the market conditions warrant. The increased demand for motor spirit during recent years has been to a large extent met by including both higher and lower boiling distillates in the motor spirit fraction. By subjecting the crude oil to high temperatures in the absence of air, frequently accompanied by high pressures, a decomposition of the more complex hydrocarbons is brought about. This action, which is technically known as 'cracking,' results in large yields of motor spirit. The motor spirit prepared in this way is rich in unsaturated compounds, possesses a characteristic odour, and is higher in specific gravity than the direct distilled petrol which comes over between the same temperatures.

Some of the petrol at present being imported into this country is naturally rich in benzene and toluene, and this is particularly the case with the Borneo spirit imported by the Shell group, and it has been found, both experimentally and in practice, that owing to the higher spontaneous ignition temperatures of benzene and toluene, mixtures containing these hydrocarbons do not so readily cause preignition or detonation in petrol engines. In view of this, petrol which does not naturally contain benzene has occasionally been mixed with benzene in order to decrease the liability to preignition.

Recent analyses of Pratt's No. 1 and Shell No. 1 spirit by Messrs. Ormandy & Moore, on behalf of *The Motor*,* give the following results:—

Pratt's No. 1 Motor Spirit:—Specific gravity, 0·729 at 15° C. (59° F.).

ENGLER DISTILLATION TEST: Initial boiling point, 33° C. (91·4° F.).

Temperature	C.°	55	60	70	80	90	100	110	120
„	F.°	131	140	158	176	194	212	230	248
Drop per cent.		—	1·0	3·5	11·5	21·5	31·0	45·0	57·5
Temperature	C.°	130	130	140	150	160	170	180	190
„	F.°	266	266	284	302	320	338	356	374
Drop per cent.		67·5	67·5	77·0	83·0	87·5	91·5	93·0	94·5

Initial boiling point is the temperature at which the first drop falls from the bulb of the thermometer when the latter is placed ½ in. below the outlet tube of flask.

Drop temperature is taken when the first drop leaves the end of the condenser.

Acid Coloration.—Acid has brick-red colour, and petrol separates out slowly.

Aromatic hydrocarbon content = 10·2 per cent. by weight.

* *The Motor*, September 7, 1921.

Shell No. 1 Motor Spirit: Specific gravity, 0·754 at 15° C.

Engler Distillation Test: Initial boiling point, 34° C.							
Temperature	C.°	57	70	80	90	100	110
"	F.°						
Drop per cent.	.	—	1·5	6·0	12·5	24·0	39·0
Temperature	C.°	120	130	140	150	160	170
"	F.°						
Drop per cent.	.	53·5	67·0	78·0	86·5	92·0	95·0

Acid Coloration.—Acid only slightly discoloured, light brown, and petrol separates out almost immediately.

Aromatic hydrocarbon content = 21 per cent. by weight.

Benzol.

Benzol had come into prominence before the war as an alternative home-produced fuel for the engines of motor vehicles, partly in consequence of the high price of petrol. Since the withdrawal of the restrictions on the use of benzol its use has become more general than before, though the motoring public do not yet fully appreciate its value as a fuel. Benzol is the commercial name for a mixture of hydrocarbons prepared by the distillation of coal tar, and also obtained by stripping the gas which is produced as a by-product from coke ovens. Commercial benzol consists almost entirely of a mixture of the hydrocarbon benzene (C_6H_6: not to be confused with the petroleum fraction 'benzine') and the hydrocarbon toluene (C_7H_8). The usual commercial grades are '90 per cent. benzol,' which on distillation from a retort yields 90 per cent. of distillate at 100° C., and consists of approximately 70 per cent. benzene and 30 per cent. toluene, together with traces of the xylenes (C_8H_{10}), and '100 per cent. benzol,' which on distillation from a retort yields 100 per cent. of distillate at 100° C., and contains a higher proportion of the hydrocarbon benzene than 90 per cent. benzol.

There is little to choose between these two bodies as motor fuels, and provided they have been satisfactorily refined they are both preferable to pure benzene, as the mixtures do not so readily solidify in cold weather. Pure benzene solidifies at a temperature of + 6° C. (43° F.), and boils at 80·4° C. It possesses a specific gravity of ·88 at 15° C., and a gross heat value of about 18,090 B.Th.U.

Both commercial benzol and pure benzene possess very high temperatures of spontaneous ignition, and they will withstand compressions of about 200 lbs. per square inch in internal combustion engines without being affected by preignition. This property, together with the high specific gravity, accounts for the increased mileage per gallon obtained when using benzol as fuel instead of petrol. Benzol gives about 16 per cent. greater mileage than petrol, and also gives greater power to the engine. When changing over from petrol to benzol it is advantageous slightly to reduce the size of jet, though it is not absolutely necessary to make any modification. The colour of benzol for motor use should be perfectly clear and white, as yellowish colour indicates unsatisfactory refining. Certain bodies (mainly phenols, unsaturated hydrocarbons and sulphur containing compounds) are present in benzol when it is first prepared by distillation. These compounds are removed by treatment with caustic soda solution and afterwards with concentrated sulphuric acid. If these bodies are not removed there is a liability for the benzol to form resinous substances after prolonged standing, and also to form gummy deposits in the engine. Petrol undergoes a similar refining process during its preparation, but it is rare to meet with badly refined petrol nowadays, as the quality necessary for the motor spirit market is well understood by the petroleum firms. Petrol and benzol are perfectly soluble in each other, and can be used with satisfaction in the form of mixtures.

BRITISH STANDARD SPECIFICATION FOR BENZOL FOR MOTOR FUEL.*

Report No. 135, 1921 (*Abstract*).

(1) The term 'Benzole' shall denote a liquid consisting essentially of a mixture of benzene and not more than 30 per cent. by volume of toluene and xylenes.

(2) The material shall be a clear 'water white' liquid, free from undissolved water and other visible impurities.

(3) The specific gravity at 15·5° C. (60° F.) shall be not less than 0·870, and not more than 0·885.

(4) When 100 cc. of the material are distilled in the Standard Distillation Apparatus, at a rate of 7 cc. per minute, there shall distil at 760 mm. pressure—

Not less than	60 cc. at or below	90° C. (194° F.).
„ „	75 cc. „	100° C. (212° F.).
„ „	90 cc. „	120° C. (248° F.).

The flask shall be dry at a temperature not exceeding 125° C. (257° F.). The temperature recorded by the thermometer shall be corrected for emergent stem and barometric pressure.

(5) The amount of non-volatile residue remaining when 20 cc. of the material are evaporated, and subsequently heated for two hours on a water bath at 100° C. (212° F.), shall not exceed 0·01 per cent. by weight.

(6) The coloration imparted to pure sulphuric acid (90 per cent. H_2SO_4), free from nitric acid, when 90 cc. of the material are shaken with 10 cc. of the acid for five minutes at ordinary temperatures, shall be not more than a light brown.

(7) The total sulphur content shall not exceed 0·4 per cent. by weight. Freedom from acid and alkali.

(8) The material shall give no reaction for free acid or alkali when tested.

(9) The material shall give no reaction for sulphuretted hydrogen when tested.

(10) The freezing point shall not be higher than —14° C. (7° F.).

Detailed descriptions of the methods employed in testing are given in the original publication.

Alcohol.

Although the heat value of alcohol per lb. is comparatively small, yet, on account of its heaviness as a vapour, and the small volume of air required to burn it compared with benzene and petrol, it yields 89·2 B.Th.U. per cub. ft. of mixture at 60° F. and atmospheric pressure. Moreover, the products of combustion are 6½ per cent. greater in volume than that of the unburnt mixture, with corresponding increase in the pressure developed. There is thus, thermally considered, not very much to choose between alcohol and petrol; alcohol is, in fact, an excellent fuel for suitably designed internal combustion engines, and is largely used in Germany, where its production is encouraged by the Government; in 1904 the price of alcohol in Germany was only 9*d.* per gallon when purchased in large bulk.
